Decreased movement in the thoracic cage during respirations also occurs with immobility. This decrease may be due to loss of tonus in muscles involved with respirations, pressure on the chest wall because of the patient's position in bed, or depression of the respiratory system by various pharmaceutical agents.

Musculoskeletal System

Effects of immobility on the musculoskeletal system are rapidly seen in patients confined to bed. People attempting to walk after several days of bed rest are often surprised to find how weak their legs have become. Immobility (musculoskeletal disuse) leads to decreased muscle size (**atrophy**), tone, and strength; decreased joint mobility and flexibility; bone demineralization; and limited endurance, resulting in problems with ADLs.

Immobility is often the cause of contractures and ankylosis, a consolidation and immobilization of a joint. Contractures result from atrophy of muscles and from a decrease in the muscle's strength, coordination, and endurance, resulting in an inability to function. A joint can be permanently fixed when ankylosed.

The process of bone demineralization (osteoporosis) is also increased in immobile patients. Normally, the stress and strain of weight-bearing activity stimulate bone formation and balance it with the natural destruction of bone. With immobility, however, bone formation slows while breakdown increases, resulting in a net loss of bone calcium, phosphorus, and bone matrix. This condition, disuse osteoporosis, is characterized by bones that may be either spongy or brittle. Bone demineralization may result in pathologic fractures related to the bone's brittleness, bone deformities related to the bone's sponginess, arthropathy (joint disease) related to calcium depletion in the joints, or renal calculi (stones) related to the excessive excretion of calcium through the kidneys and urinary tract.

Metabolic Processes

Because the resting body requires less energy, the cellular demand for oxygen is decreased, leading to a decreased metabolic rate. In many immobilized patients, however, factors such as fever, trauma, chronic illness, or poor nutrition can actually increase the body's metabolic demands and increase catabolism (the breakdown of the body's protein stores to provide energy to meet the body's energy requirements). If unchecked, this process results in muscle wasting and a negative nitrogen balance. Anorexia, or decreased appetite, often accompanies and compounds this problem. Negative nitrogen balance and poor nutrition thus worsen the muscle atrophy and weakness already resulting from immobility. Numerous fluid and electrolyte imbalances, alterations in the exchange of nutrients and gases at the cellular level, and gastrointestinal (GI) problems can all result from metabolic disturbances.

Gastrointestinal System

Immobility leads to disturbances in appetite, decreased food intake, altered protein metabolism, and poor digestion and utilization of food. If people increase food intake while decreasing energy expenditure, weight gain will result. Normal muscular activity in the GI tract also slows down in an immobile person, which often results in constipation, poor defecation reflexes, and an inability to expel feces and gas adequately.

Urinary System

In a nonerect patient, the kidneys and ureters are level, and urine remains in the renal pelvis for a longer period of time before gravity causes it to move into the ureters and bladder. Urinary stasis favors the growth of bacteria that, when present in sufficient quantities, may cause urinary tract infections. Poor perineal hygiene, incontinence, decreased fluid intake, or an indwelling urinary catheter can increase the risk for urinary tract infection in an immobile patient.

Immobility also predisposes the patient to renal calculi, or kidney stones, which are a consequence of high levels of urinary calcium; urinary retention and incontinence resulting from decreased bladder muscle tone; the formation of alkaline urine, which facilitates growth of urinary bacteria; and decreased urine volume.

Skin

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

In patients who are immobile, especially those who are older or debilitated, the impaired circulation that accompanies immobility may result in serious skin breakdown. Prolonged pressure over bony prominences produces areas of breakdown, leading to pressure injuries. Pressure injuries are described in detail in Chapter 33.

Psychosocial Outlook

When a person can no longer move the body purposefully and needs to depend on someone else for assistance with simple self-care activities, the person's sense of self is often threatened. Skeletal deformities can influence body image, an inability to meet role expectations can decrease self-concept, and a prolonged period of lying dependent in bed can lead to feelings of worthlessness and diminished self-esteem.

Immobility can produce exaggerated emotional responses to the stresses of everyday living. Patients can become apathetic, possibly because of decreased sensory stimulation, and develop altered thought processes. Lack of mobility can also diminish a person's opportunities to interact socially and deprive that person of normal support systems. Coping difficulties are common for both immobilized patients and their families. Furthermore, the amount of time immobilized patients spend resting often disrupts their usual sleep–wake patterns and may interfere with both the quantity and quality of their sleep.

Remember **Kelsi Lester**, the 10-year-old girl who is unconscious. Due to her current state, Kelsi is at high risk for developing any or all of the possible complications associated with immobility, including thrombi, pneumonia, constipation, urinary tract infection, and skin breakdown. Although she is unconscious, the effects of immobility ultimately can affect her psychosocial outlook. The nurse would integrate knowledge of the effects of immobility when developing Kelsi's plan of care that would include close frequent assessment, early detection, and prompt intervention to prevent any possible complications.

NURSING PROCESS FOR ACTIVITY

Assessing

The comprehensive nursing assessment uses both interview and physical assessment skills to obtain data about the patient's mobility and activity status. When alterations in a patient's physical or mental health state result in impaired mobility, additional specific assessment skills are needed to determine the patient's physical limitations.

Nursing History

During the nursing history, interview patients regarding their daily activity level, endurance, exercise and fitness goals, mobility problems, physical or mental health alterations that affect mobility, and external factors affecting mobility. Questioning patients about their fitness goals is important to provide an indication of the patient's view of health. This interviewing strategy communicates to patients that you expect them to be exercising and is itself a powerful teaching tool.

Social determinants of health are conditions in the patients environments that may affect the patient's functioning and quality of life (Healthy People 2030, n.d.). Ask about sociocultural factors that may impact a patient's mobility and their ability to participate in activities, such as:

- Access to physical activity opportunities
- Safe neighborhoods and environments
- Income
- Services that provide practical support for participation in physical activities, such as child-care, advice and encouragement

This information helps us to understand factors that may influence a patient's health and use of health care and shape more effective interventions (Healthy People, 2030, n.d.).

The accompanying Focused Assessment Guide 34-1 (on page 1256) illustrates elements common to obtaining a

mobility status history. When a problem exists, assess the nature of the problem, its onset and frequency, known causes, severity and symptoms, effects on everyday functioning, the interventions attempted by the patient, and the results.

Physical Assessment

Physical assessment of mobility status includes an assessment of general ease of movement and gait; alignment, joint structure, and function; muscle mass, tone, and strength; and endurance. Table 34-5 (on page 1257) provides normal findings and significant alterations related to these assessments. During this assessment, direct attention to both structure and function. The patient's ability to stand, walk, sit up, and grasp are important because these enable the patient to wash, dress, and feed oneself and perform other basic ADLs.

Focused Assessment Guide 34-1

MOBILITY AND EXERCISE

Factors to Assess	Questions and Approaches
Daily activity level	Describe the activities you normally carry out during a routine day and types of physical exercise that are part of your daily lifestyle. • Activities of daily living • Type, frequency, duration of physical exercise • Past history of activity and exercise; recent changes
Endurance	Describe how much and what type of activity makes you tired. • History of dizziness, dyspnea, frequent pauses in activity to rest, pounding heart, or marked increase in respiratory rate after moderate activity
Exercise/fitness goals	What exercise or fitness goals are you currently working on? • Attitudes about exercise and physical fitness • Knowledge of the benefits of exercise • Motivation to exercise
Mobility problems	Do you experience any problems with movement or with more vigorous activity or exercise? If yes, please describe these problems. • Nature of the problem (including symptoms) • Onset of disturbance and frequency • Known causes • Effect of problem on everyday functioning • Interventions attempted and results
Physical or mental health alterations	Are there any physical or mental health problems that may be affecting your mobility? • Decrease of strength or endurance (e.g., myocardial infarction, congestive heart failure, chronic obstructive pulmonary disease, cancer, gastrointestinal disorders) • Neuromuscular impairment (multiple sclerosis, Parkinson's disease, spinal injuries) • Musculoskeletal impairment (arthritis, fractures, muscular dystrophy) • Perceptual or cognitive impairment (cerebrovascular accident, brain tumor or trauma, vision disorders, dementia) • Pain or discomfort (burns, rheumatoid arthritis, chronic pain syndrome, postoperative pain) • Depression or severe anxiety (neurosis, schizophrenia)
External factors affecting mobility	Is there anything else you can think of that limits your ability to get around or participate in activities? • Environmental factors (stairs, lack of railings or other assistive devices, poor lighting, unsafe neighborhood) • Financial resources

Older adults make up an increasingly larger part of the general population. Functional decline and subsequent difficulties related to completion of ADLs and instrumental activities of daily living (IADLs) in older adults can have significant consequences (Yoo et al., 2020). Changes in mobility status contribute to this functional decline (Gray-Miceli, 2017; Tasheva et al., 2020). Moderate amounts of aerobic physical activity can reduce the risk of functional decline by as much as 30%, allowing older adults to continue with ADLs (American Geriatrics Society, 2016). Assessment of an older adult's ability to participate in physical activities and exercise and to care for themselves is an important part of a mobility assessment. This assessment can provide clues to changes in health and prevent, or prevent further, functional decline. See the accompanying Focus on the Older Adult (on page 1258) for an example of a tool (Katz Index of Independence in Activities of Daily Living) to use to measure the older adult's capacity to care for oneself and assist nurses to detect subtle changes in health and prevent functional decline. Additional information related to functional health is discussed in Chapter 27.

GENERAL EASE OF MOVEMENT AND GAIT

Begin the physical assessment of an ambulatory patient the moment the patient walks into the room. Voluntarily controlled, fluid, and coordinated body movements are key to the integrated functioning of the skeletal, muscular, and nervous systems. Note whether the patient's body movements are quick and sure or slow and deliberate. These observations communicate both a sense of the person's emotional status and self-care abilities. Common involuntary

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

movements that may be observed include tremors (continuous quivering of whole muscles or major portions of a muscle) and tics (irregularly occurring spasmodic movements such as winking, grimacing, or shoulder shrugging).

Note the gait (manner of walking) of the patient who is ambulatory. The patient's movements while walking should be coordinated and the posture well balanced. The arms should swing freely in a rhythm alternating with the legs. Figure 34-4 (on page 1258) illustrates stance and swing, the two phases of the normal gait. The heel of the right foot strikes the ground (stance), while the toe of the left foot pushes off and leaves the ground, moving the leg from behind to in front of the body (swing). While one leg is in the stance phase, the other is in the swing phase. Detection of gait abnormalities is important because gait abnormalities may place the person at risk for injury and may indicate a neuromuscular disorder or intoxication.

Table 34-5 Overview of Physical Assessment of Mobility Status

COMPONENT	NORMAL FINDING	SIGNIFICANT ALTERATIONS
General ease of movement	Body movements are: • Voluntarily controlled (purposeful) • Fluid • Coordinated	Involuntary movements: • Tremors • Tics • Chorea • Athetosis • Dystonia • Fasciculations • Myoclonus • Oral–facial dyskinesias
Gait and posture	Head erect, vertebrae are straight. Knees and feet point forward. Arms at side with elbows flexed. Arms swing freely in alternation with leg swings. While one leg is in the stance phase, the other is in the swing phase.	Abnormalities of gait and posture: • Spastic hemiparesis • Scissors gait • Steppage gait • Sensory ataxia • Cerebellar ataxia • Parkinsonian gait • Gait of old age • Use of assistive devices for ambulation
Alignment	Independent maintenance of correct alignment: • In the standing and sitting position, a straight line can be drawn from the ear through the shoulder and hip. • In bed, the head, shoulders, and hips are aligned.	Abnormal spinal curvatures Inability to maintain correct alignment independently
Joint structure and function	Absence of joint deformities Full range of motion	Limitation in the normal range of motion Increased joint mobility Swelling or tenderness in or around the joint Heat or redness Crepitation Deformities Muscle atrophy, nodules, skin changes Asymmetry of involvement
Muscle mass, tone, and strength	Adequate muscle mass, tone, and strength to accomplish movement and work	Atrophy, hypertrophy Hypotonicity (flaccidity), spasticity Paresis or paralysis
Endurance	Ability to turn in bed, maintain correct alignment when sitting and standing, ambulate, and perform self-care	Physiologic or psychological inability to tolerate an increase in activity:

activities	• Significantly increased pulse, respiration, blood pressure after rest • Shortness of breath, dyspnea • Weakness • Pallor • Confusion • Vertigo • Pain

Note whether the patient uses any assistive devices such as a wheelchair, brace, cane, walker, or crutches to aid in ambulation. Also, determine whether the assistive device is meeting the patient's needs, if it is required for mobility, and if it is being used safely.

ALIGNMENT

Correct body alignment permits optimal musculoskeletal balance and operation and promotes optimal physiologic functioning. Deviations in body alignment may result from chronic poor posture, trauma, muscle damage, or nerve dysfunction. Pain, fatigue, and a person's mental and emotional status may also influence alignment.

Observe alignment when a patient is standing, sitting, or lying (Fig. 34-5 on page 1258). Note whether the patient is able to maintain correct alignment independently.

Focus on the Older Adult

KATZ INDEX OF INDEPENDENCE IN ACTIVITIES OF DAILY LIVING

ACTIVITIES POINTS (1 OR 0)	INDEPENDENCE: (1 POINT)	DEPENDENCE: (0 POINTS)
	NO supervision, direction, or personal assistance	WITH supervision, direction, personal assistance, or total care
BATHING POINTS:____	(1 POINT) Bathes self completely or needs help in bathing only a single part of the body such as the back, genital area, or disabled extremity.	(0 POINTS) Needs help with bathing more than one part of the body or getting in or out of the tub or shower. Requires total bathing.
DRESSING POINTS:____	(1 POINT) Gets clothes from closets and drawers and puts on clothes and outer garments, complete with fasteners. May have help tying shoes.	(0 POINTS) Needs help with dressing self or needs to be completely dressed.
TOILETING POINTS:____	(1 POINT) Goes to toilet, gets on and off, arranges clothes, cleans genital area without help.	(0 POINTS) Needs help transferring to the toilet or cleaning self or uses bedpan or commode.
TRANSFERRING POINTS:____	(1 POINT) Moves in and out of bed or chair unassisted. Mechanical transferring aides are acceptable.	(0 POINTS) Needs help in moving from bed to chair or requires a complete transfer.
CONTINENCE POINTS:____	(1 POINT) Exercises complete self-control over urination and defecation.	(0 POINTS) Is partially or totally incontinent of bowel or bladder.
FEEDING	(1 POINT) Gets food from plate into mouth without help. Preparation of food may be done by another person.	(0 POINTS) Needs partial or total help with feeding or requires parenteral feeding.

TOTAL POINTS = _____ 6 = High (*patient independent*) 0 = Low (*patient very dependent*)

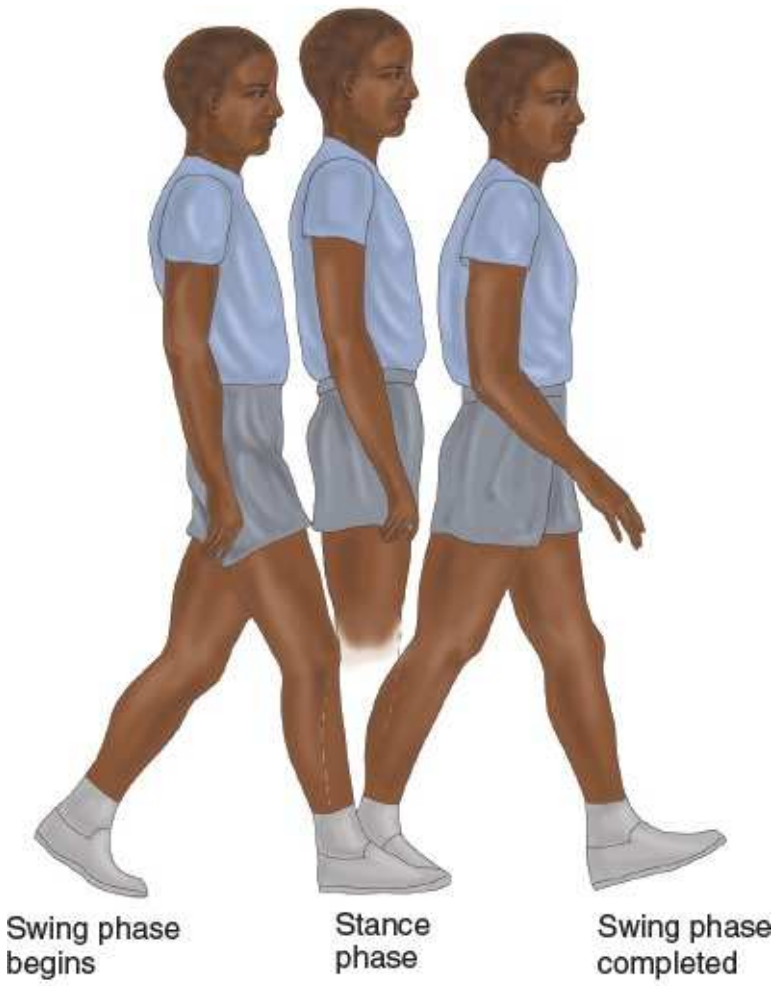

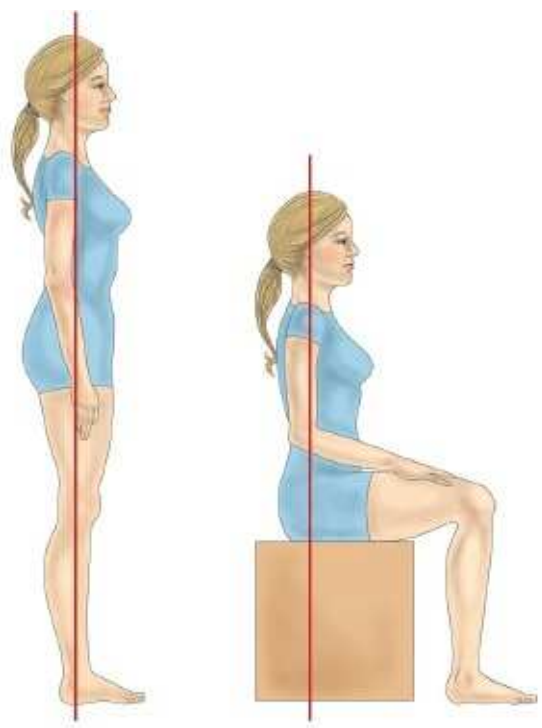

FIGURE 34-4. The stance and swing phases of normal gait

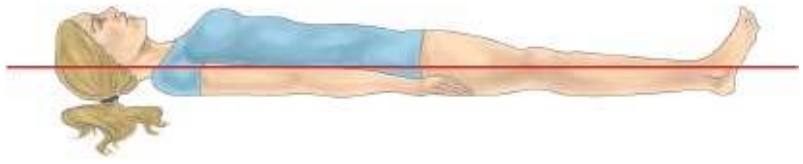

FIGURE 34-5. Adequate alignment (posture). In the sitting and standing positions, a straight line can be drawn from the ear through the shoulder and hip. In bed, the head, shoulders, and hips are aligned.

A patient's body is in correct body alignment in the standing position when:

- The head is held erect and in the midline.
- The face is in the forward position, in the same direction as the feet.
- The chest is held upward and forward.
- The spinal column is upright, and the curves of the spine are within normal limits.
- The abdominal muscles are held upward, with the abdomen comfortably tucked in and the buttocks downward.
- The arms hang comfortably at the sides.
- The knees are extended in a slightly flexed position—not bent or hyperextended in the knee-locked position.
- The feet are at right angles to the lower legs.
- The line of gravity goes through the midline, from the middle of the forehead to a midpoint between the feet;

laterally the line of gravity runs vertically from the middle of the skull to the posterior of the foot.
- The base of support is on the soles of the feet, and weight is distributed through the soles and heels.

Correct body alignment when sitting is similar to correct alignment when standing except that the hips are flexed, the knees are flexed and not crossed, and the base of support is on the buttocks and upper thighs. The weight is distributed evenly on the buttocks and thighs. The thighs are parallel and the popliteal area should be free of the edge of the chair to prevent circulatory stasis and possible nerve injury. The patient's forearms are supported either on the armrests, lap, or on a flat surface in front of the chair.

JOINT STRUCTURE AND FUNCTION

Use inspection and palpation to examine joints, their range of motion, and the surrounding tissue. Range of motion is the maximum degree of movement of which a joint is normally capable. When assessing joint mobility, note the following:

- Size, shape, color, and symmetry of joints: note any masses, deformities, or muscle atrophy
- Range of motion of each joint
- Any limitation in the normal range of motion or any unusual increase in the mobility of a joint (instability); range of motion varies among people and decreases with aging
- Muscle strength when performing range-of-motion exercises against resistance
- Any swelling, heat, tenderness, pain, nodules, or crepitation (palpable or audible crunching or grating sensation produced by motion of the joint)
- Comparison of findings in one joint with those of the opposite joint

MUSCLE MASS, TONE, AND STRENGTH

Adequate skeletal muscle mass, tone, and strength are prerequisites to appropriate body movement and work performance. Mass refers to muscle size. Assess muscle mass throughout the body and compare one muscle group to another using tape measurements. Hypertrophy refers to increased muscle mass resulting from exercise or training. Atrophy describes muscle mass that is decreased through disuse or neurologic impairment. Patients experiencing muscle wasting as a result of a chronic disease process such as cancer may report visible changes in muscle mass.

The slight residual tension that remains in a resting normal muscle with an intact nerve supply is termed muscle tone. Assess muscle tone by flexing and extending the elbow or knee and noting the degree of resistance to these movements. Decreased tone, also known as hypotonicity or **flaccidity**, results from disuse or neurologic impairments and is described as a weakness of the involved area. **Spasticity** or hypertonicity, increased tone that interferes with movement, is also caused by neurologic impairments and is often described as a stiffness, tightness, or pulling of the muscle.

The nurse would need to assess closely the muscle tone of **Kelsi Lester**, the 10-year-old girl who is unconscious. The nurse would be alert for evidence of flaccidity, which could result from lack of use or possibly impairment of her nervous system due to the accident.

Muscle strength varies greatly from one person to another and even within the same person and is affected by muscle use. Test muscle strength by asking the patient to move actively against resistance. For example, instruct the patient to push the examiner's palms apart or to push the foot against the examiner's palm. When comparing muscle groups, remember that a person's dominant side tends to be stronger.

Impaired muscle strength or weakness is termed **paresis**. The absence of strength secondary to nervous impairment is called **paralysis**. Hemiparesis refers to weakness of one half of the body, and hemiplegia is paralysis of one half of the body. Paraplegia is paralysis of the legs, and quadriplegia is paralysis of the arms and legs.

Assess whether the patient's muscle strength is adequate for the performance of tasks the patient deems necessary. For example, a patient whose primary means of ambulation is a wheelchair requires upper body strength.

ENDURANCE

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

When assessing endurance, evaluate the patient's ability to turn in bed, maintain correct alignment when sitting or standing, ambulate, and perform self-care activities. When a physical or psychological factor is believed to be affecting endurance, evaluate the following:

- Vital signs while the patient is at rest
- Ability to perform the activity (e.g., ambulation)
- Patient's response during and after the activity
- Vital signs immediately after the activity
- Vital signs after the patient has rested for 3 minutes

Significant findings indicating that a person's exercise tolerance has been reached include noticeably increased pulse, respirations, and blood pressure; shortness of breath, dyspnea; weakness; pallor; confusion; and vertigo (sensation of spinning).

Examples of Actual or Potential Health Problems and Needs

MOBILITY/ACTIVITY

Actual or Potential Health Problems and Needs	Possible Etiologic Factors	Potential Signs and Symptoms
Activity intolerance	Any condition that interferes with the transport of oxygenated blood to tissue (e.g., cardiac problems such as congestive heart failure and arrhythmias; respiratory problems, especially chronic obstructive pulmonary disease; circulatory problems; diabetes mellitus) Immobility Generalized weakness Physical deconditioning Musculoskeletal impairment (fracture, arthritis) Neuromuscular impairment (muscular dystrophy, multiple sclerosis)	Altered response to activity: Exertional dyspnea, shortness of breath, excessive increase in respiratory rate Weak pulse, excessive increase in pulse rate, change in rhythm Blood pressure that fails to increase with activity or that decreases Weakness, pallor, confusion, vertigo Reports of fatigue or pain with activity
Impaired Ability to Transfer	Decreased strength and endurance Pain or discomfort Decreased muscle control, mass, or strength Joint stiffness Obesity Imbalance between oxygen supply/demand	Physical inability to move purposefully or a reluctance to move Limited range of motion Limited ability to perform fine or gross motor skills Slowed, jerky, or uncoordinated movements Postural instability
Risk for Activity Intolerance	Immobility Physical deconditioning Sedentary lifestyle	—

Diagnosing Actual or Potential Health Problems and Needs

An assessment of a patient's mobility and activity status may lead to the identification of one or more diagnoses or patient problems related to mobility, activity, and/or immobility. Following the formulation of the diagnoses or patient problems, the nurse communicates findings to other nursing and health care professionals through the use of the written and spoken word. The written diagnosis or patient problem becomes a permanent part of the patient's health record. Examples of diagnoses/patient problems with related etiology and signs and symptoms can be found in the box titled Examples of Actual or Potential Health Problems and Needs: Mobility/Activity.

Outcome Identification and Planning

If the patient is not experiencing any mobility or activity problems, expected patient outcomes are directed toward the promotion of physical fitness. For example, the patient will:

- Identify personal benefits of regular exercise
- List support systems that will reinforce exercise efforts
- Follow a program of regular physical exercise that improves cardiovascular function, endurance, flexibility, and strength

Patients at risk for specific mobility or activity problems may require different expected outcomes. For example, the patient will:

- Demonstrate correct body alignment
- Demonstrate full range of joint motion
- Demonstrate adequate muscle mass, tone, and strength to perform ADLs and/or IADLs

Patients who are immobile require outcomes directed toward preventing complications related to inactivity and its effects on the body systems. For example, the patient will:

- Be free from alterations in skin integrity
- Show signs of adequate circulation
- Maintain muscle mass, tone and strength

Individualize outcomes for more specific problems (e.g., for the patient learning to walk with crutches or needing to master transfer techniques with only upper body mobility).

Consider **Maggie Wyatt**, the woman being discharged after treatment for a fracture. An appropriate outcome for Ms. Wyatt would be that she demonstrates ability to transfer herself from the bed to the chair and then to the car, with the assistance of a support person.

Implementing

The use of ergonomics and safe patient handling and mobility strategies are discussed in the following sections. Nursing strategies designed to promote correct body alignment, mobility, and fitness are described, as well as interventions to prevent complications from immobility. Techniques for the use of graduated compression stockings and pneumatic compression devices, as well as performing range-of-motion exercises, are discussed.

It is important to remember that the National Institute for Occupational Safety and Health (NIOSH) (2013), Joint Commission, and the Occupational Safety & Health Administration (OSHA) recommend a no-lift policy in conjunction with technology, assistive devices, education, and a culture of safety for all health care facilities (Fragala et al., 2016; OSHA and Joint Commission Resources Alliance, 2017). Implementing safe patient handling and mobility programs improves the quality of patient care and reduces the risk of harm for patients and health care workers (Nelson, 2015; OSHA and Joint Commission Resources Alliance, 2017). Incorporating safe patient handling and mobility strategies, techniques for turning and moving a patient in bed, moving a patient from bed to stretcher and from bed to chair, and logrolling a patient are discussed. Also included are sections on preparing and helping patients to ambulate after bed rest and nursing strategies to promote exercise.

Application of Ergonomics to Prevent Injury

Providing patient care places demands on the nurse's musculoskeletal system. Musculoskeletal disorders plague the nursing profession, resulting in a significant burden on the health care sector and health care workers (Davis & Kotowski, 2015; OSHA, n.d.b). Ergonomics includes proper body movement in daily activities, the prevention and correction of problems associated with posture, and the enhancement of coordination and endurance.

Techniques to prevent back stress include:

- Develop a habit of erect posture (correct alignment). Slouching can strain neck and back muscles. When sitting, use the chair back to support the whole spine, keeping shoulders back but relaxed. Balance the head over the shoulders, avoid leaning forward, and hold in the stomach muscles.
- Use the longest and the strongest muscles of the arms and the legs to help provide the power needed in strenuous activities. The muscles of the back are less strong and more easily injured when used improperly.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

- Use the internal girdle and a long midriff to stabilize the pelvis and to protect the abdominal viscera when stooping, reaching, lifting, or pulling. The internal girdle is made by contracting the gluteal muscles in the buttocks downward and the abdominal muscles upward. It is helped further by making a long midriff by stretching the muscles in the waist. Figure 34-6 illustrates correct and incorrect use of the internal girdle.
- Work as closely as possible to an object that is to be lifted or moved. This brings the body's center of gravity close to that of the object being moved, permitting most of the burden to be borne by the leg and arm muscles, rather than the back. Figure 34-7 illustrates a proper and an improper way to pick up an object.
- Face the direction of your movement. Avoid twisting your body.

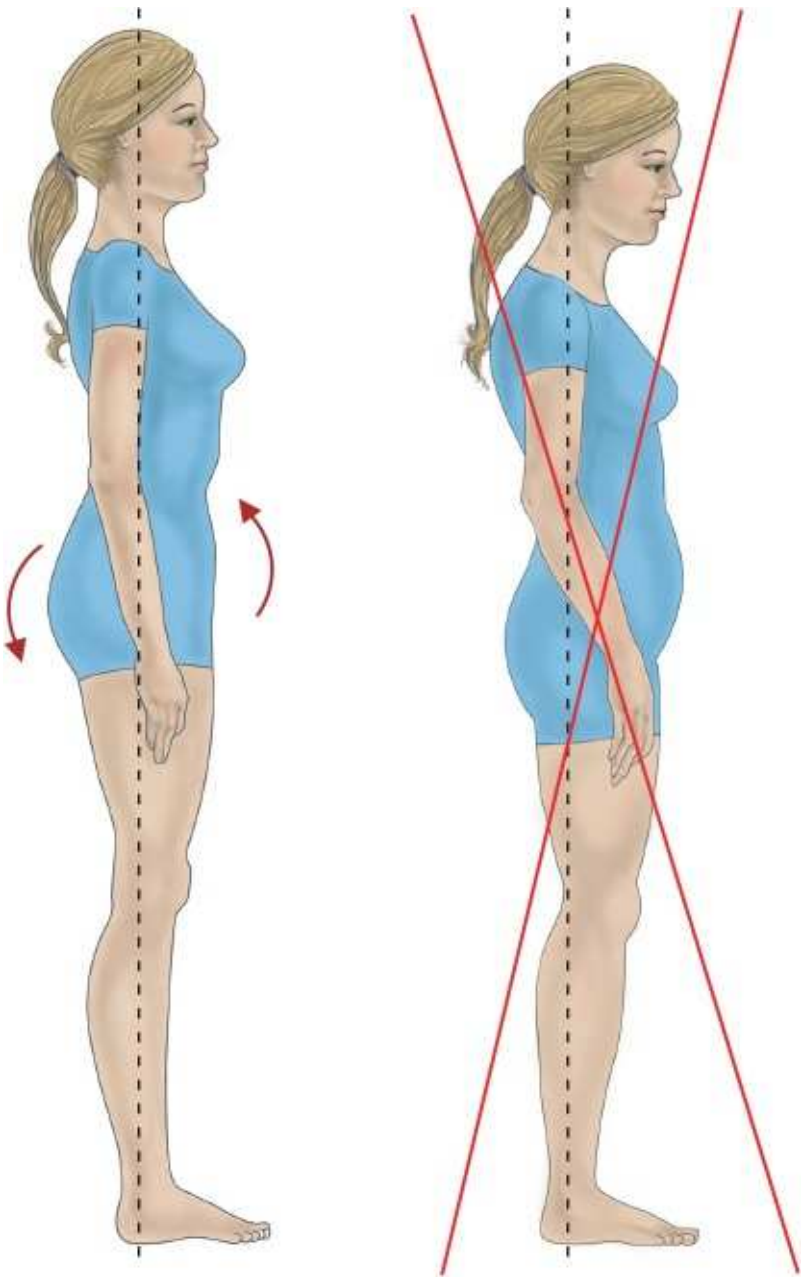

FIGURE 34-6. *(Left)* Correct. Internal girdle "on." Abdominal muscles contracted, giving a feeling of upward pull, and gluteal muscles contracted, giving a downward pull. *(Right)* Incorrect. Slouch position, showing abdominal muscles relaxed and body out of good alignment.

- Use the weight of the body as a force for pulling or pushing, by rocking on the feet or leaning forward or backward. This reduces the amount of strain placed on the arms and the back.
- Slide, roll, push, or pull an object, rather than lift it, to reduce the energy needed to lift the weight against the pull of gravity.

FIGURE 34-7. *(Left)* Correct. A good position for lifting is illustrated. This person is using the long and strong muscles of the arms and legs and holding the object so that the line of gravity falls within the base of support. *(Right)* Incorrect. This is an incorrect position for lifting because pull is exerted on the back muscles and leaning causes the line of gravity to fall outside the base.

Box 34-1 Safe Handling of Patients With Dementia

- Be aware that communication problems and weakness can make the handling of patients with dementia challenging.
- Face the patient when speaking. Speak slowly.
- Use clear, short sentences.
- Call patient by name.
- Use calm, reassuring tone of voice.
- Allow time for response.
- Offer simple, one-step instructions.
- Repeat verbal cues and prompts as necessary; this is helpful when thought processes are delayed.
- Determine if the patient experiencing dementia has receptive aphasia. This inability to understand what is being said results in noncompliance with verbal instructions.
- Phrase instructions positively. For example, remind the patient to “Stand up” until the chair is correctly positioned, instead of saying “Don’t sit down.” The patient may not register the “Don’t” and will try to sit too early. Positive instructions are more likely to result in successful maneuvers.
- Ask one question at a time, allow the patient to answer, and repeat the question if necessary.
- Allow the patient to focus on the task; avoid correcting the process of the action unless it would be dangerous to the patient not to do so.
- Identify the patient’s established patterns of behavior, customs, traits, and everyday habits and try to incorporate these habits into desired activities. For instance, a patient with dementia may resist or become frightened when a morning shower is attempted if the patient was accustomed to evening baths. Another patient may have difficulty getting out of bed in the morning for the simple reason that he is being asked to get out on what he considers the wrong side of the bed.

Source: Adapted from Eliopoulos, C. (2018). *Gerontological nursing* (9th ed.). Wolters Kluwer; Jootun, D., & Pryde, A. (2013). Moving and handling of patients with dementia. *Journal of Nursing Education and Practice, 3*(2), 126–131; Toughy, T. A., & Jett, K. (2018). *Ebersol and Hess’ gerontological nursing & healthy aging* (5th ed.). Elsevier; and Varnam, W. (2011). How to mobilize patients with dementia to a standing position. *Nursing Older People, 23*(8), 31–36.

- Use the weight of the body to push an object by falling or rocking forward and to pull an object by falling or rocking backward.
- Push rather than pull equipment when possible. Keep arms close to your body and push with your whole body, not just your arms.
- Begin activities by broadening your base of support. Spread the feet to shoulder width.
- Make sure that the surface is dry and smooth when moving an object to decrease the effects of friction. Rough, wet, or soiled surfaces can contribute to increased friction, increasing the amount of effort required to move an object.
- Flex the knees, put on the internal girdle, and come down close to an object that is to be lifted.
- Break up heavy loads into smaller loads. Take breaks from lifting or moving to relax and recover.

Ensuring Safe Patient Handling and Mobility

Safe patient handling and transfers involve the use of patient assessment criteria, screening and algorithms for patient handling and mobility decisions, and proper use of patient handling equipment. Keep the patient in good alignment and protect the patient from injury while being moved. The use of safe patient handling devices and techniques is critical in the prevention of patient care–related injuries.

SAFE PATIENT TRANSFER AND MOBILITY

User training, device wear and tear, suitability of equipment, and correct operation of equipment are important factors related to prevention of patient injury and safe patient handling and mobility (Elnitsky et al., 2014; Monaghan, 2020a; Monaghan, 2019).

Follow these recommended guidelines when moving and lifting patients:

- Assess the patient. Know the patient’s medical diagnosis and health issues, capabilities, and any movement not allowed. Apply braces or any device the patient wears before helping from bed.
- Assess the patient’s ability to assist with the planned movement. Encourage patients to assist in their own transfers. Encouraging patients to perform tasks that are within their capabilities promotes independence. It is important to eliminate or reduce unnecessary tasks to reduce the risk of injury and increase the patient’s self-esteem and mobility levels.
- Assess the patient’s ability to understand instructions and cooperate with the staff to achieve the movement. Patient engagement during handling and mobility is an important factor in preventing adverse events (Elnitsky et al., 2014;

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

Gallahger et al., 2019). Box 34-1 outlines general guidelines to consider related to mobility and safe handling of people with dementia.

- Ensure that enough staff are available and present to safely move the patient. See the Reflective Practice box at the beginning of the chapter (on page 1241).
- Assess the area for clutter, accessibility to the patient, and availability of devices. Remove any obstacles that may make moving and lifting inconvenient.
- Use a screening or assessment tool to aid in patient assessment and decision making regarding safe patient handling and mobility (Arnold, 2019; VA Mobile Health, n.d.). Use of a standardized tool supports consistency and appropriate use of SPHM equipment to assist patients with the appropriate level of mobility (Arnold, 2019; Boynton et al., 2020). Figures 34-8 and 34-9 (on page 1264) provide examples of screening/assessment tools.

Assessment Criteria and Care Plan for Safe Patient Handling and Movement

I. Patient's Level of Assistance:
_____ Independent—Patient performs task safely, with or without staff assistance, with or without assistive devices.
_____ Partial Assist—Patient requires no more help than standby, cueing, or coaxing, or caregiver is required to lift no more than 35 lb of a patient's weight.
_____ Dependent—Patient requires nurse to lift more than 35 lb of the patient's weight, or patient is unpredictable in the amount of assistance offered. In this case assistive devices should be used.

An assessment should be made prior to each task if the patient has varying level of ability to assist due to medical reasons, fatigue, medications, etc. When in doubt, assume the patient cannot assist with the transfer/repositioning.

II. Weight-Bearing Capability
_____ Full
_____ Partial
_____ None

III. Bilateral Upper-Extremity Strength
_____ Yes
_____ No

IV. Patient's level of cooperation and comprehension:
_____ Cooperative—may need prompting; able to follow simple commands.
_____ Unpredictable or varies (patient whose behavior changes frequently should be considered as unpredictable), not cooperative, or unable to follow simple commands.

V. Weight: _____ Height: _____
Body Mass Index (BMI) [needed if patient's weight is over 300 lb][1]:_____
If BMI exceeds 50, institute Bariatric Algorithms

The presence of the following conditions are likely to affect the transfer/repositioning process and should be considered when identifying equipment and technique needed to move the patient.

VI. Check applicable conditions likely to affect transfer/repositioning techniques.

_____ Hip/Knee/Shoulder Replacements	_____ Respiratory/Cardiac Compromise	_____ Fractures
_____ History of Falls	_____ Wounds Affecting Transfer/Positioning	_____ Splints/Traction
_____ Paralysis/Paresis	_____ Amputation	_____ Severe Osteoporosis
_____ Unstable Spine	_____ Urinary/Fecal Stoma	_____ Severe Pain/Discomfort
_____ Severe Edema	_____ Contractures/Spasms	_____ Postural Hypotension
_____ Very Fragile Skin	_____ Tubes (IV, Chest, etc.)	

Comments: _____
_____
_____

VII. Appropriate Lift/Transfer Devices Needed:

Vertical Lift: _____
_____

Horizontal Lift: _____
_____

Other Patient Handling Devices Needed: _____
_____

Sling Type: Seated_____ Seated (Amputee)_____ Standing_____ Supine_____ Ambulation _____ Limb Support _____

Sling Size: _____

Signature: _____ **Date:** _____

[1]If patient's weight is over 300 lb, the BMI is needed. For Online BMI table and calculator see: http://www.nhlbi.nih.gov/guidelines/obesity/bmi_tbl.htm.

FIGURE 34-8. Sample assessment tool for safe patient handling and movement. (*Source:* VHA Center for Engineering & Occupational Safety and Health [CEOSH]. [2016]. *Safe patient handling and mobility guidebook*. http://www.tnpatientsafety.com/pubfiles/Initiatives/workplace-violence/sphm-pdf.pdf)

- Decide which equipment to use. Protocols and algorithms are available to aid decision making to prevent injury to staff and patients. Figures 34-9 (on page 1264) and 34-10 (on page 1265) provide direction for selection of SPHM equipment/devices based on screening/assessment data.

- Plan carefully what you will do before moving or lifting a patient. Assess the mobility of attached equipment. You may injure the patient or yourself if you have not planned well. Communicate the plan with staff and the patient to ensure coordinated movement.

Test/Assessment Level	Description of Test	Pass Response	PASS =
Assessment Level 1 Assessment of: • sitting balance • upper extremity and core strength • ability to sit upright without getting tachycardic, diaphoretic and/or light-headed; i.e., sitting tolerance	**Sit and Shake:** From semi-reclined position or at EOB, ask patient to sit upright for up to 1 minute (if there is any concern regarding orthostatic hypotension or postural intolerance); then reach across midline and shake hands with caregiver – repeat with other hand. (Patient's feet may either be flat on floor or dangling.) **Safe Mode:** Use sling and lift to assist to side of bed (e.g., sternal precautions, abdominal incision) or bed in chair position, then complete "Sit and Shake."	**Sit:** Able to follow commands and sit unsupported (i.e., unsupported by sling or bed surface) for up to 1 minute. **Shake:** Able to maintain seated balance while challenged by reaching across midline of trunk with one or both hands and shaking caregiver's hand.	**Pass** Assessment Level 1 "Sit and Shake" = **Proceed to Assessment Level 2, "Stretch"** **Fail = Mobility Level 1 Patient** *As appropriate, follow Critical Care Early/Progressive Mobility Program protocol to advance through BMAT Assessment Levels.*
Assessment Level 2 Assessment of: • leg strength in preparation for weight bearing • control and strength of leg muscles, including quadriceps and lower leg muscles • foot drop	**Stretch:** While sitting upright unsupported, extend one leg and straighten knee (knee remains below hip level) and point toes/pump ankle between dorsiflexion/plantar flexion x 3 repetitions. (Patient's feet may either be flat on floor or dangling.) **Safe Mode:** Continue to use sling and lift (mobile or overhead/ceiling), bed in Fowler's or chair position to complete "Stretch."	**Stretch:** Able to extend leg and straighten knee = engage quadriceps; then able to pump ankle for 3 repetitions = AROM/move ankle between dorsiflexion/plantar flexion = engage calf muscles/skeletal muscle pump and assist with venous return/fluid shifts.	**Pass** Assessment Level 2 "Stretch" = **Proceed to Assessment Level 3, "Stand"** **Fail = Mobility Level 2 Patient**
Assessment Level 3 Assessment of: • ability to shift forward, raise buttocks and rise smoothly; balance and strength to rise • standing tolerance for up to 1 minute, which allows for fluid shifts and other compensatory changes to occur • static standing balance	**Stand:** With feet flat on floor about shoulder width apart, shift forward, raise buttocks/rise and stand upright for up to 1 minute (if there is any concern regarding orthostatic hypotension, postural intolerance or syncope). **Safe Mode:** Use sit-to-stand lift and vest/sling, or ambulation vest/pants and lift. *Always default to using Safe Mode if concerned regarding orthostatic hypotension/syncopal event or other compensatory changes.*	**Stand:** Able to rise, maintain balance and upright standing position for up to 1 minute. *The majority of patients who exhibit orthostatic hypotension do so within the first minute of standing, which is the rationale for 1 minute.* Use walker, cane, crutches or prosthetic leg(s) as appropriate to assist.	**Pass** Assessment Level 3 "Stand" = **Proceed to Assessment Level 4, "Step"** **Fail = Mobility Level 3 Patient**
Assessment Level 4 Assessment of: • pre-ambulation weight shift abilities • further assessment of leg strength • dynamic standing balance, which further allows for fluid shifts and other compensatory changes to occur • cognitive ability to follow directions	**Step:** 1) March- or step-in-place taking small steps (not high-marching steps) x 3 repetitions; if able to pass then 2) Step forward with one foot, weight-bear/shift weight onto foot and return foot to starting position; repeat with other foot. **Safe Mode:** Use ambulation vest/pants and lift; consider use of bed in chair position and egress from end-of-bed. *Always default to using Safe Mode if concerned regarding orthostatic hypotension/syncopal event, other compensatory changes or falls.*	**Step:** Able to perform both marching-in-place and forward step and return with one foot and then the other. Use walker, cane, crutches or prosthetic leg(s) as appropriate.	**Pass Assessment Level 4 "Step" = Progress through Discharge Planning** Continue to complete BMAT per protocol; address medical issues and stability; use multidisciplinary approach: work on discharge goals for best destination/placement; consider functional status, ongoing equipment needs and ADL's **Fail = Remain a Mobility Level 4 Patient**

Patient's BMAT Mobility Level	Assessment Level				Test Options in SAFE MODE *(See Figure A, page one for Description of Basic Test)*	Patient Care and Strengthening in SAFE MODE SPHM Equipment to Consider for patient care/strengthening NOTE: Consult with PT/OT per facility protocol
	1. Sit & Shake*	2. Stretch*	3. Stand*	4. Step*		
Mobility Level 1 = Fails/unable to "Sit and Shake" ***As appropriate, follow Critical Care Early/ Progressive Mobility Program protocol.***	FAIL	NA	NA	NA	1) Perform with patient sitting upright in bed 2) Using lift and sling help patient sit at Edge of Bed (EOB) *As appropriate, follow Critical Care Early/Progressive Mobility Program protocol to advance through BMAT Assessment Levels.*	**Goals:** Avoid complications of immobility, engage and strengthen postural muscles and progress to Level 2. 1)Edge of Bed (EOB) dangling with sling and lift: work on sitting balance and reaching across midline; perform calf pump exercises 2)Bed in Fowler's or chair position: sitting supported or unsupported to cross midline and shake hands; also perform calf pump exercises 3)Lift and repo sheet: for boosting and turning 4)Lift and multistraps: for turning and limb holding 5)Lift and sling: for bed to chair/commode transfer 6)Friction Reducing Device (FRD): for PROM/AROM exercises
Mobility Level 2 = Passes "Sit and Shake;" Fails/unable to "Stretch"	PASS	FAIL	NA	NA	1) Perform with patient sitting upright in chair position 2) While at EOB dangling and secured by sling and lift	**Goals:** Avoid complications of immobility, engage and strengthen postural and lower extremity muscles, assist with fluid shifts and progress to Level 3. 1) FRD: partial squats and leg AROM exercises – bed flat or tilt position 2) Lift and repo sheet: boosting and turning 3) Lift and multistraps: limb holding or turning 4) Lift and sling: bed to chair/toilet transfer 5) In bed: perform additional calf pump exercises
Mobility Level 3 = Passes" Sit and Shake," and "Stretch;" Fails/unable to "Stand"	PASS	PASS	FAIL	NA	1)Using sit-to-stand lift with vest: evaluate patient's tolerance for standing upright and weight bearing; monitor patient's BP and HR; maintain balance for up to 1 minute. 2)Using standing/ambulation vest or pants and floor-based or ceiling lift: starting with patient's feet flat on floor, instruct patient to rise and stand; monitor patient's BP, HR, standing balance and tolerance for up to 1 minute. As appropriate, after testing in Safe Mode, use walker, cane, crutches, prosthetic leg(s) to evaluate standing tolerance and to progress to "Step."	**Goals:** Strengthen muscles in upright position, assist fluid shifts, avoid falls and progress to Level 4. 1)Sit-to-stand lift with vest/sling: stand for 1-2 minutes; shift weight from one foot/leg to the other, 2 – 3 deep breaths 2)Squats using FRD with bed in tilt position 3)Lift and multistraps: limb holding 4)Powered or non-powered sit-to-stand lift for bed to chair/toilet transfers (e.g., quick night-time transfer to and from toilet) 5)If using aid (walker, cane, crutches, prosthetic), after standing with sit-to-stand lift, work on standing with aid.
Mobility Level 4 = Passes "Sit and Shake," "Stretch" and "Stand;" Fails/unable to "Step"	PASS	PASS	PASS	FAIL	1) If a sit-to-stand lift with vest was used and patient passed "Stand:" evaluate first portion of "Step," march-in-place, while patient is still secure in vest attached to sit-to-stand lift. 2) Using ambulation vest or pants attached to lift: evaluate "Step" by instructing patient to march-in-place. If able to perform march-in-place, instruct patient to advance step with one foot and return foot to starting position. If able to pass, repeat with other foot. Use walker, cane, crutches or prosthetic leg(s) as appropriate.	**Goals:** Improve standing tolerance and endurance with stepping and weight-shifts, balance and ambulation; avoid falls; consider mobility, functional status, and discharge goals. 1)Lift and ambulation vest/pants for standing, stepping-in-place, weight-shifting/balance activities, and walking 2)Set distance goals to improve endurance and confidence with lift and without lift after passing "Step." 3)If using aid (walker, cane, crutches, prosthetic) to pass "Step," assure that aid is always easily accessible and used for transfers in-room and during hallway ambulation.
Progress through Discharge Planning = Passes all 4 Assessments Review Discharge Goals; Post-acute Discharge Planning	PASS	PASS	PASS	PASS	• Continue to complete BMAT per protocol; with any change in status adjust Mobility Level and goals as needed. • While improving/maintaining mobility, continue to address medical issues and stability as needed; evaluate other medical conditions/treatment plan prior to physician release. • Mobility goals may include: independence with bed mobility and transfers; improve balance, standing tolerance, endurance with walking; independence with aid(s) - walker, cane, crutches, prosthetic(s).	**Multidisciplinary approach:** • Compare pre-admit status, including ability to perform ADLs, to discharge status; i.e., previous level of function (PLOF) compared to post-acute functional status; review rehabilitation goals – have they been met? • Review discharge goals and guide discharge recommendations; appropriate post-acute discharge destination and equipment needs.

NOTE: *Always default to the safest testing/lifting/transfer method (e.g., total lift and sling) if there is any doubt in the patient's ability to perform the task.*

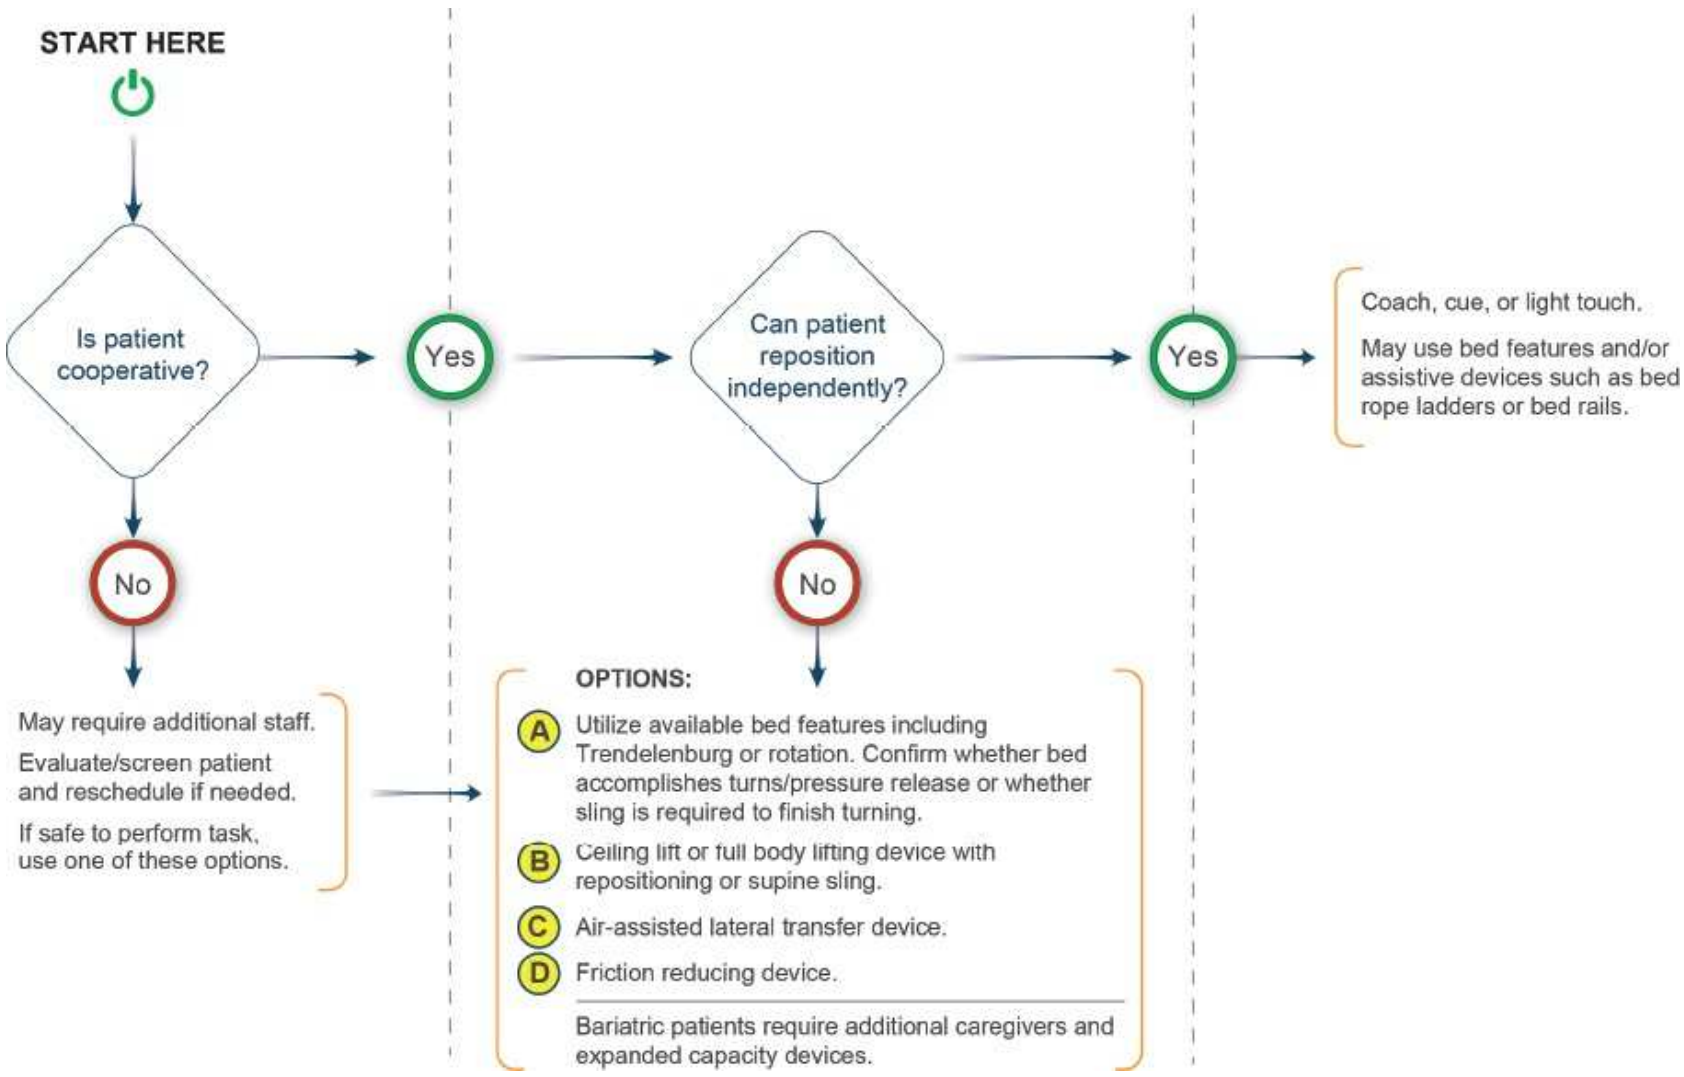

FIGURE 34-10. Example of an algorithm (assessment tool) to aid in decision making regarding safe patient handling and mobility to reposition a patient in bed. (*Source*: VA Mobile Health. [n.d.]. *Safe patient handling*. [Version 1.3.3]. Algorithm 3. [Mobile app]. U. S. Department of Veteran Affairs. https://mobile.va.gov/app/safe-patient-handling)

- Explain to the patient what you plan to do. Then use what abilities the patient has to assist you. This technique often decreases the effort required and the possibility of injury to you.
- If the patient is in pain, administer the prescribed analgesic sufficiently in advance of the transfer to allow the patient to participate in the move more comfortably.
- Elevate the bed as necessary so that you are working at a height that is comfortable and safe for you.
- Lock the wheels of the bed, wheelchair, or stretcher so that they do not slide while you are moving the patient.
- Be sure the patient is in good body alignment while being moved and lifted to protect the patient from strain and muscle injury.
- Support the patient's body properly. Avoid grabbing and holding an extremity by its muscles.
- Avoid friction on the patient's skin during moving.
- Use friction-reducing devices whenever possible, especially during lateral transfers.
- Move your body and the patient in a smooth, rhythmic motion. Jerky movements tend to put extra strain on muscles and joints and are uncomfortable for the patient.
- Use SPHM equipment/devices when moving patients. Be sure that you understand how the device operates and that the patient is properly secured and informed of what will occur. If you are not comfortable with the operation of the equipment, obtain assistance from a caregiver who is.
- Ensure that the equipment used meets weight requirements. Bariatric patients (BMI >50) require bariatric transfer aids and equipment. Bariatric transfer aids and equipment are designed to be used with people who are obese.

Consider **Mrs. Nguyen**, the woman caring for her husband at home. The nurse would evaluate the need for assistive devices and secure the identified items for patient care. The nurse would incorporate safe patient handling and moving guidelines when role modeling the proper techniques for moving and lifting Mr. Nguyen. In addition, the nurse would use these guidelines to develop a teaching plan for Mrs. Nguyen to ensure safety for all involved when moving and lifting Mr. Nguyen. After teaching Mrs.

Nguyen, the nurse would observe her performing the technique to ensure understanding.

SPHM EQUIPMENT AND DEVICES

Many devices and equipment are available to aid in transferring, repositioning, lifting, and/or moving patients. It is important to use the right equipment and appropriate device based on patient assessment and desired movement and to use the equipment in the proper manner (Fragala et al., 2016). Several types and examples of SPHM equipment and devices are outlined here.

Gait Belts

A gait belt is a device used for transferring patients and assisting with ambulation (Fig. 34-11 on page 1266). The belt, which often has handles, is placed around the patient's waist and secured by Velcro fasteners or a buckle or clip. The handles can be placed in a variety of configurations so that the caregiver can have better access to, improved grasp of, and control of the patient. Some belts are handheld slings that go around the patient, providing a firm grasp for the caregiver and facilitating the transfer. The gait belt is used to steady the patient, not to pull the patient up or as a lifting device stabilization during pivoting. Gait belts also allow the nurse to assist in ambulating patients who have leg strength, can cooperate, and require minimal assistance. Do not use gait belts on patients with abdominal or thoracic incisions or chest trauma. Gait belts should also not be used with patients exhibiting behavioral aggression, as the belt might be used as a weapon and for patients at risk for suicide, as the belt might be used for self-harm (Wintersgill, 2019).

FIGURE 34-11. Gait belt.

Standing Assist and Repositioning Aids

Some patients need minimal assistance to stand up. With an appropriate support to grasp, they can lift themselves. Many types of non-powered standing assist and repositioning devices can provide leverage and help a patient to stand (VHACEOSH, 2016). These devices can be freestanding or attached to the bed or wheelchair. Other aids have a pull bar to assist the patient to stand, and then a seat unfolds under the patient. After the patient sits on the seat, the device can be wheeled to the toilet, chair, shower, or bed.

Lateral-Assist Devices

Lateral-assist devices reduce patient–surface friction during side-to-side transfers. Roller boards, slide boards, transfer boards, inflatable mattresses, and friction-reducing lateral-assist devices are examples of these devices, which make transfers safer and more comfortable for the patient. For example, an inflatable lateral-assist device is a flexible mattress that is placed under the patient. An attached, portable air supply then inflates the mattress, which provides a layer of air under the patient. This air cushion allows nursing staff to perform the move with much less effort. Another example is a transfer board, usually made of smooth, rigid, low-friction material (such as coated wood or plastic). The board, which is placed under the patient, provides a slick surface for the patient during transfers, reducing friction and the force required to move the patient. A third type of lateral sliding aid is made of a special fabric that reduces friction. Some devices have long handles that reduce reaching by staff to improve safety and make the transfer easier

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

(Fig. 34-12).

Friction-Reducing Sheets

Friction-reducing sheets can be used under patients to prevent skin shearing when moving patients in bed and when assisting with lateral transfers. Their use reduces friction and the force required to move patients. However, use of these sheets may require excessive force and overexertion by the caregiver and increase the risk of musculoskeletal injuries for health care personnel (Battiste-McKinney & Halvorson, 2018; VHACEOSH, 2016). This possibility needs to be considered when planning patient handling and mobility interventions (VHACEOSH, 2016).

FIGURE 34-12. Lateral-assist device with long handles to reduce reaching by staff.

FIGURE 34-13. Mechanical lateral-assist device.

Mechanical Lateral-Assist Devices

Mechanical lateral-assist devices include specialized stretchers and eliminate the need to slide the patient manually. Some devices are motorized, whereas others use a hand crank. A portion of the device moves from the stretcher to the bed, sliding under the patient, bridging the bed and stretcher (Fig. 34-13). The device is then returned to the stretcher, effectively moving the patient without any pulling by staff members.

Transfer Chairs

Chairs that can convert into stretchers are available. These are useful with patients who have no weight-bearing capacity, cannot follow directions, and/or cannot cooperate. The back of the chair bends back, and the leg supports elevate to form a stretcher configuration, eliminating the need for lifting the patient. Some of these chairs have built-in mechanical aids to perform the patient transfer, as detailed previously.

Powered Stand-Assist and Repositioning Lifts

These devices can be used with patients who have some weight-bearing ability, can follow directions, and are cooperative. A simple sling is placed around the patient's back and under the arms. Some devices come with breathable slings that can remain under the patient, reducing the risk for the nurse in turning the patient to position the sling. Standing/ambulation vests may be used instead of a sling (Boynton et al., 2020); a vest may provide additional

stability and security in the upper body area, distributing pressure over a larger area, often with extra padding at potential pressure areas and/or leg straps (Enos, 2019). Once in the sling or vest, the patient rests the feet on the device's footrest and places the hands on the handle. The device mechanically assists the patient to stand, without any assistance from the nurse (Fig. 34-14). Once the patient is standing, the device can be wheeled to a chair, the toilet, or bed. Some devices have removable footrests and can be used as a walker. Some have scales incorporated into the device that can be used to weigh the patient. Limb slings and turning bands can be used in conjunction with some lifts to support a body part, such as a limb during dressing changes, and to turn or reposition a patient in bed (Enos, 2019). The duration of time spent in slings should be limited to reduce risk for pressure injury, especially for vulnerable populations (Peterson et al., 2015).

FIGURE 34-14. Stand-assist aid.

Powered Full-Body Lifts

These devices are used with patients who cannot bear any weight to move them out of bed, into and out of a chair, and to a commode or a stretcher. A full-body sling is placed under the patient's body, including head and torso, then the sling is attached to the lift (Fig. 34-15). As mentioned previously, some of these slings are made to stay under the patient to decrease strain on the staff during placement. The device slowly lifts the patient. Some devices can be lowered to the floor to pick up a patient who has fallen. These devices are available on portable bases and ceiling-mounted tracks. The duration of time spent in slings should be limited to reduce risk for pressure injury, especially for vulnerable populations (Peterson et al., 2015).

FIGURE 34-15. Powered full-body lift.

QSEN SAFETY AND EVIDENCE-BASED PRACTICE

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

Providing safe patient care involves the effective use of best-practice guidelines and safety-enhancing technologies related to patient handling and mobility. Nurses have a responsibility to use technology and standardized practices to ensure safe patient handling and mobility, and as a result, minimize the risk of harm to patients and health care providers.

Positioning Patients in Bed

Positioning that maintains correct body alignment and facilitates physiologic functioning contributes to the patient's psychological and physical well-being. The force of gravity pulls parts of the body out of alignment unless adequate support is provided. Various positions are, therefore, protective in nature only when the appropriate positions are maintained.

COMMON DEVICES TO PROMOTE CORRECT ALIGNMENT

Many devices can help maintain proper body alignment and muscle tonus while the patient is in bed and can alleviate discomfort or pressure on various parts of the body.

Foam Wedges and Pillows

Foam wedges and pillows are used primarily to provide support or to elevate a body part. Wedges and pillows of different sizes are useful for different parts. Pillows intended for the head are usually full-sized or large-sized pillows. Small wedges and pillows are ideal for support or elevation of the extremities, shoulders, or incisional wounds. Specially designed wedges and heavy pillows are useful to elevate the upper part of the body when an adjustable bed is unavailable, such as at home. When placing the support, assess for proper alignment. For example, excess cervical flexion would not be comfortable or useful in maintaining adequate respiratory patterns.

Mattresses

A mattress must be firm but have sufficient "give" to permit proper body alignment, as well as to be comfortable and supportive. A patient who must remain in a bed with a nonsupportive mattress may report backache and other discomforts.

Special mattresses, pads, and types of beds used to help prevent pressure injuries are discussed in Chapter 33.

Adjustable Beds

The nurse can elevate the head and/or foot of an adjustable bed to the desired degree. This positioning is discussed later in the chapter. Adjustable beds also allow the bed to be raised so that the mattress is flexed at the level of the knees. Flexion of the knees when the head of the bed is elevated 30 degrees helps to prevent shearing at the sacrum (Baranoski & Ayello, 2020).

It is also possible to alter the height of the bed, raising or lowering the bed to change the distance from the bed to the floor. Position the bed at the height that will let the patient stand with the least amount of effort. Health care workers use the higher bed positions so that they do not strain their backs while providing bed care. However, a lower bed position between treatments decreases the risk of injury if the patient were to fall out of bed. General guidelines for safe use of beds are discussed in Chapter 32.

Many beds used in patient care environments have improvements to support transfer and repositioning of the patient. Some beds easily convert to a chair, bypassing the need for bed-to-chair transfers. Other beds are designed to align the patient's hip with the pivot point in the bed, minimizing slippage toward the foot of the bed when the head of the bed is raised and reducing the need to reposition the patient. Many new mattress surfaces are designed to eliminate the need for frequent repositioning by the nurse; some provide a cushion of air under the patient during movement, reducing friction; and others have surfaces that can rotate to move the patient as needed for care. Some beds incorporate technology to reduce migration by the patient down in the bed as a result of head-of-bed elevation and the effects of gravity and resulting tissue shearing (Lustig et al., 2020). Additional discussion about patient care beds is provided in Chapter 32.

Consider **Mrs. Nguyen**, the older woman caring for her husband after his stroke. If necessary and not already in the home, an adjustable bed or pressure-relieving mattress pads or coverings could be recommended to help her provide care to her husband. This would be beneficial to both Mrs. Nguyen and

her husband.

Trapeze Bar

A trapeze bar (Fig. 34-16) is a handgrip suspended from a frame near the head of the bed. A patient can grasp the bar with one or both hands and raise one's trunk from the bed. The trapeze makes moving and turning considerably easier for many patients and facilitates transfers into and out of bed. It can also be used when a patient needs to perform exercises that strengthen some muscles of the upper extremities (e.g., biceps).

FIGURE 34-16. A trapeze device makes it possible for the patient to lift part of the body from the bed, facilitating turning and moving up in bed.

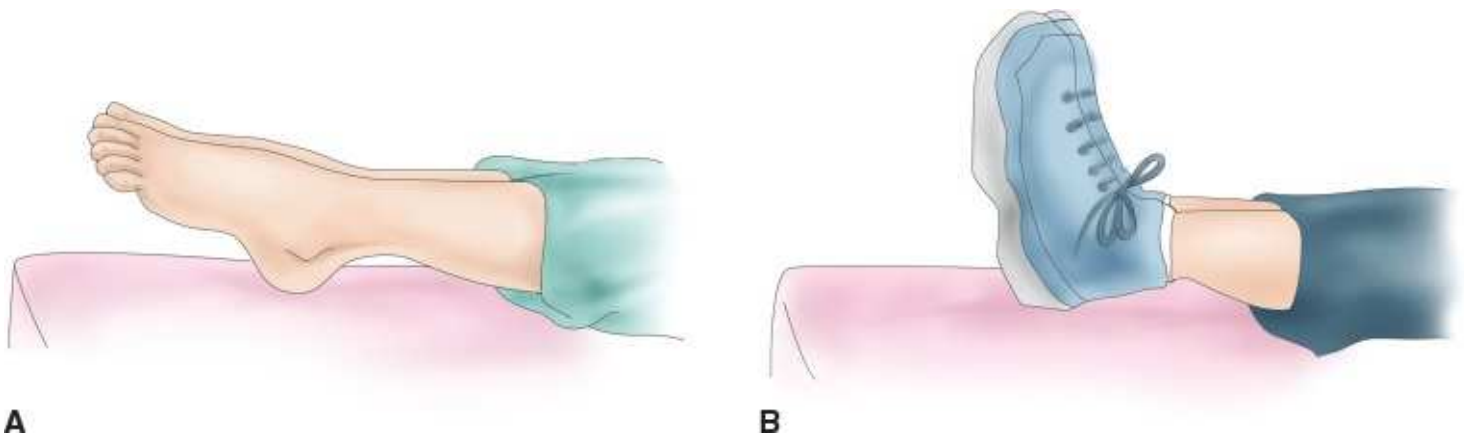

FIGURE 34-17. A. Plantar flexion occurs when the foot is not supported. **B.** When high-top sneakers support the feet, the dorsiflexion position is maintained.

Additional Equipment

The toes drop downward and the feet are in plantar flexion when the feet are unsupported in the dorsiflexion position. Because of the pull of gravity, this position of the feet occurs naturally when the body is at rest. If maintained for extended periods, plantar flexion can cause an alteration in the length of muscles, and the patient may develop a complication called **footdrop**. In this position, the foot is unable to maintain itself in the perpendicular position, heel–toe gait is impossible, and the patient experiences extreme difficulty in walking. The use of a foot support, such as a foot board, foot boot, splints, or high-top sneakers (Morton, 2018), helps avoid this complication. Figure 34-17 demonstrates a foot in plantar flexion versus the dorsiflexion position maintained by wearing a high-top canvas sneaker.

If top bedding must be kept off the patient's lower extremities, a device called a cradle is used. A cradle is usually a frame that supports the bed linens away from the patient to relieve pressure and to prevent anything from touching the legs and feet (Hinkle et al., 2022), while providing privacy and warmth. There are a number of sizes and shapes of cradles. If used, securely fasten the cradle to the bed so that it does not slide or fall on the patient.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

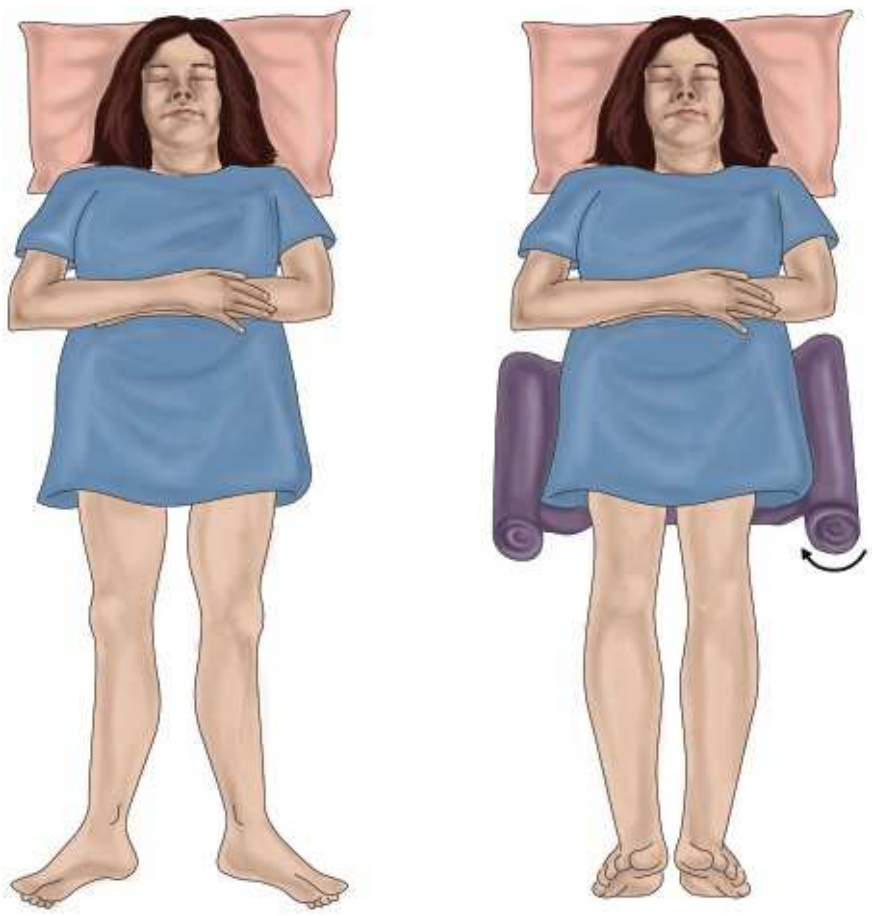

FIGURE 34-18. Trochanter rolls prevent external rotation of the hips of a bedridden patient. The patient is placed on a folded sheet so that the top edge is at the hips and the lower edge is about one third of the way down the thighs. Towels or bath blankets are rolled under each side until the roll is snugly against the patient's hips and thighs. The support cannot unroll, and the weight of the patient keeps it secure.

Trochanter rolls are used to support the hips and legs to prevent external rotation of the hips (Hinkle et al., 2022). Figure 34-18 illustrates and describes how to use trochanter rolls. Properly placed pillows can also be used to help prevent this external rotation, but they tend to slip out of place and require frequent adjustment to be effective.

If a patient is paralyzed or unconscious, hand–wrist splints or hand rolls may be necessary to provide a means for keeping the thumb in the correct position, that is, slightly adducted and in apposition to the fingers. A hand roll can be created by folding a washcloth and rolling it. Once placed against the palm of the hand, it can effectively keep the hand in a functional position (Fig. 34-19). A commercial plastic or aluminum splint also may be used to hold the thumb in place regardless of the hand position. Encourage patients who are not moving their fingers to do finger exercises, with special attention to having the thumb touch the tip of each finger.

Side rails can assist the patient in rolling from one side to the other or to sitting up without calling for assistance. Using the side rails can help the patient retain or regain muscle efficiency. When using side rails, be sure to explain their use to patients and their families and follow the protocol of the health care facility. If a patient requests that side rails be raised for additional security, the patient must have the ability to raise and lower the side rails independently. Safe use of side rails is discussed in Chapters 28 and 32.

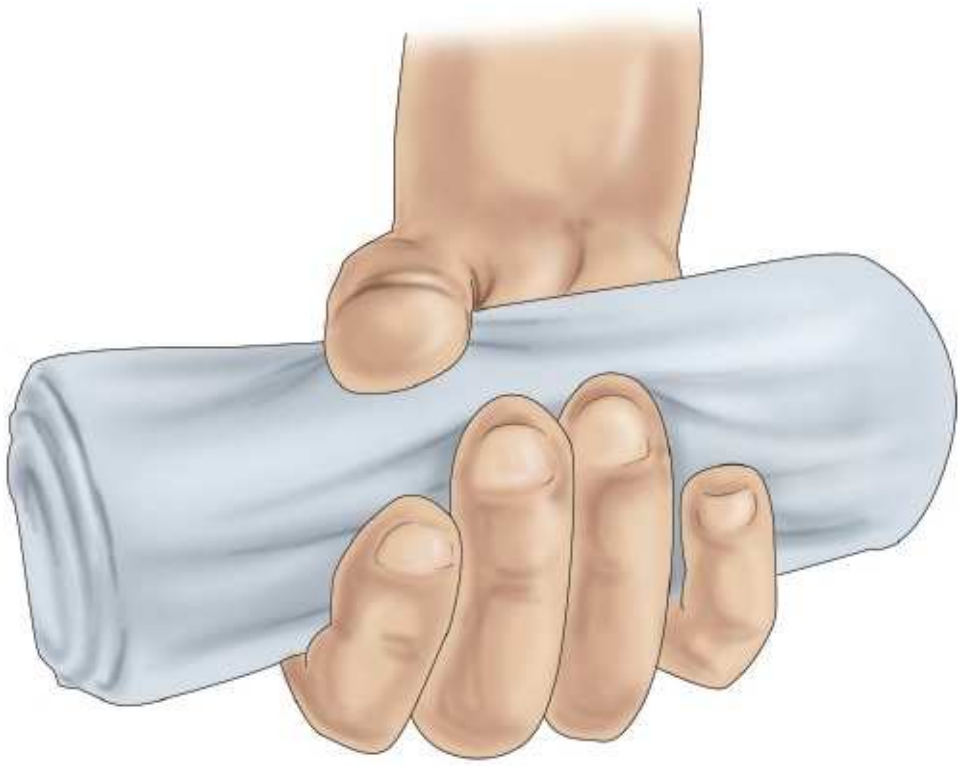

FIGURE 34-19. A hand roll helps maintain functional position.

POSITIONING

Patients may be unaware of the importance of correct body alignment and regular position changes when on bed rest or experiencing decreased mobility. Whenever possible, teach both the patient and family/caregivers the following:

- Correct positioning techniques
- The need to change positions regularly
- The importance of using the time allotted to position changes to exercise the extremities and to assess pressure areas

Regular repositioning redistributes the body's weight and provides pressure relief (Baranoski & Ayello, 2020; McNichol et al., 2021). Repositioning occurs when patients are moved into another position to relieve pressure off a particular part of the body or to redistribute the pressure on a body part (McNichol et al., 2021). Numerous studies have examined turning schedules; the traditional every-2-hour turn schedule may not be the most appropriate approach for every patient (Baranoski & Ayello, 2020). Individual patient characteristics and the use of support surfaces impact the effects of pressure redistribution. Research suggests the frequency of repositioning/turning should be evaluated and reevaluated and tailored to the specific needs of the individual patient based on the patient's unique responses to the care provided (Baranoski & Ayello, 2020; McNichol et al., 2021). When the patient is unable to change position independently, use a repositioning schedule, to assist with and document the rotation of positions. Chapter 33 provides additional discussion of pressure-relieving interventions and nursing care to prevent pressure injuries. Table 34-6 describes common body positions and measures to prevent potential complications associated with each position.

Fowler's Position

The semi-sitting position, or Fowler's position, calls for the head of the bed to be elevated 45 to 60 degrees. This position is often used to promote cardiac and respiratory functioning because abdominal organs drop in this position, providing maximal space in the thoracic cavity. This is also the position of choice for eating, conversation, and urinary and intestinal elimination.

Variations of Fowler's position include high-Fowler's and low-Fowler's, or semi-Fowler's position. In the high-Fowler's position, the head of the bed is elevated 90 degrees. When a bedside table with a pillow on top of it is placed in front of the patient in high-Fowler's position, the patient can lean forward and rest the arms on the pillow, assuming a posture that allows for maximal lung expansion. In low-Fowler's or semi-Fowler's position, the head of the bed is elevated only 30 degrees.

In Fowler's position, the buttocks bear the main weight of the body. In this position, the heels, sacrum, and scapulae are at risk for skin breakdown and require frequent assessment. The semi-Fowler's (semi-reclining) position should be avoided in patients at risk for alterations in skin integrity; raising the head of the bed even a few centimeters increases the shearing force over the sacral area. See Table 34-6 for information about correct positioning and nursing actions to prevent complications associated with this position.

Supine or Dorsal Recumbent Position

In the supine position, the patient lies flat on the back with the head and shoulders slightly elevated with a pillow unless contraindicated, such as spinal anesthesia or surgery on the spinal vertebrae. Correct alignment in the supine position is illustrated in Table 34-6.

Side-Lying or Lateral Position

In the side-lying position, the patient lies on the side and the main weight of the body is borne by the lateral aspect of the lower scapula and the lateral aspect of the lower ilium. Because many people routinely fall asleep in the side-lying position, this is a comfortable alternative to the supine position for the patient on bed rest. Although it relieves pressure on the scapulae, sacrum, and heels and allows the legs and feet to be comfortably flexed, support pillows are needed for correct positioning (see Table 34-6).

The oblique position or 30-degree side-lying position is a variation of the side-lying position. This position is recommended as an alternative to the side-lying position because it places significantly less pressure on the trochanter and sacrococcygeal areas (Baranoski & Ayello, 2020; McNichol et al., 2021). The patient turns toward the side with the hip of the top leg flexed at a 30-degree angle (instead of the 90 degrees side-lying position) and the knee flexed at 35 degrees. The calf of the upper leg is positioned slightly behind the body's midline. Pillows support the patient's back and calf of the top leg (Fig. 34-20 on page 1272).

Another variation of the lateral position is Sims' position. In this position, the patient again lies on the side, but the lower arm is behind the patient and the upper arm is flexed at both the shoulder and the elbow. In this position, the main body weight is borne by the anterior aspects of the humerus, clavicle, and ilium. As a result, the major pressure points differ from those in the lateral and other bed-lying positions (see Table 34-6).

Prone Position

In the prone position, the person lies on the abdomen with the head turned to the side. The body is straight in the prone

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

position because the shoulders, head, and neck are in an erect position; the arms are easily placed in correct alignment with the shoulder girdle; the hips are extended; and the knees can be prevented from flexing or hyperextending. When patients on bed rest use this position periodically, it helps to prevent flexion contractures of the hips and knees. However, the pull of gravity on the trunk when the patient lies prone produces a marked lordosis or forward curvature of the lumbar spine. The position is thus contraindicated for people with spinal problems. The pull of gravity on the feet may result in plantar flexion unless the legs and feet are positioned carefully (see Table 34-6).

Using Graduated Compression Stockings and Pneumatic Compression Devices

Venous stasis, thrombophlebitis, and the development of venous thrombosis are potential complications of immobility (described in Chapter 31). Graduated compression stockings and pneumatic compression devices are passive interventions prescribed to aid in the prevention of these complications. These mechanical methods of prophylaxis may be used alone or in conjunction with pharmacologic prophylaxis for venous thromboembolism (VTE) (AACN, 2016; National Institute for Health and Care Excellence [NICE], 2019; Sachdeva et al., 2018).

Table 34-6 Body Positions, Potential Complications, and Preventive Actions

POSITION	COMPLICATION TO BE PREVENTED	SUGGESTED PREVENTIVE ACTIONS
Fowler's Position 	Flexion contracture of the neck	Allow the head to rest against the mattress or be supported by a small pillow only.
	Exaggerated curvature of the spine	Use a firm support for the back; position the patient so that the angle of elevation starts at the hips.
	Dislocation of the shoulder	Support the forearms on pillows to elevate them sufficiently so that no pull is exerted on the shoulders.
	Flexion contracture of the wrist	Support the hand on pillows so that it is in natural alignment with the forearm.
	Edema of the hand	Support the hand so that it is slightly elevated in relation to the elbow.
	Flexion contractures of the fingers and abduction of the thumbs	Provide hand–wrist splints if necessary.
	Impaired lower extremity circulation and knee contracture, pressure on heels	Elevate the knees for only brief periods; place one or two pillows under the lower legs from below the knees to the ankles; avoid pressure on the popliteal vessels; avoid using the knee gatch.
	External rotation of the hips	Use trochanter roll.
	Footdrop	Support the feet in dorsal flexion. Use footboard; high-top sneakers can also be used.
Supine Position 	Exaggerated curvature of the spine and flexion of the hips	Provide a firm, supportive mattress; use a bed board if necessary.
	Flexion contracture of the neck	Place pillows under the upper shoulders, neck, and head so that the head and neck are held in the correct position.
	Internal rotation of the shoulders and extension of	Place pillows or arm supports under the forearms so that the upper

	the elbows (hunched shoulders)	arms are alongside the body and the forearms are pronated slightly.
	Flexion of the lumbar curvature	Place rolled towel or small pillow under lumbar curvature if needed.
	Extension of the fingers and abduction of the thumbs	Use hand–wrist splints if appropriate.
	External rotation of the femurs	Place sandbags or a trochanter roll alongside the hips and the upper half of the thighs.
	Hyperextension of the knees	Place a pillow under the lower legs from below the knees to the ankles.
	Footdrop	Use a footboard or make an improvised firm foot support to hold the feet in dorsal flexion; high-top sneakers may also be recommended.
Side-Lying or Lateral Position 	Lateral flexion of the neck	Place a pillow under the head and the neck.
	Inward rotation of the arm and interference with respiration	Place a pillow under the upper arm; lower arm should be flexed and positioned comfortably.
	Extension of the finger and abduction of the thumbs	Provide hand–wrist splint if necessary.
	Internal rotation and adduction of the femur	Use one or two pillows as needed to support the leg from the groin to the foot.
	Twisting of the spine	Ensure that both shoulders are aligned with both hips.
Sims' Position 	Lateral flexion of the neck	Place a small pillow under the head unless the drainage of oral secretions is desired.
	Damage to nerves and blood vessels in the axillae of the lower arm	Carefully position lower arm behind and away from the patient's back.
	Internal shoulder rotation and adduction	Abduct the upper shoulder slightly so that the shoulder and elbow are flexed; place a pillow between the chest and upper arm.
	Internal rotation and adduction of the hip; lumbar lordosis	Place a pillow under the upper flexed leg from the groin to the foot.
	Twisting of the spine	Ensure that both shoulders are aligned with both hips.
	Footdrop	Support the lower foot in dorsiflexion with a sandbag.
Prone Position 	Flexion on the cervical spine	Place a small pillow under the head.
	Hyperextension of the spine; impaired respirations	Place some suitable support under the patient between the end of the rib cage and the upper

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

	abdomen if this facilitates breathing and space is available.
Footdrop	Move the patient down in bed so that the feet are over the mattress, or support the lower legs on a pillow just high enough to keep the toes from touching the bed.

GRADUATED COMPRESSION STOCKINGS

Graduated compression stockings (GCS) may be used for patients at risk for venous thromboembolism and pulmonary embolism and to help prevent thrombophlebitis (AACN, 2016; Sachdeva et al., 2018). Manufactured by several companies, GCS are made of elastic material and are available in either knee or thigh-high length. By applying pressure, graduated compression stockings increase the velocity of blood flow in the superficial and deep veins and improve venous valve function in the legs, promoting venous return to the heart. By preventing pooling of the blood, clot formation is less likely. Use of graduated compressions stockings is a prescribed intervention. When assisting with graduated compression stockings, follow these general nursing guidelines:

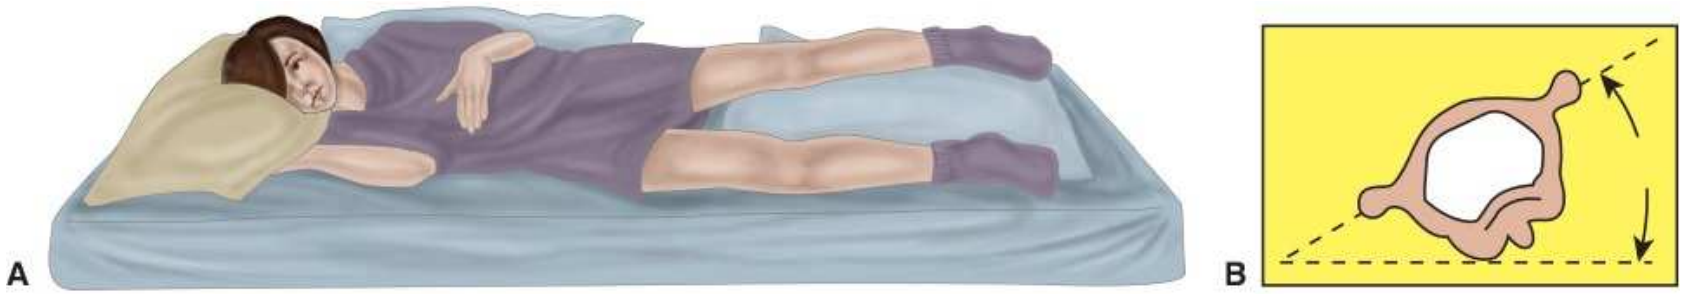

FIGURE 34-20. Modified lateral position (oblique position) is an alternative to the side-lying position, with 30-degree lateral tilt of the hips, resulting in significantly less pressure on the trochanter area. (*Source:* **B.** Used with permission from McNichol, L., Ratliff, C., & Yates, S [Eds.]. [2021]. Wound, Ostomy and Continence Nurses Society Core Curriculum: Wound management [2nd ed.]. Wolters Kluwer.)

- Measure the patient's legs to determine the proper size of stocking. Each leg should have a correct fitting stocking; if measurements are different, then two different sizes of stocking need to be ordered to ensure correct fitting on each leg (Muñoz-Figueroa & Ojo, 2015). The manufacturer whose stockings are being used gives directions for measuring. Some stockings fit either leg; others are designated right or left. An improperly fitting stocking is uncomfortable and ineffective and possibly even harmful (Muñoz-Figueroa & Ojo, 2015).
- Assess the skin condition and neurovascular status of the legs. Report abnormalities before continuing with the application of the stockings.
- Be prepared to apply the stockings in the morning before the patient is out of bed and while the patient is supine. If the patient is sitting or has been up and about, have the patient lie down with legs and feet elevated for at least 15 minutes before applying the stockings. Otherwise, the leg vessels are congested with blood, reducing the effectiveness of the stockings.
- Do not massage the legs. If a clot is present, it may break away from the vessel wall and circulate in the bloodstream.
- Check the legs regularly for redness, blistering, swelling, and pain. Some recommend checking the legs at least once every 8 hours; others recommend twice a day. Remove the stockings completely once a day to bathe the legs and feet.
- Launder the stockings as necessary, but at least every 3 days. Soiled stockings irritate the skin. Dry the stockings on a flat surface to prevent them from stretching. If using a clothes dryer, set on low heat and remove as soon as the cycle is complete. The patient may need two pairs of stockings, to wear one pair while the second pair is being cleaned.
- Always remove graduated compression stockings during morning care and inspect the legs. Then, reapply the stockings before the patient is out of bed.

PNEUMATIC COMPRESSION DEVICES

Intermittent pneumatic compression devices (PCD) (also known as sequential compression devices [SCD]) may be used in conjunction with graduated compression stockings or alone. They are composed of an air pump, connecting tubes, and extremity sleeves that apply intermittent or sequential pressure to the legs to enhance blood flow and venous return, stimulating the normal muscle-pumping action in the legs (refer to Box 31-5 in Chapter 31). PCD/SCD should be kept on at all times except when patients are walking (Wilson et al., 2018). Use of a pneumatic compression

device is a prescribed intervention and may be prescribed for high-risk surgical patients, those with decreased mobility or chronic venous disease, and patients at risk for deep vein disorders.

Turning the Patient in Bed

Frequently, a patient cannot turn in bed without assistance. Nurses need to use their knowledge of correct alignment to turn the patient from the back onto the side, from the back onto the abdomen, and from the abdomen onto the back. One suggested decision-making strategy is outlined in Figure 34-10 (on page 1265). Refer to Figure 34-9 on page 1264 for another decision-making tool with suggestions for associated SPHM equipment. If the patient is fully able to assist in turning, allow the patient to complete the movement independently, with safe supervision. If the patient is partially able or unable to assist, friction-reducing devices, lifting/repositioning sheets, lateral transfer devices, and a full-body sling are potential equipment to consider, based on screening and assessment. Consider available bed features (turning, pressure release, rotation) to assist with the action (VA Mobile Health, n.d.). When turning the patient, the bed should be at the height of the caregivers' elbows to ensure a comfortable working height (VA Mobile Health, n.d.; VHACEOSH, 2016). The technique for assisting a patient with repositioning in bed is described and illustrated in Skill 34-1 (on pages 1290–1292).

Consider **Mrs. Nguyen**, the older woman who will be caring for her husband at home, and Kelsi Lester, the 10-year-old girl who is unconscious. Identifying and arranging for appropriate SPHM equipment for the Nguyen's home and teaching Mrs. Nguyen how to turn and reposition her husband in bed and assist him to get out of bed will be an important part of safe care at home. An individualized turning and repositioning schedule for Kelsi would be essential to prevent alterations in her skin integrity.

Moving a Patient Up in Bed

One suggested decision-making strategy is outlined in Figure 34-10 (on page 1265) to aid in safely moving a patient in bed. Refer to Figure 34-9 (on page 1264) for another decision-making tool with suggestions for associated SPHM equipment. If the patient is fully able, caregiver assistance is not needed and the patient may or may not use a positioning aid. If the patient is fully able to assist in moving up in the bed, allow the patient to complete the movement independently, with safe supervision. The patient assists movement either by pushing with the feet flat against the bed or by using an overbed trapeze. If the patient is partially able or unable to assist, friction-reducing devices, lifting/repositioning sheets, and a full-body sling are potential equipment to consider, based on screening and assessment. Consider available bed features to assist with the action (VA Mobile Health, n.d.). When turning the patient, the bed should be at the height of the caregivers' elbows to ensure a comfortable working height (VA Mobile Health, n.d.; VHACEOSH, 2016). Bariatric patients require additional caregivers and expanded capacity devices (VA Mobile Health, n.d; VHACEOSH, 2016). Repositioning a patient in bed is described and illustrated in Skill 34-1 on pages 1290–1292.

Moving a Patient From Bed to Stretcher

Considerable care must be taken when moving a patient from a bed to a stretcher or treatment table, or vice versa, to prevent injury to the patient and caregivers. A suggested decision-making strategy is outlined in Figure 34-21 on page 1274. Refer to Figure 34-9 on page 1264 for another decision-making tool with suggestions for associated SPHM equipment. If the patient is fully able to assist in the transfer, allow the patient to complete the movement independently, with supervision for safety. If the patient is partially able or not able to assist at all consider use of a friction-reducing device and/or a lateral-transfer device, or ceiling lift or full-body lifting device with seated or supine sling (VA Mobile Health, n.d.; VHACEOSH, 2016). If the patient is unconscious or weakened, additional staff are needed to support the extremities and the head. Bariatric patients require additional caregivers and expanded capacity devices (VA Mobile Health, n.d; VHACEOSH, 2016). One possible set of actions to move a patient from the bed to a stretcher (lateral move) are described in Skill 34-2 on pages 1292–1295. When returning the patient to the bed, the same techniques are used.

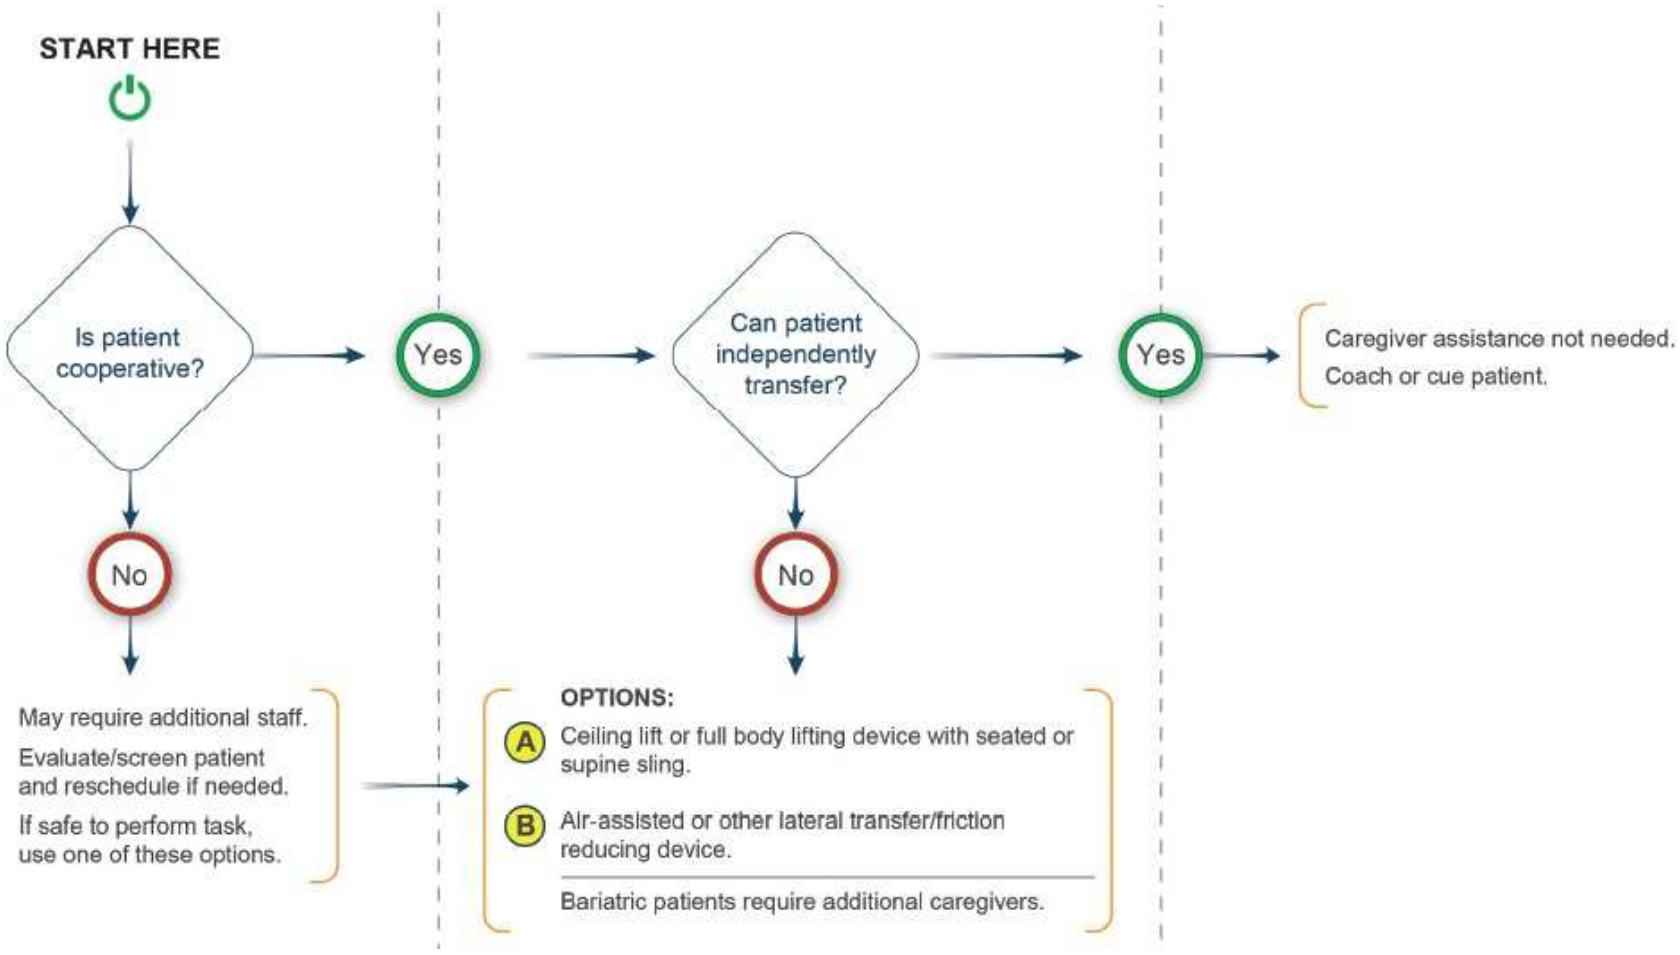

FIGURE 34-21. Example of an algorithm to aid in decision making regarding safe patient handling and mobility to transfer a patient from bed to stretcher. (*Source:* VA Mobile Health. [n.d.]. *Safe patient handling*. [Version 1.3.3]. Algorithm 2. [Mobile app]. U.S. Department of Veteran Affairs. https://mobile.va.gov/app/safe-patient-handling)

Moving a Patient From Bed to Chair

Preliminary assessment of vital signs provides baseline data before moving the patient out of bed; subsequent recordings determine the effect of this activity on the patient. The patient's apparel should be sufficient to prevent embarrassment and provide warmth yet not impede movement.

One suggested decision-making strategy is outlined in Figure 34-22 to aid in safely moving a patient out of bed to a chair. Refer to Figure 34-9 on page 1264 for another decision-making tool with suggestions for associated SPHM equipment. Assess the patient's ability to cooperate with the action, ability to bear weight, and balance when standing. If the patient is fully able to bear weight and cooperative, allow the patient to transfer independently with personal assistive devices as indicated, with safe supervision (VA Mobile Health, n.d.). Decisions for use of SPHM equipment and devices and actions are based on whether or not the patient is cooperative or not; has partial abilities or lack of abilities for weight bearing; and has reliable or unreliable standing balance. Consider use of seated transfer aids, non-powered standing aids, sit-to-stand lifts; powered standing assist devices, or a ceiling lift or full-body lifting device with a seated sling (VA Mobile Health, n.d.; VHACEOSH, 2016). Always transfer to the patient's stronger side (VA Mobile Health, n.d.). Bariatric patients require additional caregivers and expanded capacity devices (VA Mobile Health, n.d; VHACEOSH, 2016). When returning the patient to the bed, the same techniques are used.

Recall **Maggie Wyatt**, the woman being discharged with an external fixation device in place. In assessing the situation, the nurse would need to determine how much Maggie can help with the transfer. From there, the nurse would then determine if another person is needed to help transfer Maggie and the need for SPHM transfer aids or equipment. Realizing that the device is heavy and cumbersome, the nurse would determine that another staff person is needed, as well as an assistive device.

Assisting With Range-of-Motion Exercises

Range of motion is the complete extent of movement of which a joint is normally capable. Engaging in routine tasks —such as bathing, eating, dressing, and writing—helps use muscle groups that keep many joints in effective range of motion. When all or some of one's normal ADLs are impossible, it is important to give attention to the joints not

being used or to those that are limited in their use.

Unless contraindicated, encourage active, active-assistive, or passive range-of-motion exercises regularly and include them in the patient's plan of care. In **active exercise**, the patient independently moves joints through their full range of motion (isotonic exercise). In active-assistive exercise, the nurse may provide minimal support and assistance if the patient cannot do the exercise independently. In **passive exercise**, the patient is unable to move independently, and the nurse moves the joint through its range of motion. Both active and passive exercises improve joint mobility and increase circulation to the affected part, but only active exercise increases muscle mass, tone, and strength and improves cardiac and respiratory functioning. Thus, exercises should be as active as the patient's physical condition permits. It is also helpful to teach isometric exercises to patients to increase muscle mass, tone, and strength.

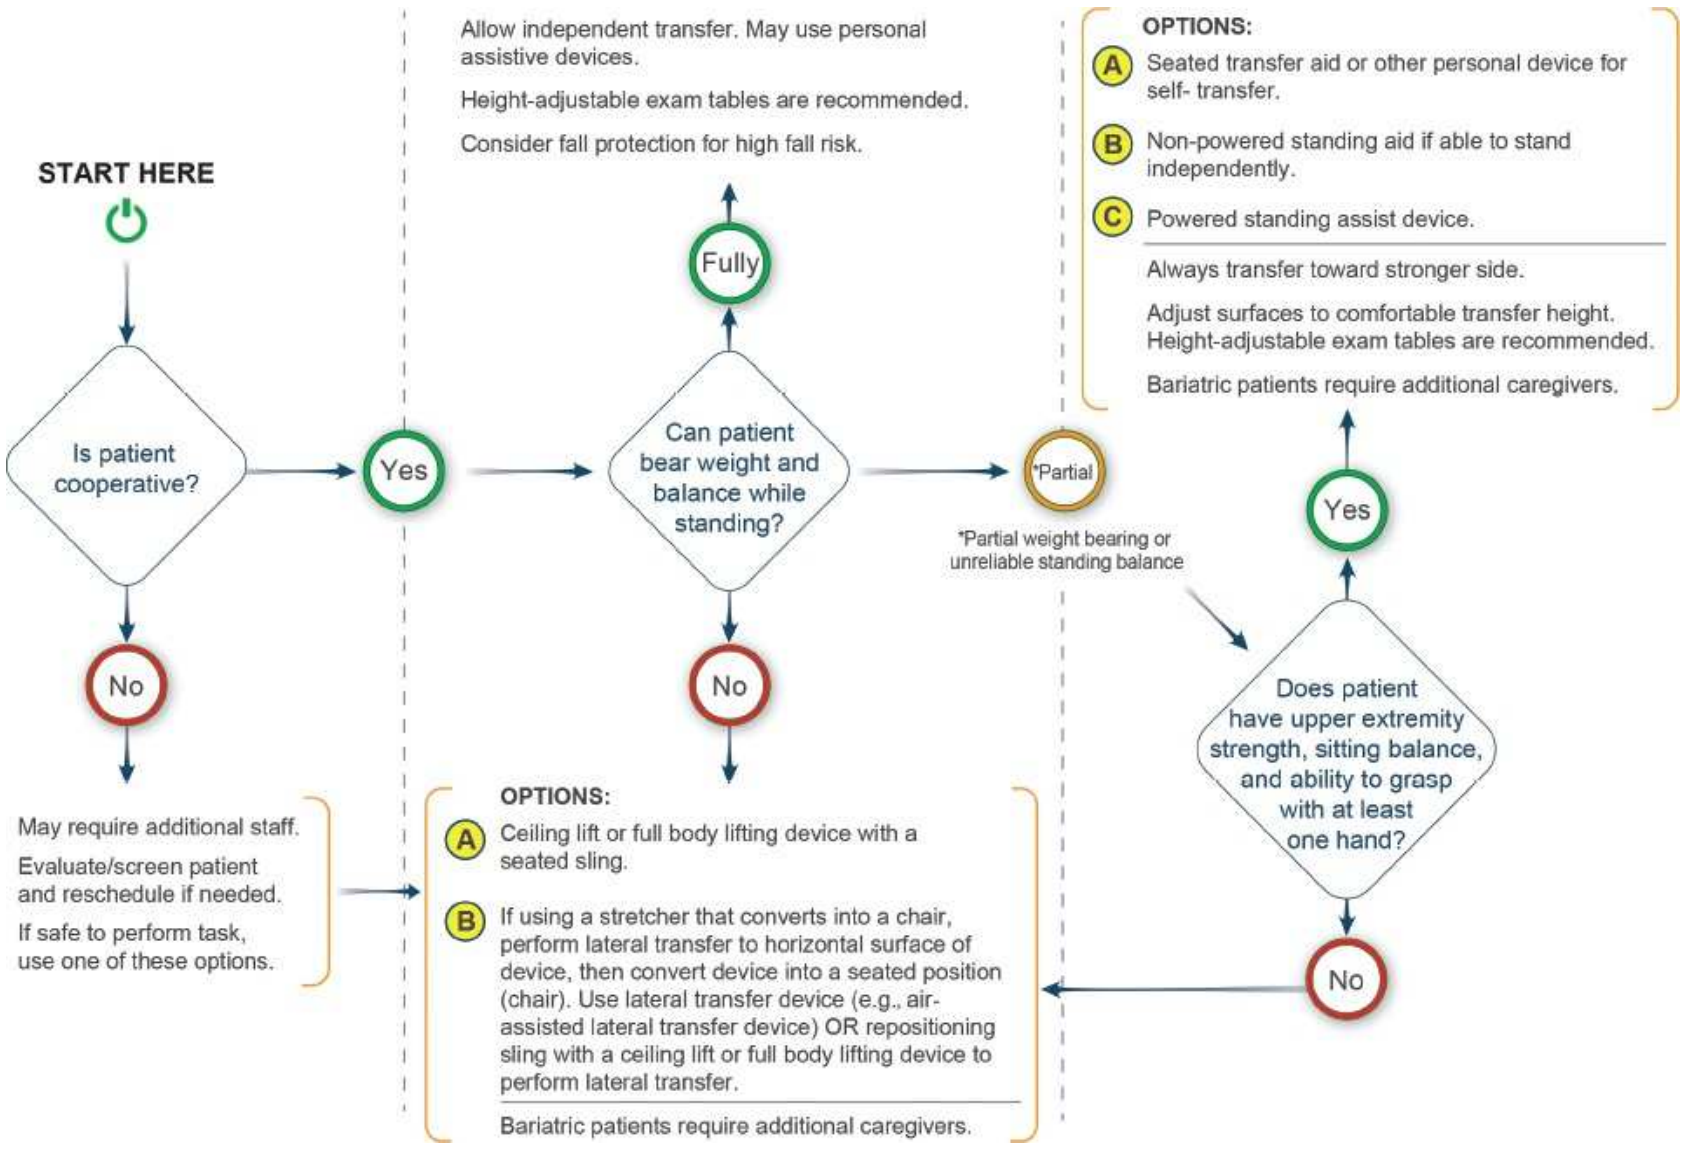

FIGURE 34-22. Example of an algorithm to aid in decision making regarding safe patient handling and mobility to transfer a patient from bed to a chair. (VA Mobile Health. [n.d.]. *Safe patient handling*. [Version 1.3.3]. Algorithm 1. [Mobile app]. U.S. Department of Veteran Affairs. https://mobile.va.gov/app/safe-patient-handling)

Include directives in the plan of care for range-of-motion exercises, specifying what, how, and when, so that all who care for the patient observe the same routine. In some care environments, nurses may work closely with physical therapists in designing and implementing exercise programs. Refer to Table 34-2 (on page 1243) for an explanation of terms related to movement. The following are basic guidelines to follow when helping to put the patient's joints through range of motion:

- Teach the patient what exercise is being undertaken, why, and how it will be done. A show-and-tell technique is often helpful.
- Avoid overexertion and continuing exercises to the point that the patient develops fatigue. The exercises are not meant to exhaust or tax the patient. It may be necessary to delay certain exercises until the patient's condition allows.
- Avoid neck hyperextension and attempts to achieve full range of motion in all joints with older adults. These movements may prove painful. Encourage adequate range of motion in those joints necessary to perform ADLs.
- Start gradually and work slowly. All movements should be smooth and rhythmic. Irregular and jerky movements are uncomfortable for patients.
- Move each joint until there is resistance but not pain. Report uncomfortable reactions and stop exercises until further instructions are obtained.
- Return the joint to a neutral position, that is, its normal position of alignment, when finishing each exercise.
- Keep friction at a minimum when moving extremities to avoid injuring the skin.
- Use range-of-motion exercises twice a day, and do the exercises regularly to build up muscle and joint capabilities. Perform each exercise two to five times. It is possible to perform many of the exercises when the patient is being

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

bathed as part of that procedure. Encourage routine tasks such as eating, dressing, self-bathing, and writing to help to put certain joints through range of motion.

- Expect the patient's respiratory and heart rate to increase during exercise. These rates should return to usual resting levels within 3 minutes. If they do not, the exercises are probably too strenuous for the patient.
- Use passive exercises as necessary, but encourage active exercises of the same kind when the patient is able to do so independently. Exercises should continue at home after a discharge, as necessary.

Think back to **Maggie Wyatt**, the woman being discharged after treatment for a fracture. Range-of-motion exercises are essential for Maggie to maintain function. Although physical therapy would probably develop the exercise regimen, the nurse would need to reinforce these instructions with Maggie before discharge. In addition, the nurse would observe Maggie performing the active range-of-motion exercises, giving encouragement and correcting any misunderstandings, and would assist with the passive exercises until she goes home.

The goal of range-of-motion exercises is to keep the patient in the best possible physical state when bed rest is necessary or movement is restricted. Consult with the health care team regarding appropriate interventions and the need for collaboration with a physical therapist.

Concept Mastery Alert

Caution is necessary when performing range-of-motion exercises with patients who are unresponsive because these patients are unable to report pain.

Patient Mobility

Fortunately, for most patients, prolonged periods of bed rest are no longer considered necessary during most illnesses. Routine activity and mobilization of patients is an important activity and is appropriate for most patient populations (Arnold et al., 2018; Liu et al., 2018; Nack et al., 2019; Tasheva et al., 2020). Early, routine mobilization of critically ill patients is safe and reduces hospital length of stay, shortens the duration of mechanical ventilation, shortens the length of stay, and improves muscle strength and functional independence (Campbell et al., 2015; Dammeyer et al., 2013; Dirkes & Kozlowski, 2019). Specialized equipment contributes to early mobilization and allows it to occur safely and comfortably for staff and patients (Arnold et al., 2018; Dirkes & Kozlowski, 2019). A wide variety of walking devices are available, such as wheeled walkers, knee walkers, platform walkers; platform walkers serve as a holder for medical equipment and also provide support for the patient while ambulating (Henecke et al., 2015; Nack et al., 2019).

Early mobility moves along a continuum, beginning when the patient may not be capable of active participation through activities in bed, such as scheduled turning or the bed-in-chair position. Upright-tilt beds progressively tilt from supine to full standing; edge-of-bed sitting helps the patient move toward physical independence (Nack et al., 2019). Ceiling and floor lifts may be paired with transfer or walking slings to accomplish early mobility around and beyond the bed (Nack et al., 2019). Activity, even as mild as a short walk around the room, down the hall, from the bedroom to the living room, or out into the yard, is important for the body.

Patients who are not confined to bed for long periods, who sleep well, and who experience possibly short periods of rest during the day may not require special considerations for increased physical activity in preparation for ambulation. However, interventions to assist patients to regain and achieve mobility must be implemented to varying degrees for most patients, including those experiencing bed reset or acute inactivity associated with hospitalization or disease state (Dirkes & Kozlowski, 2019). Early mobility is important to prevent complications of immobility and for the successful transition to post-acute care environments (Dirkes & Kozlowski, 2019). Refer to the accompanying Research in Nursing display regarding the experiences of older adults with ambulation during a hospital stay.

PHYSICAL CONDITIONING TO PREPARE FOR MOBILITY AND AMBULATION

Certain exercises that strengthen the overall efficiency of the musculoskeletal system can be done in bed. Check for physical activity restrictions or other contraindications before beginning any exercises.

Quadriceps and Gluteal Setting Drills (Sets)

Quadriceps drills are isometric exercises—exercises in which muscle tension occurs without a significant change in the length of the muscle. One of the most important muscle groups used in walking is the quadriceps femoris. This muscle group helps extend the leg and flex the thigh. To help reduce weakness and make first attempts at walking easier, encourage bedridden patients to contract this muscle group frequently. Following are techniques for quadriceps drills:

- Have the patient contract or tighten the muscles on the front of the thighs. The patient has the feeling of pushing the knees downward into the mattress and pulling the feet upward.
- Have the patient hold the position just described while counting slowly to four and then relax the muscles for an equal count. Emphasize that relaxation is important to prevent muscle fatigue.
- Caution the patient not to hold the breath during these exercises to avoid straining the heart.
- Teach the patient to do quadriceps drills two or three times each hour, four to six times a day, or as prescribed.
- Instruct the patient to stop the exercise short of muscle fatigue.

The muscles in the buttocks can be exercised in the same way by pinching the buttocks together and then relaxing them. This is called gluteal setting. Tightening and holding the abdominal muscles for 6 seconds and then relaxing them also strengthen this muscle group to facilitate walking.

Pushups

The muscles of the arms and shoulders may also need strengthening before the patient is ready to be out of bed. Exercises should improve the strength needed to hold onto or get into a chair and to move about with greater ease. They are part of the preparation for patients who must learn to walk on crutches.

Research in Nursing

Bridging the Gap to Evidence-Based Practice

Older Adults Experiences With Ambulation During Hospitalization

Routine activity and mobilization of patients is an important activity and is appropriate for most patient populations. Early, routine mobilization of patients reduces hospital length of stay and improves muscle strength and functional independence. Older adults often lose their ability to independently ambulate during hospitalization (King et al., 2021), increasing the risk for complications associated with immobility. Best practice dictates that nurses encourage ambulation as part of the plan of care. What are the experiences of older adults with ambulation during hospital admission?

Related Research

King, B., Bodden, J., Steege, L., & Brown, C. J. (2021). Older adults experiences with ambulation during a hospital stay: A qualitative study. *Geriatric Nursing, 42*(1), 225–232. https://doi.org/10.1016/j.gerinurse.2020.08.005

The purpose of this qualitative study was to understand older adults' perceptions of and experiences with ambulation during a hospital admission. Community-swelling older adults (n = 11) who had a hospital admission within the past year were recruited to participate in five focus group meetings, each lasting 90 minutes. Two researchers conducted all focus groups, with one researcher conducting all interviews and one recording observations of the participants. The focus group meetings were audio recorded and transcribed verbatim. Observations of group interactions, pauses in the conversation, and non-verbal communications were recorded. Data analysis was conducted by two researchers using open coding, creating subcategories and categories. Weekly analysis meetings were used to compare and discuss consistency in coding, with joint reanalysis of disagreement in codes to reach consensus. Constant comparative analysis was used to compare data obtained from different participants. Data analysis resulted in a vivid understanding and description of the participants' experiences with walking during hospitalization. Member checking was used to verify accuracy of the data analysis. Participants described high complexity in deciding whether or not they could ambulate; six categories were identified, including *uncertainty*, *restriction messaging*, *non-welcoming space*, *caring for nurse and self*, *feeling isolated*, and *presenting self*. Numerous barriers influenced participants' decisions, including the physical environment, threats to personal dignity, a sense of isolation, and the desire to no burden the nursing staff with requests to ambulate. The researchers concluded that holder adults perceive hospitals as an unwelcoming space for physical movement and identify specific danger zones that exist within hospitals that preclude them from walking. The researchers suggested that this information provides critical insight into the need for interventions to improve older adult patient ambulation.

Implications for Nurses

The results of this study suggest that nurses need to consider possible barriers to ambulation by older adults in the

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

hospital in order to implement appropriate interventions to address these barriers, support ambulation, and prevent complications of immobility. Nurses have a responsibility to improve older adult patient ambulation in the most efficient, effective, and safe manner possible.

A trapeze attached to the bed of a patient who has limited use of the lower part of the body helps the patient to move about in bed and strengthens muscles in the upper part of the body. However, this does not strengthen the triceps, which is the muscle group necessary for crutch walking or for moving from a bed to a chair. More suitable exercises are pushups, which are done as follows:

- While sitting up in bed without support, the patient can do pushup exercises to strengthen the triceps. Instruct the patient to lift the hips off the bed by pushing down with the hands on the mattress. If the mattress is too soft, a block of books can be placed on the bed under the patient's hands.
- Pushups may also be done with the patient lying in bed on the abdomen. Instruct the patient to place the hands near the outstretched body at about shoulder level, with palms down on the mattress and elbows bent sharply. Then have the patient straighten the elbows to lift the head and shoulders off the bed.
- Pushups may also be done when the patient sits in an armchair or wheelchair. The patient places the hands on the arms of the chair and then raises the body out of the seat.
- Pushups should be done three or four times a day, increasing the number as upper body strength improves.

Remember **Maggie Wyatt**, the woman with a fracture being discharged? Due to bed rest, her physical conditioning may be less than what it was before the fracture. Therefore, exercises—such as quadriceps and gluteal setting exercises and pushups in bed—could help to improve Maggie's conditioning, allowing her to participate more fully in her care. These exercises will prepare Maggie for transferring from the bed to the chair or from the chair to the car.

Dangling

Dangling refers to the position in which the person sits on the edge of the bed with legs and feet over the side of the bed. This exercise can help prepare patients for being out of bed. One method is carried out as follows:

- Place the patient in the sitting position in bed for a few minutes. This will accustom the patient to this position and help prevent feelings of faintness.
- Place the bed at a height that will allow the patient to reach the floor with their feet or the height to reach a footstool, on which the patient can rest their feet while dangling.
- Encourage the patient to make use of a stand-assist device, either freestanding or attached to the side of the bed to move toward the side of the bed and to a side-lying position, facing the side of the bed on which the patient will sit.
- Encourage the patient to make use of the stand-assist device to pivot a quarter of a turn and swing their legs over the side of the bed. Support the shoulders and legs if needed.
- Alternatively, use a sling and ceiling lift or floor lift to move the patient to a sitting position.
- Rest the patient's feet on the floor or on the footstool. This gives a sense of security and lessens the likelihood that the patient will slide off the bed.
- Have the patient move the feet using an up-and-down, marching motion. This promotes circulation in the legs.
- Assess for lightheadedness or other signs of orthostatic hypotension (dizziness, nausea, tachycardia, or pallor).
- Remain with the patient and be ready to place the patient back to a lying position if feeling faint, to prevent falling out of bed.

Daily Activities for Purposeful Exercise

Many activities can be carried out in ways that encourage patients to move and gain the benefit of exercise, improving physical conditioning. When patients understand the purpose, they often adopt other exercises for themselves. For example, position the over the bed table so that the patient must use shoulder and arm muscles to reach it, instead of placing it so that little effort is required to take things from it. Place the signal cord (call light) so that the patient must

move either the arm or shoulder to reach it, as long as it is definitely within reach. Encourage patients to sit up and reach for the overbed table, to pull it close, and then to push it back in place. In addition, encourage patients to try to carry out self-care activities, including washing their back independently or putting on socks while still in bed.

In a hospital setting, ADLs may be one of the few independent activities that a patient can perform. Allowing patients to do as much as they can independently is vital. Be sure to offer encouragement and praise. Collaborate with the occupational therapist when necessary to determine types of adaptive equipment that would help the patient achieve maximal functional independence. Box 34-2 provides examples of adaptive equipment. Providing the necessary adaptive tools, coupled with encouraging independence, will create the optimal outcome.

Box 34-2 Adaptive Equipment to Assist With Activities of Daily Living

- Long-handled bath sponges
- Reachers
- Long-handled shoehorns and sock aids
- Elastic shoelaces
- Utensils that are enlarged, specially angulated, or have special grips
- Velcro devices
- Universal cuffs (to hold silverware, comb, toothbrush, and the like, in palm)
- Feeding devices such as plates or bowls with suction-cup bottoms and/or lips to help with scooping food
- Splints and positioning equipment
- Shower chairs
- Transfer benches
- Environmental adaptations (grab bars, ramps)

PROVIDING ASSISTANCE WITH WALKING

Physical inactivity associated with health conditions and health care can have many unfavorable consequences. Early mobility plays an important role in the patient's physical and psychological well-being (Arnold et al., 2018). Nurses caring for patients who have experienced physical deconditioning will often work in collaboration with physical medicine and rehabilitation health care providers. Before getting the patient out of bed, do the following:

- Use a screening or assessment tool to assess the patient's ability to walk and the need for SPHM devices and assistance to guide decision making (VA Mobile Health, n.d.; VHACDOSH, 2016). Suggested decision-making tools and suggested associated SPHM equipment are outlined in Figures 34-9 (on page 1264) and 34-22 (on page 1275).
- Consider use of a gait belt for any patient who is not independent to promote safety (Wintersgill, 2019). A gait belt is used to steady the patient, not as a lifting device (Wintersgill, 2019).
- Explain to the patient exactly what is to be done: transfer technique from bed to erect position, projected distance to be ambulated, assistance available, and the correct manner of using it. Instruct the patient to alert the nurse immediately if feeling dizzy or weak.
- Ensure that the patient has a clear path for ambulation.
- Provide skid-proof footwear.

Assist the patient to an erect position for ambulation, pausing after the patient is seated at the edge of the bed and again after the patient first stands to ensure that the patient feels steady. Use SPHM devices as necessary, to prevent injury to the nurse and patient. Reinforce the need to stand erect and to hold the head high to achieve the full benefits of walking. Patients who are fearful of walking often tend to look at their feet. Remind the patient to take deep breaths to aerate the lungs while walking. Because patients who are walking for the first time after prolonged bed rest often feel faint or weak, plan ambulation for a short distance, gradually increasing the distance as tolerated.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

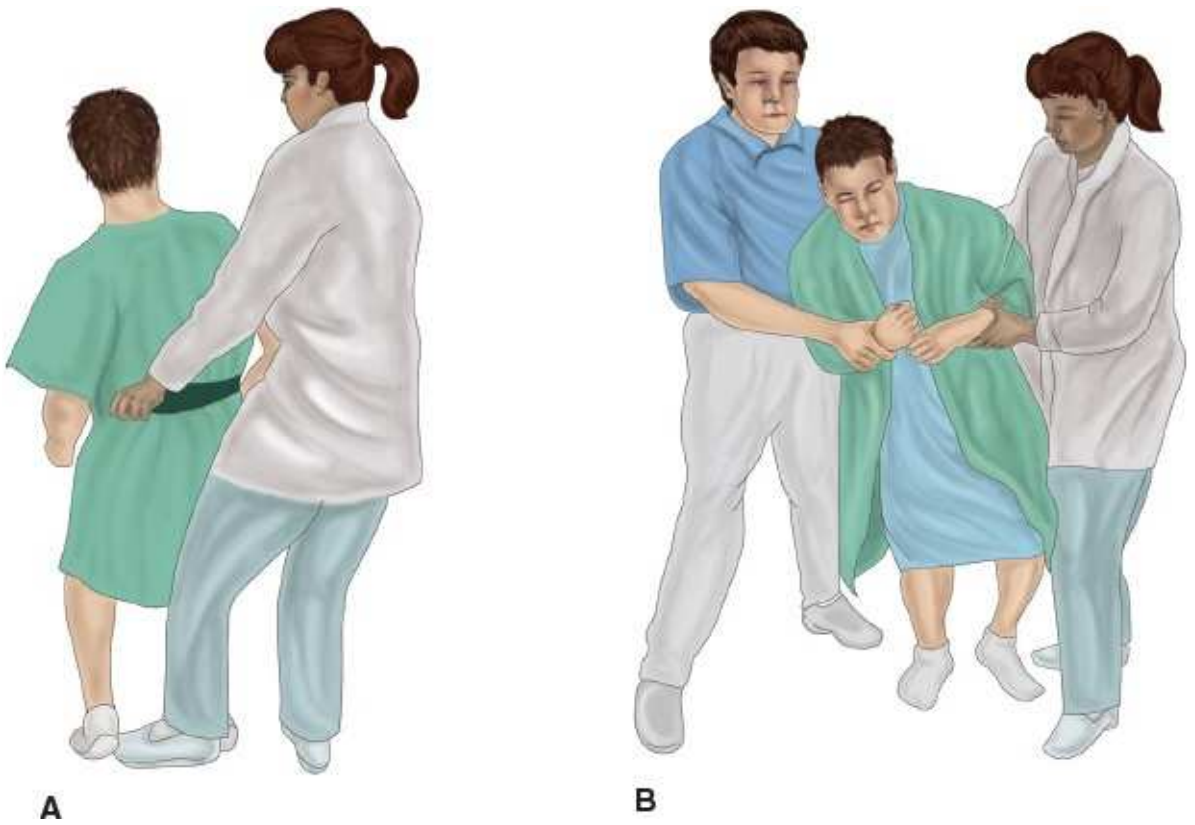

FIGURE 34-23. A. One nurse guiding a patient to the floor. **B.** Two nurses lowering a patient to the floor.

Should a patient faint or begin to fall while walking, stand with feet apart to create a wide base of support and rock the pelvis out on the side facing the patient. Use the gait belt and guide the patient slowly to the floor, supporting them on your thigh and your large quadriceps muscle, and protecting the patient's head (Wintersgill, 2019) (Fig. 34-23A). When two nurses are assisting a patient who starts to fall or faint, they both should use one hand to grasp the gait belt to support the patient and grasp the patient's hand or wrist with their other hand. After they have steadied the patient, they can slowly lower the patient to a chair or the floor (Fig. 34-23B).

One-Nurse Assist

Patients who require minimal nursing assistance may walk well with the nurse walking alongside. Provide support by standing at the patient's side and placing both hands at the patient's waist. Supporting the patient at the waist helps the patient to maintain an erect posture and prevents unintentionally pulling the patient to one side. Use of a gait belt snugly secured around the patient's waist also provides this type of support. Grasp the belt securely in the back, and walk behind and slightly to the side of the patient (Fig. 34-24).

Frequently, it is necessary to assist the patient with intravenous (IV) therapy equipment to walk. Secure a portable IV pole that moves easily. The patient walks with the assistance of the nurse and the portable IV pole. Ensure that all the equipment is secure before walking and be alert for any tension or sudden action that might dislodge or interfere with the infusion. Also, consider reviewing this technique with family members/caregivers who are assisting with ambulation and are unfamiliar with how to steady the patient, maneuver equipment, and navigate through crowded or narrow areas.

When a patient has weakness on one side, stand on the weaker or affected side and stabilize the patient by grasping the gait belt. Support the patient's weak arm by using one hand to support the patient's forearm and hand.

Two-Nurse Assist

A two-nurse assist is the safer method to use when there is uncertainty about the patient's ability to walk. Use of a gait belt snugly secured around the patient's waist provides assistance support the patient (Wintersgill, 2019). Each nurse should grasp the belt securely with the hand nearest the patient at the handle on each side of the patient. Support the patient's near arm by holding the patient's lower arm or hand. Walk slightly behind and to the side of the patient.

MOBILITY AIDS FOR WALKING

Various devices can assist a patient with walking. Some early mobilization devices were discussed earlier in the chapter. Other common devices to enhance the patient's balance and ability to bear weight include walkers, canes, braces, and crutches. Typically, a patient is fitted for one of these devices and instructed in its use in the department of physical medicine or physical therapy. In this instance, the nurse's concern is chiefly to reinforce the teaching the patient has received and to ensure that the patient continues to use the device properly to assist in safe ambulation. In some health care settings, however, nurses may be responsible for fitting patients with the device and teaching them the appropriate way to use the device. Whenever you assess a patient who has been using a walker, cane, brace, or crutches for a period of time, determine whether the device is still needed, whether it continues to meet the patient's needs, and whether the patient continues to use it properly.

FIGURE 34-24. Assistance with ambulation. The nurse stands on the patient's weaker side and grasps the gait belt.

Mobility aids can enable older patients to independently fulfill their needs and enhance functional capacity (Eliopoulos, 2018). Some older adults, however, may consider the use of a mobility aid a visible symbol of weakness or an indication of decline in capabilities and loss of independence. Many patients refuse to use them and keep them out of sight. If the mobility aid is intended for short-term use (e.g., after hip replacement surgery), the response may be more positive. Be sensitive to a patient's perspective regarding these devices and focus on the meaning the aid has for the patient, rather than simply emphasizing how to use it. Allow patients some control over their mobility decisions while still ensuring a safe environment. General guidelines for helping patients who need the assistance of a walker, cane, brace, or crutches include the following:

- Whenever possible, instruct the patient and family members/caregivers in the correct use of the device before it is needed (e.g., before surgery). If family members/caregivers are knowledgeable, they can reinforce the teaching as needed.
- When ready to begin walking with the new device, make sure the patient is wearing rubber-soled, well-fitting shoes and that there is a clear path for ambulation (clean, flat, dry, well lit). Use a gait belt, especially if the patient is at high risk for falls.
- Before moving, make sure the patient is steady on the feet when standing; instruct the patient to stand erect, looking straight ahead. The nurse should walk behind and slightly to one side of the patient (in cases of hemiparesis or hemiparalysis, walk on the patient's affected side). Should the patient lose balance, be prepared to grasp the patient's shoulder and the gait belt to steady the patient.

Walker

A walker is a lightweight metal frame (usually aluminum) with four legs (see Fig. 34-25A). Walkers improve balance by increasing the patient's base of support, enhancing stability during ambulation, and supporting the patient's weight (Eliopoulos, 2018). The walker can provide a sense of security and support. There are several types of walkers, specified according to the arm strength and balance needs of the patient. Most walkers have four legs with rubber tips. Some walkers have wheels on the front legs. These walkers are best for patients with a gait that is too fast for a walker without wheels and for patients who have difficulty lifting a walker. Because lifting repeatedly is not required, energy expenditure and stress to the back and upper extremities is lower than with a standard walker. Walkers also are available with wheels on all four legs. Patients who require a larger base of support and do not rely on the walker to bear weight can use these. If full-body weight is applied to this type of walker, it could roll away, resulting in a fall. Wheeled walkers are best for patients who need minimal weight bearing from the walker. Walkers often prove to be difficult to maneuver through doorways and congested areas. They should not be used on stairs or an escalator (American Academy of Orthopedic Surgeons (AAOS), 2015).

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

FIGURE 34-25. A. A walker is a lightweight metal frame with a broad, four-point base of support. **B.** Three types of canes: single-ended canes with half-circle handle; single-ended canes with straight handles; three- or four-prong canes are recommended for patients with poor balance.

When the patient stands between the back legs of the walker with arms relaxed at the side, the top of the walker should line up with the crease on the inside of the patient's wrist. When the patient's hands are placed on the grips, elbows should be slightly bent, flexed about 15 degrees (MFMER, 2019d). The walker's rubber tips should be intact to prevent slipping. In general, patients lift the walker without wheels ahead of themselves and step into it.

Instruct a patient using a walker to do the following:

- Wear nonskid shoes or slippers.
- When rising from a seated position, use the chair arms for support. Once standing, place one hand at a time on the walker and move forward into it.
- Begin by gripping the top of the walker at the grips, then lift and position or push the walker forward, about one step ahead, keeping the back upright—do not hunch over the walker (MFMER, 2019d). Place one leg inside the walker, keeping the walker in place. Do not step all the way to the front (AAOS, 2015). Push straight down on the grips of the walker and then step forward with the remaining leg into the walker, keeping the walker still. Repeat the process by moving the walker forward again.
- If the patient has an injured or weaker leg, the injured/weaker leg should be moved into the walker first, followed by the stronger or unaffected leg (American Academy of Orthopedic Surgeons, 2015; MFMER, 2019d).
- Caution the patient to avoid pushing the walker out too far in front and leaning over it. Patients should always step into the walker, rather than walking behind it, staying upright as they move (MFMER, 2019d).
- Never attempt to use a walker on stairs or an escalator.

Canes

Canes widen a person's base of support, providing improved balance (AAOS, 2015; Eliopoulos, 2018). Canes should not be used for bearing weight (Eliopoulos, 2018). Canes come in several variations (see Fig. 34-25B): single-ended canes with half-circle handles (recommended for patients requiring minimal support and those who will be using stairs frequently), single-ended canes with straight handles (recommended for patients with hand weakness because the handgrip is easier to hold but not recommended for patients with poor balance), or canes with three (tripod) or four prongs (quad cane) or legs to provide a wide base of support (recommended for patients with poor balance).

Many canes are adjustable. The cane should fit so that when the patient stands with the cane's tip 4 inches (10 cm) to the side of the foot, the cane extends from the floor to the crease in the patient's wrist. The elbow should be bent slightly, flexed 15 degrees when holding the cane (AAOS, 2015; MFMER, 2019e). Rubber tips on the cane prevent slipping and accidents. Inspect these regularly to ensure that they are intact. Teach patients to stand erect when walking with a cane and not to lean out over the cane.

When walking with a cane, instruct patients to hold the cane in the hand opposite the side that needs support (AAOS, 2015; MFMER, 2019e). If the cane is used for stability, the patient may hold it in either hand. Ambulation proceeds in the following fashion:

1. The patient stands with weight evenly distributed between the feet and the cane.
2. The cane is held on the patient's stronger side and is advanced one small stride ahead (AAOS, 2015).
3. Supporting weight on the stronger leg and the cane, the patient advances the weaker foot forward,

parallel with the cane.

4. Supporting weight on the weaker leg and the cane, the patient brings the stronger leg forward to finish the step (AAOS, 2015).

Teach patients to position their canes within easy reach when they sit down so that they can rise easily.

Braces

Braces that support weakened leg muscles are available in many variations. Nursing responsibilities include knowing when the brace is to be worn and the correct technique for applying the brace, monitoring to ensure correct use of the brace by the patient, and observing for any untoward problems the brace might cause (e.g., skin irritation). Muscle changes such as those occurring with growth and development or brought about by illness (atrophy) may require the brace to be refitted to maintain its effectiveness.

Crutches

Sometimes it is necessary for patients to use crutches for a time to avoid putting any weight on one leg or foot. The two types of crutches most commonly used are axillary crutches and forearm crutches (Fig. 34-26).

FIGURE 34-26. Axillary (*left*) and forearm (*right*) crutches.

Forearm crutches have a supportive frame extends beyond the handgrip for the lower arm to help guide the crutch. Axillary crutches require significant upper body and arm strength to use. Fitting of and the procedure for crutch walking is usually the responsibility of a physical therapist, but it is important for the nurse to be knowledgeable about the patient's progress and the gait being taught. Be prepared to guide the patient at home or in the hospital after the initial teaching is completed (Fig. 34-27). When using axillary crutches, remind the patient that the support of body weight should come primarily on the hands and arms while using the crutches, not in the axillary areas where pressure may damage nerves and cut off circulation. Also, the crutches should not be forced into the axillae each time the body moves forward. Teaching Tips 34-1 summarizes the important content to reinforce regarding crutch walking.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

FIGURE 34-27. Assisting patient to stand erect facing forward in a tripod position.

Teaching Tips 34-1

CRUTCH WALKING

Health Topic	Teaching Tip	Why Is This Important?
Safety measures	Routinely inspect crutch tips.	Rubber crutch tips increase surface tension and help prevent slipping.
	Replace worn crutch tips.	Water decreases surface friction and increases the risk of slipping.
	Inspect the structure of your crutches routinely for cracks in a wooden crutch or bends in an aluminum crutch. Discard and replace damaged crutches (Cleveland Clinic, 2019).	Bends or cracks in crutches alter body alignment and decrease the ability to support weight, posing a safety hazard.
Correct positioning for use of crutches	Prevent pressure on the axillae. When standing up straight, the top of the crutches should be about 1 to 2 inches below the armpits (AAOS, 2015). Weight should rest on the hands, not on the underarm supports (AAOS, 2015).	Pressure placed on the axillae can cause damage to nerves and circulation.
	Keep elbows close to sides. The handgrips of the crutches should be even with the top of the hips (AAOS, 2015).	This helps stabilize the crutches to prevent the patient from falling.
	Prevent crutches from getting closer than 12 inches to feet.	This prevents the patient from tripping over the crutches.
Functioning at home	*To rise from a chair:* Slide forward to the edge of the chair. Extend the injured leg to prevent any weight bearing. Place crutches on unaffected side, lean forward, and push off using the crutches.	Patient needs to learn that everyday occurrences may be challenging and, if not done correctly, may end up with injury to affected leg.
	To climb stairs: Advance unaffected leg past crutches, then place weight on unaffected leg. Advance affected leg and then crutches to the step. Continue with this order until top of stairs is reached.	

To descend stairs:
Move crutches and affected leg first, followed by the unaffected leg.

Promoting Exercise

PREVENTING ILLNESS AND PROMOTING WELLNESS THROUGH EXERCISE

The *Healthy People 2030* guidelines identify that regular physical activity can improve the health and quality of life of people of all ages and helps prevent certain chronic diseases such as hypertension, type 2 diabetes, and cardiovascular disease (USDHHS, n.d.). Vigorous physical activity is not always needed to achieve positive results. Studies have shown that moderate physical activity can be beneficial when incorporated into daily routines (MEFR, 2019c). Current recommendations encourage children and adolescents to be active through moderate-to-vigorous physical activity for 60 minutes or more a day and adults to minimally engage in activity that requires moderate effort, such as brisk walking for 2.5 to 5 hours or more a week (USDHHS, 2018).

An ongoing program of regular physical activity provides substantial health benefits and is essential for healthy aging (USDHHS, 2018). Physical activity guidelines for older adults who are fit and have no chronic conditions are the same as for all adults. Older adults should be as physically active as their abilities and conditions allow. Older adults should include exercises that maintain or improve balance (USDHHS, 2018). See the accompanying Focus on the Older Adult display for nursing strategies to promote exercise and activity in response to age-related changes.

Nurses who role model healthy behaviors are more effective teachers. Use Promoting Health 34-1 to assess yourself before using it with others. This display reflects on self-care behaviors vital for maintaining a healthy level of activity. Promoting exercise and emphasizing wellness behaviors are challenging opportunities for nurses. It is important to be committed to assisting and supporting patients to make lifestyle changes that improve the patients' health and well-being.

Focus on the Older Adult

NURSING STRATEGIES TO PROMOTE EXERCISE AND ACTIVITY FOR AGE-RELATED CHANGES

Age-Related Changes	Nursing Strategies
Activity Intolerance	
• Decreased respiratory vital capacity • Decreased transport of oxygenated blood to tissue (as in chronic obstructive pulmonary disease or decreased cardiac output)	• Encourage patient to gradually increase physical activity and to listen to cues from one's own body. • Teach effective breathing techniques. • Instruct patient to avoid sudden position changes that may cause dizziness. • Instruct patient to avoid extreme temperatures if exercising. • Provide for sufficient hydration. • Encourage patient to avoid exercise if weak or ill. • Instruct patient to stop exercising if chest pain occurs, and consult with the health care team before resuming activity. • Instruct patient to respect fatigue. Do not push to the point of exhaustion.
Impaired Physical Mobility	
• Decreased range of motion • Decreased stability of gait	• Encourage patient to warm up before beginning exercises and to cool down after exercising. • Encourage patient to modify exercises versus forcing joints beyond the natural range of motion. • Discuss safety precautions that patient may take when exercising, such as walking in a gym or mall versus on an uneven sidewalk, and walking with a partner. • Recommend that patient wear proper footwear when exercising.

EXERCISE PROGRAMS

The benefits of exercise for each of the major body systems are so significant that developing individualized exercise programs for patients is an important nursing intervention, often in collaboration with the physical therapist and/or

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

other health care providers. Such a program should incorporate ADLs and planned exercise sessions. Depending on the patient's physical condition, exercise is designed to promote optimal fitness.

Promoting Health 34-1

ACTIVITY

Use the assessment checklist to determine how well you are meeting your needs related to oxygenation. Then develop a prescription for self-care by choosing appropriate behaviors from the list of suggestions.

Assessment Checklist

☐ almost always ☐ sometimes ☐ almost never

☐ ☐ ☐ 1. My lifestyle demonstrates that I place a high value on exercise as a component of wellness (e.g., I use stairs instead of elevators).

☐ ☐ ☐ 2. I exercise for 30 to 45 minutes three or four times per week.

☐ ☐ ☐ 3. I have sufficient energy for each day's tasks.

☐ ☐ ☐ 4. I maintain my target weight/BMI.

Self-Care Behaviors

1. Decide to make the most of everyday opportunities for exercise: Use stairs instead of elevators, walk instead of ride, park the car farther from your destination than usual and walk the distance briskly, and so forth.
2. Choose exercise activities you enjoy and plan three or four 30- to 45-minute exercise sessions weekly.
3. Obtain medical clearance for exercise if you fall in a high-risk group. Learn and observe the appropriate exercise safeguards (e.g., wear running shoes with the proper support).
4. Alternate types of exercise to avoid boredom.
5. Use part of your lunchtime for brisk walking or other exercise.
6. Invite a friend to exercise with you so you have the added support of a buddy or join a spa, health club, or exercise group.
7. Consistently use principles of ergonomics in both leisure and work activities.
8. Build up exercise sessions gradually to avoid overexertion and injury to muscles.
9. Evaluate your lifestyle to see what prevents you from exercising regularly and address these factors (low value attached to health or exercise, low motivation, lack of time, lack of rest, or faulty nutrition).

Information to promote cardiovascular health and oxygenation is available online.

Box 34-3 **Successful Exercise Programs**

Characteristics to Promote Success

- The program is individually designed (considers the person's fitness goals, interests, skills, exercise opportunities, and exercise capacity).
- The program specifies warm-up and cool-down activities and a variety of major exercise activities—variety is preferable to a single-exercise activity.
- The program specifies frequency, intensity, and duration of exercise.
- The program is convenient to perform, compatible with the person's lifestyle, and fun!
- The person in such a program should understand the program and feel confident that exercise will result in definite health benefits.

Prevention Strategies to Avoid Risks

People beginning exercise programs should be familiar with the following guidelines:

- Physically inactive people with known cardiovascular, metabolic, or renal disease and/or those with signs or symptoms suggestive of these diseases should seek medical clearance before starting an exercise program, regardless of the intensity of the exercise (Riebe et al., 2015).

- Begin a new exercise program slowly and allow your body's support structure time to accommodate to the new stress.
- Know your body and respect its limitations. Never force a joint beyond its natural range of motion.
- Increase physical activity gradually over time to meet key guidelines or health goals.
- Follow the safety guidelines for specific exercises; for example, joggers are advised to run on soft surfaces as opposed to cement or asphalt, to wear well-constructed shoes with thick soles and arch supports, and to run in a safe environment with a low pollution index.
- People who develop new symptoms when increasing their levels of activity should consult a health care provider (USDHHS, 2018).

The person's commitment to a program of regular exercise depends on the following:

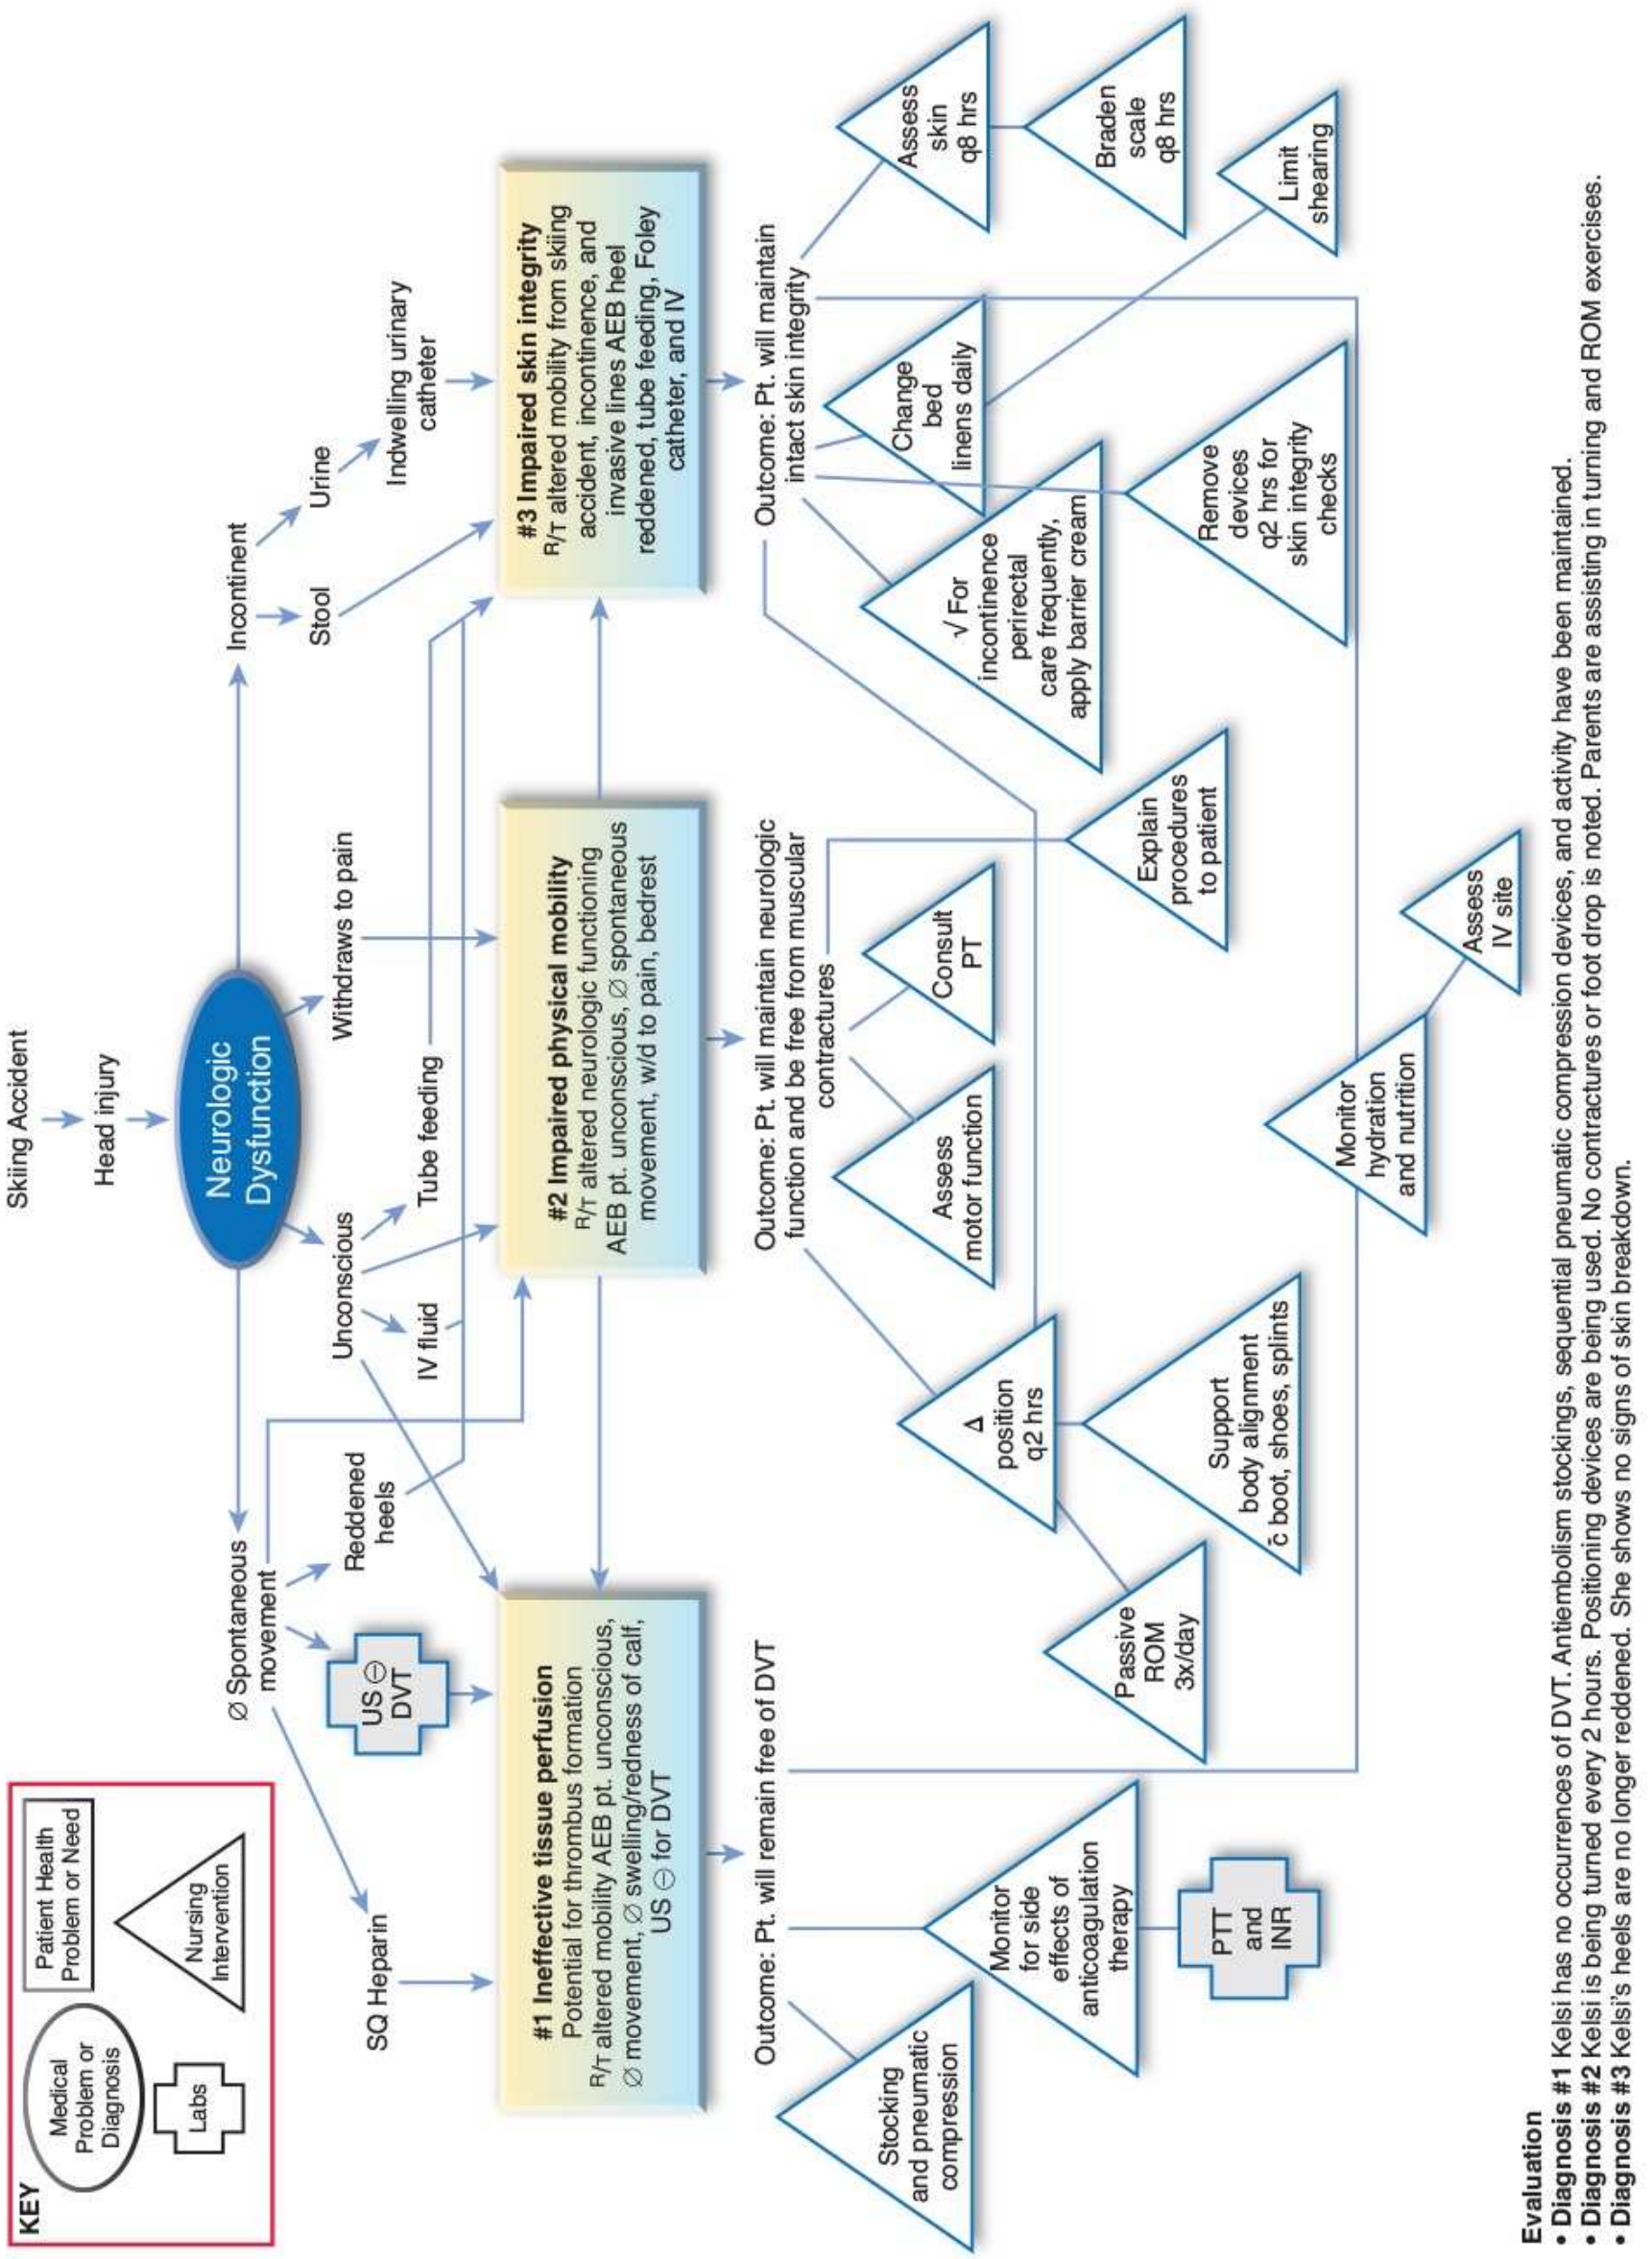
- Knowledge of the benefits of exercise and the problems related to immobility
- Appreciation of the fact that in society, sedentary lifestyles are common and most people must consciously choose to exercise
- Belief that each person is responsible for one's own health and that exercise is essential to one's well-being

Foster a commitment to regular exercise by teaching and counseling patients about exercise. To do this, be knowledgeable about the types and benefits of exercise as well as the risks associated with exercise.

When working with a patient to develop an individualized exercise prescription, use the following guidelines:

- Explore the patient's fitness goals, interests, skills, exercise opportunities, and exercise capacity.
- Assist the patient in obtaining medical clearance for exercise.
- Explore feasible exercise activities with the patient, considering the health benefits sought, the time involved, cost, any need for special equipment, precautions, and risks.
- Develop an exercise program that specifies warm-up and cool-down activities (walking, stretching) and three or four major exercise activities from which the patient can choose.
- Specify the frequency, duration, and intensity of the exercise activity. The recommended minimal frequency for activity that requires moderate effort, such as brisk walking, is two-and-a-half hours or more a week (USDHHS, 2018).
- Encourage the patient to complement the exercise program with everyday activities that require exercise.
- Try to identify with the patient any potential threats to the exercise program's successful implementation. Plan support strategies.
- Use ongoing evaluation to determine whether the exercise prescription is meeting the patient's needs and whether the patient is adhering to the prescription.
- Encourage the patient to have an exercise partner; they will encourage each other as well as keep each other company during the exercise.

Box 34-3 identifies characteristics of a successful exercise program and prevention strategies to avoid the risks associated with exercise.



Evaluating

When evaluating the effectiveness of a plan of care designed to help patients enhance, maintain, or regain mobility and fitness goals, use each nurse–patient interaction to evaluate the patient in the following respects:

- General ease of movement and gait
- Body alignment
- Joint structure and function
- Muscle mass, tone, and strength
- Endurance

An excellent time to assess these essential ingredients of well-being is when the patient is performing simple everyday tasks such as walking, undertaking hygiene measures, dressing, and eating. Because illness and enforced inactivity can affect these tasks negatively, ongoing evaluation is necessary if serious problems are to be avoided. For examples of the nursing process for activity, see the accompanying concept map for Kelsi Lester and Nursing Care Plan 34-1 (on pages 1286–1289) for Quan Hong Nguyen.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

REFLECTIVE PRACTICE LEADING TO PERSONAL LEARNING

Remember that the goal of reflective practice is to look at an experience, understand it, and learn from it. As you begin to develop expertise in implementing measures related to activity, reflect on your experiences—successes and failures—in order to improve your practice. How can you do it better next time? What did you learn today that can help you tomorrow? Begin your reflection by paying close attention to the following while performing activity and mobility interventions and providing nursing care:

- Did your commitment to engage your patients and families and to collaborate with your fellow students, instructor, and

other members of the health care team as you implemented the plan of care result in successful partnerships?
- Did your preparation and practice related to performing interventions related to activity result in your feeling confident in your ability to provide care? Did your competence and confidence inspire the patient's and family/caregiver's trust?
- How did you prioritize the data you collected? What patterns in the data did you identify? What knowledge from your learning, personal experience and intuition did you use to make decisions and develop your plan of care?
- How confident are you that the data you communicated and recorded accurately communicates the health status, health problems, issues, risks, and strengths of the patient? How successfully have you communicated this information to other members of the health care team?
- Were you aware of any cultural and/or ethnic beliefs or practices that may have influenced the patient's personal activity practices? Were you aware of any stereotypes or prejudices that might have negatively influenced the clinical encounter? If so, how did you address these?
- Did you need to modify the plan of care as a result of ongoing assessments? Did you think of better interventions to produce the expected outcomes?
- As you concluded your care, did the patient/family/caregivers know your name and know what to expect of you and your nursing care? Did the patient sense that you are respectful, caring, and competent to provide care?

Perhaps the most important questions to reflect on are: Are your patients and their families/caregivers better for having had *you* share in the critical responsibility of partnering with them to address their activity needs? Are your patients now receiving thoughtful, person-centered, prioritized, holistic, evidence-based treatment and care because of your efforts?

Nursing Care Plan for *Quan Hong Nguyen 34-1*

Quan Hong Nguyen is an alert, 75-year-old married man who was admitted to the hospital with a diagnosis of an ischemic stroke (cerebrovascular accident or brain attack; Hinkle et al., 2022) secondary to thrombosis (formation of a blood clot). He has a history of hypertension. This is his second hospital day, and the attending physicians have termed the stroke a *completed stroke;* that is, Mr. Nguyen's neurologic deficits have been unchanged for 2 days, and he is believed to be ready for more aggressive rehabilitative treatment. On hospital day 2, an assessment of Mr. Nguyen's mobility status and ability to participate in activities of daily living revealed the following data:

- *Mental status*—basically alert and able to follow simple commands; expresses his needs verbally when encouraged, but speech is slow; seems forgetful of usual routine for basic self-care activities
- *Neuromuscular status*—hemiplegia; severe motor and sensory deficits of the left side of the face and the left arm and leg
- *Muscle mass, tone, and strength*—well-developed muscles in all extremities; history of a lifetime of sports, most recently played tennis two to four times weekly; decreased muscle tone (hypotonicity, flaccidity) in left arm and leg motor function is absent in left arm and very weak in left leg; strong motor function on right extremities; incapable of weight bearing on left side; incapable of independent turning, sitting, standing, transferring, or ambulation
- *Joint mobility*—decreased on left side; otherwise full range of motion; no contractures
- *Endurance*—fatigues quickly (e.g., during complete bath)
- Some deficit in spatial–perceptual orientation (e.g., ignores objects on his left side), but it is difficult to assess this completely yet

HEALTH PROBLEM/NEED	
	Impaired Mobility in Bed Etiology: left hemiplegia and weakness Signs/Symptoms: motor function absent in left arm and weak in left leg, decreased joint mobility in left extremities, fatigue.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

EXPECTED OUTCOME	1/25/25 Whenever observed, the patient will: • Be in correct body alignment with (1) each joint on the left side higher than the joint proximal to it and (2) supportive devices in place (bed board, footboard, trochanter roll, hand–wrist splint, shoulder sling, pillows).	
NURSING INTERVENTIONS	**RATIONALE**	**EVALUATIVE STATEMENT**
At each position change (as dictated by every-2-hour turn schedule posted at the bedside), ensure the patient is in correct alignment. Follow facility positioning guidelines for the supine, side-lying (lies on unaffected side), and prone positions.	Correct positioning prevents contractures, relieves pressures, and maintains alignment. Positioning each joint higher than the preceding one prevents edema and its resulting fibrosis. Placing the patient in the prone position for 30 minutes two or three times daily helps prevent knee and hip flexion contractures.	1/27/25 Outcome being met. Every-2-hour positioning schedule being followed with patient in correct body alignment to prevent contractures. *S. Beecher, RN*
Use the following supportive devices: firm mattress, footboard, trochanter roll, shoulder sling when the patient is in the upright position, volar resting splint, and pillows.	Support devices aid in maintaining the patient in correct positioning. Firm mattress provides skeletal support. Footboard during flaccid period prevents footdrop, heel cord shortening, and plantar flexion. Trochanter roll prevents external rotation of the hip when the patient is in the dorsal position. Shoulder sling during the flaccid period prevents shoulder subluxation and shoulder–hand syndrome. Volar resting splint supports the wrist and hand in a functional position. A pillow in the axilla of the left side prevents adduction of the affected side.	
Teach both the patient and family the importance of correct positioning.	Teaching promotes self-care and lays the foundation for successful rehabilitation.	
Allow the family to participate in helping the patient to get comfortable in the different positions.	Involving the family in the patient's care facilitates the coping process.	

EXPECTED OUTCOME	By hospital day 7, 1/30/25, the patient will: • Perform quadriceps, gluteal, and abdominal settings five times daily.	
NURSING INTERVENTIONS	**RATIONALE**	**EVALUATIVE STATEMENT**
Teach the patient and family how to tighten the quadriceps, gluteal, and abdominal muscles and hold them for 6 seconds	These exercises will maintain muscle mass, tone, and strength (while the patient is on bed rest); and prevent atrophy. They also	1/30/25 Outcome partially met. Patient has demonstrated exercises correctly; however, he needs to be reminded to perform them. Family is effective in this regard.

(slow count to 4) before relaxing. A 2-minute rest should be allowed between contractions, and the patient should be cautioned not to hold his breath during these exercises. The exercises should be stopped short of muscle fatigue.	increase circulation to the exercised body parts. Holding the breath places a strain on the heart.	*Revision:* Compliment family on excellent job they are doing and reinforce importance of exercise to maximize rehabilitative potential. *S. Beecher, RN*

EXPECTED OUTCOME

By hospital day 7, 1/30/25, the patient will:

- Participate in the every-2-hour positioning schedule by assisting with turning to the degree he is able.

NURSING INTERVENTIONS	RATIONALE	EVALUATIVE STATEMENT
Teach the patient how he can help to reposition himself by grabbing onto the side rail with his right hand and also by placing his unaffected leg under the left one to move himself.	The more the patient can do independently, the more in control he will feel. These activities will pave the way to increasing independence in self-care activities.	1/27/25 Outcome met. Patient consistently assists in repositioning. *S. Beecher, RN*

HEALTH PROBLEM/NEED

ADL deficit

Etiology: decreased alertness and left-sided motor and sensory deficits

Signs/Symptoms: inability to use left arm (is right-handed), inability to ambulate, forgetfulness, fatigue.

EXPECTED OUTCOME

By hospital day 7, 1/30/25, the patient will:

- Demonstrate beginning ability to resume self-care activities despite motor and sensory deficits of left side; use right arm to (1) assist in morning hygiene; and (2) feed himself (finger foods, beverages).

NURSING INTERVENTIONS	RATIONALE	EVALUATIVE STATEMENT
Continue to assess extent of the patient's motor and sensory deficits and ability to perform self-care activities.	This facilitates recognition of any recovery of function and allows setting of appropriate goals.	1/29/25 Outcome met. For the past 2 days, patient has washed his left arm, abdomen, and legs; combed his hair; fed himself; and performed range-of-motion exercises. *S. Beecher, RN*
Set realistic short-term goals for each session with patient and reward progress: "This morning we'll see how much of your bath you are able to manage yourself!" "It must feel good to be able to do this for yourself again."	Adding *realistic* new tasks for each day gives the patient a goal to work toward; a pattern of *noticed* success encourages continued efforts.	
Approach the patient from his unaffected side, and place call bell, bedside table, phone, and so on, on this side.	This helps the patient to compensate for alterations in sensory perception.	
Teach patient how to transfer all self-	There is never only one way to do	

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

care activities to the unaffected side and how to use one-handed techniques and adaptive equipment.	anything.
Encourage the patient to brush his teeth, comb his hair, bathe and feed himself, and to assist in toileting. Explain to the family why it is critical to allow him to do these things himself, even if movements are tiring, clumsy, and initially frustrating.	This improves the patient's sense of control of his own activities of daily living and improves morale.

EXPECTED OUTCOME

On discharge to rehabilitation center, the patient will:

- Show signs of physical and mental readiness to acquire increasing independence in self-care.

NURSING INTERVENTIONS	RATIONALE	EVALUATIVE STATEMENT
Implement previously stated nursing actions.	These actions help the patient toward regaining control of his daily living and improve morale.	1/31/25 Outcome met. Patient's muscle strength and joint mobility maintained during hospitalization. Patient is now participating in self-care activities and is eager to learn skills to become more independent. *S. Beecher, RN*

SAMPLE DOCUMENTATION

1/25/25 1500, Nursing

- Dr. Steel examined the patient at 1300 and noted he is now "ready for more aggressive rehabilitative treatment." This was explained to the patient and his wife and son. The patient smiled and seemed to understand that he is out of immediate danger. Initial instructions given to the patient on how he can assist with position changes and actively exercise his left arm and leg. Correctly demonstrated these maneuvers with verbal cueing. Motor function still absent in left arm and weak in left leg. Care plan revised to incorporate new exercise goals.

S. Beecher, RN

Skill 34-1 Assisting a Patient With Repositioning in Bed

DELEGATION CONSIDERATIONS

Assisting a patient to turn in bed may be delegated to assistive personnel (AP) as well as to licensed practical/vocational nurses (LPN/LVNs). The decision to delegate must be based on careful analysis of the patient's needs and circumstances as well as the qualifications of the person to whom the task is being delegated. Refer to the Delegation Guidelines in Appendix A.

EQUIPMENT

- Friction-reducing sheet or lifting/repositioning sheet or other device (based on assessment)
- Lateral transfer device or full-body sling lift and cover sheet (based on assessment)
- Bed surface that inflates to aid in turning
- Pillows or other supports to help the patient maintain the desired position after turning and to maintain correct body alignment for the patient
- Additional caregivers and/or safe handling equipment to assist, based on assessment
- Nonsterile gloves, if indicated; other PPE as indicated

IMPLEMENTATION

ACTION	RATIONALE
1. Review the health record for prescribed interventions and plan of care for patient activity. Identify any movement limitations, conditions that may influence the patient's ability to move or be positioned, and the ability of the patient to assist with turning. **Consult a patient handling algorithm or other decision-making tool to plan an appropriate approach to moving the patient.**	Checking the health care record validates the correct patient and correct procedure. Identification of limitations and ability along with use of an algorithm helps to prevent injury and aids in determining the best plan for patient movement.
2. Gather any positioning aids or supports, if necessary.	Having aids readily available promotes efficient time management.
 3. Perform hand hygiene. Put on PPE, as indicated.	Hand hygiene and PPE prevent the spread of microorganisms. PPE is required based on transmission precautions.
 4. Identify the patient. Explain the procedure to the patient.	Patient identification validates the correct patient and correct procedure. Discussion and explanation help allay anxiety and prepare the patient for what to expect.
5. Close the curtains around the bed and close the door to the room, if possible. Position at least one nurse on either side of the bed. Place pillows, wedges, or any other support to be used for positioning within easy reach. Place the bed at an appropriate and comfortable working height (VHACEOSH, 2016). Lower both side rails.	Closing the door or curtains provides for privacy. Proper bed height helps reduce back strain while performing the procedure. Proper positioning and lowering of the side rails facilitate moving the patient and minimizes strain on the nurses.
6. If not already in place, position a friction-reducing sheet or lifting/repositioning sheet or other transfer device under the patient, based on assessment.	Friction-reducing/lifting/repositioning sheets and other transfer devices aid in preventing shearing and in reducing friction and the force required to move the patient.
7. Remove all pillows from under the patient's head, back, or legs. If moving the patient up in the bed, leave one pillow at the head of the bed, leaning upright against the headboard.	Removing pillows from under the patient facilitates movement; placing a pillow at the head of the bed prevents accidental head injury against the top of the bed.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

8. Based on the screening and assessment information, position at least one nurse or other health care provider on either side of the bed, and lower both side rails.	Proper positioning and lowering the side rails facilitate moving the patient and minimize strain on the care providers.
9. If the patient is fully able to assist in repositioning, allow the patient to complete the move independently, with supervision.	Safe supervision allows for intervention by care giver if necessary and reduces the risk for injury.
10. If the patient is partially able or unable to assist, make use of friction-reducing devices, lifting/repositioning sheets (Figure 1), lateral transfer devices, full-body sling lift and/or engage the turning or rotation to assist with the action (VA Mobile Health, n.d.).	Use of SPHM equipment is necessary to reduce risk of injury to patient and care providers (Fragala et al., 2016; OSHA and Joint Commission Resources Alliance, 2017; VA Mobile Health, n.d.).

FIGURE 1. Example of a repositioning sheet for use with a lift.

11. If turning, activate the bed-turn mechanism to inflate the side of the bed behind the patient's back.	Activating the turn mechanism inflates the side of the bed for approximately 10 seconds, aiding in propelling the patient to turn, and reducing the work required by the nurse. This helps avoid injury to the nurse or other care provider.
12. Alternatively, follow manufacturer's directions to utilize the ceiling lift or full-body lifting device with the repositioning or supine sling or air-assisted transfer device.	Use of SPHM equipment is necessary to reduce risk of injury to patient and care providers (Fragala et al., 2016; OSHA and Joint Commission Resources Alliance, 2017; VA Mobile Health, n.d.).
13. Once the patient has been repositioned, make the patient comfortable and position in proper alignment, using pillows or other supports behind the patient's back (pull the shoulder blade forward and out from under the patient), under the leg and arm, as needed. Readjust the pillow under the patient's head. Elevate the head of the bed as needed for comfort.	Positioning in proper alignment with supports ensures that the patient will be able to maintain the desired position and will be comfortable. Positioning the shoulder blade removes pressure from the bony prominence.
14. Place the bed in the lowest position, with the side rails up, as indicated. Make sure the call bell and other necessary items are within easy reach.	Adjusting the bed height ensures patient safety. Having the call bell and essential items readily available helps promote safety.
 15. Clean transfer aids, per facility policy, if not	Proper cleaning of equipment between patient use prevents the spread of microorganisms. Proper removal of PPE reduces the risk for infection transmission and contamination of other items. Hand

indicated for single-patient use. Remove gloves and other PPE, if used. Perform hand hygiene.

hygiene prevents the spread of microorganisms.

DOCUMENTATION

Guidelines

Many facilities provide areas on the bedside flow sheet to document repositioning. Be sure to document the time the patient's position was changed, use of supports, and any pertinent observations, including skin assessment. Document the patient's tolerance of the position change. Document completed assessment algorithm for patient handling and movement decision and SPHM aids used to facilitate movement.

Sample Documentation

11/10/25 1130 Patient repositioned from right side to left side; alignment maintained with wedge support behind back and pillow between legs. Skin on pressure points on right side without signs of irritation, edema, or redness. Patient reported no pain with movement. Bed-turn mechanism and friction-reducing sheet used to facilitate transfer; sheet left in place under patient. Patient partially able to assist with turn by pulling on bed rail.
—B. Clapp, RN

DEVELOPING CLINICAL REASONING AND CLINICAL JUDGMENT

UNEXPECTED SITUATIONS AND ASSOCIATED INTERVENTIONS

- *You are attempting to move a patient up in the bed when you realize your initial assessment was inaccurate and the patient is not able to participate with repositioning to the extent you thought:* Cover the patient, make sure all rails are up, lower the bed to the lowest position, and take a moment to reassess the situation using SPHM decision-making tool. Obtain the necessary equipment and number of personnel as indicated. Document the assessment and necessary equipment in the plan of care for continuity of care.

SPECIAL CONSIDERATIONS

- Institute Bariatric Algorithms for any patient who weighs more than 300 lb, or is 100 lb over ideal weight, or who has a body mass index (BMI) over 40 (VHA CEOSH, 2015).
- When moving a patient with a leg or foot problem, such as a cast, wound, or **fracture**, one caregiver should be assigned to monitor movement of that extremity to reduce risk of further injury.

Skill 34-2 Transferring a Patient From the Bed to a Stretcher

DELEGATION CONSIDERATIONS

The transfer of a patient from bed to stretcher may be delegated to assistive personnel (AP) as well as to licensed practical/vocational nurses (LPN/LVNs). The decision to delegate must be based on careful analysis of the patient's needs and circumstances as well as the qualifications of the person to whom the task is being delegated. Refer to the Delegation Guidelines in Appendix A.

EQUIPMENT

- Transport stretcher
- Ceiling lift or full-body lift
- Lateral-assist device, such as a transfer board, roller board, or air or mechanical lateral-assist device and cover sheet
- Bath blanket
- Regular blanket
- At least two assistants, depending on assessment and data
- Nonsterile gloves and/or other PPE, as indicated

IMPLEMENTATION

ACTION	RATIONALE

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

1. Identify any movement limitations, conditions that may influence the patient's ability to move or be positioned, and the ability of the patient to assist with the transfer. **Consult a patient handling algorithm, if available, to plan an appropriate approach to moving the patient.** Assess for tubes, IV lines, incisions, or equipment that may alter the positioning procedure. Gather transfer aids or supports as necessary.	Reviewing the health record and plan of care validates the correct patient and correct procedure. Checking for interfering equipment helps reduce the risk for injury. Identification of limitations and ability along with use of an algorithm helps to prevent injury and aids in determining the best plan for patient movement. Having aids readily available promotes efficient time management.
 2. Perform hand hygiene and put on PPE, if indicated.	Hand hygiene and PPE prevent the spread of microorganisms. PPE is required based on transmission precautions.
 3. Identify the patient. Explain the procedure to the patient.	Patient identification validates the correct patient and correct procedure. Discussion and explanation help allay anxiety and prepare the patient for what to expect.
4. Close the curtains around the bed and close the door to the room, if possible. Adjust the head of the bed to a flat position or as low as the patient can tolerate. Raise the bed to a height that is even with the transport stretcher (VHACEOSH, 2016). Lower the side rails, if in place.	Closing the door or curtains provides for privacy. Proper bed height and lowering side rails make transfer easier and decrease the risk for injury.
5. Place the bath blanket over the patient and remove the top covers from underneath. Remove all pillows from under the patient's head, back, or legs.	Bath blanket provides privacy and warmth. Removing pillows from under the patient facilitates movement.
6. If not already in place, position a friction-reducing sheet or lifting/repositioning sheet or other transfer device under the patient, based on assessment.	Friction-reducing/lifting/repositioning sheets and other transfer devices aid in preventing shearing and in reducing friction and the force required to move the patient.
7. Follow manufacturer's directions to utilize the ceiling lift or full-body lifting device with the repositioning or supine sling or air-assisted transfer device (Figure 1).	Use of SPHM equipment is necessary to reduce risk of injury to patient and care providers (Fragala et al., 2016; OSHA and Joint Commission Resources Alliance, 2017; VA Mobile Health, n.d.).

FIGURE 1. Example of an air-assisted transfer device.

8. Position the stretcher next (and parallel) to the bed. **Lock the wheels on the stretcher and the bed.**	Positioning equipment makes the transfer easier and decreases the risk for injury. Locking the wheels

keeps the bed and stretcher from moving.

9. At a minimum, one caregiver should be positioned on the stretcher side of the bed, and another should stand on the side of the bed without the stretcher. Depending on the transfer device, other care givers should be positioned accordingly.

Team coordination provides for patient safety during transfer.

10. Use the friction-reducing sheet to roll the patient away from the stretcher (Figure 2). Place the transfer device under the patient (Figure 3).

The transfer board or other lateral-assist device reduces friction, easing the workload to move patient.

11. **At a signal given by one of the caregivers and based on the manufacturer's directions for use of the device, move the patient from the bed to the stretcher (Figure 4).**

Working in unison distributes the work of moving the patient and facilitates the transfer.

12. Once the patient is transferred to the stretcher (Figure 5), remove the SPHM device or leave in place for future use, based on device type and facility policy. Provide a pillow and other supports as indicated. Secure the patient and raise the side rails. To ensure the patient's comfort, cover the patient with blanket and remove the bath blanket from underneath.

Positioning in proper alignment with supports ensures that the patient will be able to maintain the desired position and will be comfortable. Side rails promote safety. Blanket promotes comfort and warmth.

FIGURE 2. Using sheet to roll patient away from stretcher.

FIGURE 3. Positioning transfer device under patient.

FIGURE 4. Transferring patient onto stretcher.

FIGURE 5. Patient on stretcher.

13. Clean transfer aids, per facility policy, if not indicated for single-patient use. Remove gloves and any other PPE, if used. Perform hand hygiene.

Proper cleaning of equipment between patient use prevents the spread of microorganisms. Proper removal of PPE reduces the risk for infection transmission and contamination of other items. Hand hygiene prevents the spread of microorganisms.

DOCUMENTATION

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

Guidelines

Document the time and method of transport, and patient's destination, according to facility policy. Document the completed assessment algorithm for patient handling and movement decision and the use of transfer aids and number of staff required for transfer.

Sample Documentation

5/12/25 1005 Patient transferred to stretcher via air-assisted lateral transfer device. Three caregivers required. Transported to radiology for chest x-ray.
—*M. Joliet, RN*

DEVELOPING CLINICAL REASONING AND CLINICAL JUDGMENT

UNEXPECTED SITUATIONS AND ASSOCIATED INTERVENTIONS

- *Your patient needs to be transported to another department by stretcher. The patient is very heavy and somewhat confused, so you are concerned about his ability to cooperate with the transfer:* Consult a Bariatric Algorithm. Confirm that the patient handling equipment and stretcher meet weight, width, and height requirements of the patient (VHA CEOSH, 2015). Obtain the assistance of additional caregivers; bariatric patients and use of expanded capacity equipment requires more caregivers (VHA CEOSH, 2015). Use bariatric equipment and devices to move the patient (VHA CEOSH, 2015).

SPECIAL CONSIDERATIONS

- If the patient is unconscious or weakened, additional caregivers are needed to support the extremities and the head to reduce risk of further injury.
- Some mechanical lateral-transfer aids are motorized, and others use a hand crank. If a mechanical lateral-assist device is used, follow the manufacturer's directions for safe movement of the patient. Be familiar with weight restrictions for individual pieces of equipment.
- Keep in mind that the transfer of patients is often delegated to AP. Before moving patients, all personnel need to complete instructions about this skill and must be able to provide return demonstrations of transfer skills. When a patient is being transferred, communicate clearly any mobility restrictions or special care needs.
- Bariatric patients require additional caregivers and expanded capacity devices (VA Mobile Health, n.d; VHACEOSH, 2016). Institute Bariatric Algorithms for any patient who weighs more than 300 lb, or is 100 lb over ideal weight, or who has a BMI over 40 (VHA CEOSH, 2015).

DEVELOPING CLINICAL REASONING AND CLINICAL JUDGMENT

. Work through the Concept Map for Kelsi Lester on page 1285 and the Nursing Care Plan for Quan Hong Ngyuen on pages 1286–1289 to help develop your clinical reasoning and clinical judgment skills.
. Simulate a mobility impairment for yourself (i.e., you have to use crutches or a walker, cane, or wheelchair) and attempt to perform your usual daily activities, ideally including visiting a public place, such as a school or mall. How did you feel about the restriction of your movement? How can nurses best assist patients who are coping with these restrictions? How did the public respond to your impairment, and what effects might such responses have on people with mobility impairments? Are public spaces adequately adapted to meet the needs of those with mobility impairments? What measures are needed to address any deficiencies? Did you identify any safety needs?
. Suppose a friend is confined to bed for several months after a motorcycle accident that resulted in severe orthopedic and internal injuries. What nursing measures would you recommend to avoid the hazards of immobility?

PRACTICING FOR NCLEX

. A nurse is developing an exercise program for a patient who has COPD. Which instructions would the nurse include in a teaching plan for this patient? Select all that apply.

a. Teach the patient to avoid sudden position changes that may cause dizziness.
b. Recommend that the patient restrict fluid intake until after exercise.
c. Instruct the patient to push a little further beyond fatigue each session.
d. Tell the patient to avoid exercising in very cold or very hot temperatures.
e. Encourage the patient to modify exercise if weak or ill.
f. Recommend that the patient consume a high-carb, low-protein diet.

. A nurse is providing active-assistive range-of-motion exercises for a patient who is recovering from a stroke. During

the session, the patient reports that they are "too tired to go on." What actions are appropriate at this time? Select all that apply.

a. Stop performing the exercises.
b. Decrease the number of repetitions performed.
c. Reevaluate the plan of care.
d. Move to the patient's other side to perform exercises.
e. Encourage the patient to finish the exercises and then rest.
f. Assess the patient for additional symptoms of intolerance.

. A nurse assists a patient with ambulation for the first time following a knee replacement. Shortly after beginning to walk, the patient tells the nurse that they are dizzy and feel like they might fall. Place these nursing actions in the order in which the nurse should perform them to protect the patient:

a. Grasp the gait belt.
b. Stay with the patient and call for help.
c. Place feet wide apart with one foot in front.
d. Gently slide the patient down to the floor, protecting their head.
e. Pull the weight of the patient backward against your body.
f. Rock your pelvis out on the side of the patient.

. A nurse caring for patients in a pediatric office assesses children's achievement of developmental milestones. Which patient finding requires follow-up with the pediatrician?

a. 4-month-old infant who is unable to roll over
b. 6-month-old infant who is unable to hold head up
c. 11-month-old infant who cannot walk unassisted
d. 18-month-old toddler who cannot jump

. A nurse is caring for a patient with lower extremity paralysis. Which action will the nurse take to prevent external rotation of the hip and foot?

a. Use a trochanter roll.
b. Apply SCDs.
c. Obtain a prescription for antiembolism stockings.
d. Have the patient maintain low-Fowler's position.
e. Have the patient cross their arms on their chest and place a pillow between their knees.
f. Place a cervical collar on the patient's neck and gently roll them to the other side of the bed.

. A nursing student asks the primary nurse why an immobile patient developed two urinary tract infections (UTIs) in the 6 months. How does the nurse best explain this patient's risk for UTI?

a. Improved renal blood supply to the kidneys
b. Urinary stasis
c. Decreased urinary calcium
d. Acidic urine formation

. A nurse on a medical-surgical unit notes a patient with pneumonia and is experiencing dyspnea. What action will the nurse take to improve the dyspnea?

a. Encourage the patient to ambulate.
b. Suggest the patient use music or television as distraction.
c. Place the patient in Fowler's position.
d. Tell the patient to take several deep breaths, then hold their breath for 5 seconds.

. A nurse is assisting a postoperative patient with conditioning exercises to prepare for ambulation. Which instructions from the nurse are appropriate for this patient? Select all that apply.

a. Do full-body pushups in bed six to eight times daily.
b. Breathe in and out smoothly during quadricep-setting exercises.
c. Place the bed in the lowest position or use a footstool for dangling.
d. Dangle on the side of the bed for 30 to 60 minutes.
e. Allow the nurse to bathe you completely to prevent fatigue.
f. Perform quadriceps two to three times per hour, four to six times a day.

. A nurse is caring for a patient who is on bedrest following a spinal injury. Which action is appropriate to prevent foot drop?

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

a. Maintain the supine position with supination on the feet.
b. Ask the family to bring in high-top sneakers to maintain foot dorsiflexion.
c. Encourage hyperextension of the feet with adaptive devices or splints.
d. Use pillows to keep the feet in the abducted position.

. A nurse is instructing a patient recovering from a stroke on proper use of a cane. What information will the nurse include in the teaching plan?
a. Support weight on the stronger leg and cane and advance weaker foot forward.
b. Hold the cane in the same hand of the leg with the most severe deficit.
c. Stand with as much weight distributed on the cane as possible.
d. Avoid using the cane to rise from a sitting position, as this is unsafe.

. A patient has a fractured left leg, which has been casted. Following teaching from the physical therapist for using crutches, the nurse reinforces which teaching point with the patient?
a. Lean on the crutches using the axillae to bear body weight.
b. Keep elbows close to the sides of the body.
c. When rising, extend the uninjured leg to prevent weight bearing.
d. To climb stairs, place weight on affected leg first.

. A nurse working in a long-term care facility uses proper principles of ergonomics when moving and transferring patients to avoid back injury. Which action should be the focus of these preventive measures?
a. Carefully assessing the patient care environment
b. Using two nurses to lift a patient who cannot assist
c. Wearing a back belt to perform routine duties
d. Properly documenting the patient lift

. A nurse is assisting a patient who is 2 days postoperative from a cesarean section dangle in preparation for sitting in a chair. After assisting the patient to stand up, the patient's knees buckle and she tells the nurse she feels faint. What is the appropriate nursing action?
a. Supporting the patient as she stands, waiting a few moments, then continuing the move to the chair
b. Calling for assistance and continuing the move with the assistance of another nurse
c. Lowering the patient back to the side of the bed and pivoting her back into bed
d. Having the patient sit down on the bed and dangle her feet before moving

. A patient who injured the spine in a motorcycle accident is receiving rehabilitation services in a short-term rehabilitation center. The nurse caring for the patient tells the AP not to place the patient in which position?
a. Side-lying
b. Fowler's
c. Sims'
d. Prone

. A nurse is using the Katz Index of Independence in Activities of Daily Living (ADLs) to assess the mobility of a hospitalized patient. During the patient interview, the nurse documents the following patient data: "Patient bathes self completely but needs help with dressing. Patient toilets independently and is continent. Patient needs help moving from bed to chair. Patient follows directions and can feed self." Based on this data, which score would the patient receive on the Katz index?
a. 2
b. 4
c. 5
d. 6

. Two nurses are repositioning a patient and pulling the patient up in bed. Which of these steps is most appropriate to prevent injury to the nurses?
a. Telling the patient to cross their arms and legs
b. Pulling the patient from underneath the axilla toward the top of the bed
c. Avoiding using a draw sheet to lift or reposition the patient
d. Ensuring the bed is at the level of the nurses' hips
e. Facing the head of the bed and rocking in synchrony

. A nurse is getting a patient with right hemiparesis out of bed to the chair. What will the nurse say to the patient?
a. "Stand on the weaker leg and pivot toward the chair."

b. "I will call the lift team to carry you to the chair."
c. "The chair is by your non-affected leg for smoother movement."
d. "Avoid putting your hospital socks on, as that will restrict your feet moving."

ANSWERS WITH RATIONALES

. **a, d.** Teaching points for exercising for a patient with COPD include avoiding sudden position changes that may cause dizziness and avoiding extreme temperatures. The nurse should also instruct the patient to remain adequately hydrated, respect fatigue as a sign of activity intolerance and not push to the point of exhaustion, and avoid exercise if weak or ill. Older adults should consume a high-protein, high-calcium, and vitamin D–enriched diet.

. **a, c, f.** When a patient reports fatigue during range-of-motion exercises, the nurse should stop the activity, reevaluate the plan of care, and assess the patient for further symptoms indicating the activity is not tolerated. The exercises can be rescheduled for times of the day when the patient is feeling more rested, or spaced out at different times of the day.

. **c, f, a, e, d, b.** When a patient is being moved or ambulated and starts to fall, the nurse places their feet wide apart with one foot in front, rocks their pelvis out toward the side of the patient, grasps the gait belt, supports the patient by pulling the patient's weight backward against their body, gently slides the patient down their body toward the floor while protecting the patient's head, and remains with the patient while calling for help.

. **b.** By 5 months, head control is usually achieved. An infant usually rolls over by 6 to 9 months. By 15 months, most toddlers can walk unassisted. By 2 years, most toddlers can jump.

. **a.** The trochanter roll is used to support the hips and legs to prevent external rotation. SCDs and antiembolism stockings are used to prevent DVT. Fowler's position allows for foot rotation and increases sacral pressure.

. **b.** In a nonerect patient, the kidneys and ureters are level, limiting or delaying urinary drainage from the kidney pelvis to ureter and bladder. The resulting urinary stasis favors the growth of bacteria that can promote urinary tract infections. Regular exercise, not immobility, improves blood flow to the kidneys. Immobility predisposes the patient to bone demineralization, resulting in increased urinary calcium levels and alkaline urine, contributing to renal calculi and urinary tract infection, respectively.

. **c.** High-Fowler's position promotes maximal lung expansion and is the position of choice during episodes of dyspnea. Encouraging ambulation during distress will increase dyspnea. Distracting the patient is not addressing the underlying cause of dyspnea, which is activity. Holding the breath increases demands on the heart.

. **b, c, f.** Breathing in and out smoothly during quadricep-setting exercises maximizes lung inflation. The patient should perform quadricep-setting exercises two to three times per hour, four to six times a day, or as ordered. The patient should never hold their breath during exercise drills because this places a strain on the heart. Pushups are usually done three or four times a day and involve only the upper body. Dangling for a few minutes is done to adjust to the upright position; dangling for 30 to 60 minutes is impractical for the nurse to supervise and may prove unsafe. The nurse should place the bed in the lowest position or use a footstool for dangling. The nurse should also encourage the patient to be as independent as possible to prepare for return to normal ambulation and ADLs.

. **b.** To prevent foot drop, the nurse should support the feet in dorsiflexion using a footboard and/or high-top sneakers for further support. Supination involves lying patients on their back or facing a body part upward, and hyperextension is a state of exaggerated extension. Abduction involves lateral movement of a body part away from the midline of the body. These positions do not prevent foot drop.

. **a.** The proper procedure for using a cane is to (1) stand with weight distributed evenly between the feet and cane; (2) support weight on the stronger leg and the cane and advance the weaker foot forward, parallel with the cane; (3) support weight on the weaker leg and cane and advance the stronger leg forward ahead of the cane; (4) move the weaker leg forward until even with the stronger leg and advance the cane again as in step 2. The patient should keep the cane within easy reach and use it for support to rise safely from a sitting position.

. **b.** The patient should keep the elbows at the sides, prevent pressure on the axillae to avoid damage to nerves and circulation, extend the injured leg when rising to prevent weight bearing, and advance the unaffected leg first when climbing stairs.

. **a.** Preventive measures should focus on careful assessment of the patient care environment so that patients can be moved safely and effectively. Using lifting teams and assistive patient handling equipment rather than two nurses to lift increases safety. The use of a back belt does not prevent back injury. The methods used for safe patient handling and mobility should be documented but are not the primary focus of interventions related to injury prevention.

. **c.** If a patient becomes faint and their knees buckle when moving from bed to a chair or ambulating, the nurse should stop the activity, as the patient has demonstrated a clear risk for falling. The nurse should lower the patient back to the side of the bed, pivot her back into bed, cover her, and raise the side rails. Assess the patient's vital signs and for the presence of other symptoms. When vital signs are stable, another attempt can be made with the assistance of another staff. Instruct the patient to remain in the sitting position on the side of the bed for several minutes to allow the circulatory system to adjust to a change in position and prevent hypotension related to a sudden change from the supine position.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

. **d.** While placing the patient in the prone position for 30 minutes two or three times daily helps prevent knee and hip flexion contractures, it is contraindicated in patients who have spinal problems. The pull of gravity on the trunk when the patient lies prone produces a marked lordosis or forward curvature of the lumbar spine.

. **b.** The total score for this patient is 4. On the Katz Index of Independence in ADLs, one point is awarded for independence in each of the following activities: bathing, dressing, toileting, transferring, continence, and feeding.

. **d.** The nurses should face the direction the patient will move and rock in synchrony prior to moving the patient in that direction. A lifting or repositioning sheet or device is used to decrease friction and facilitate movement. While the patient can cross their arms, they can also be instructed to press their feet into the mattress to assist movement. The bed should be at the level of the nurses' elbows.

. **c.** When transferring a patient, the chair is placed on the unaffected or stronger side, rather than the weaker or affected side. Lifting and carrying a patient unless absolutely necessary poses an unnecessary risk for injury to patient and staff. Patients should wear proper shoes, sturdy slippers, or hospital-issued socks with grips to prevent sliding and/or falling.

Rest and Sleep

Jeanette and Abby Clark

Jeanette accompanies her 15-year-old daughter, Abby, to the clinic. While the daughter is having some routine laboratory testing done in another department, Mrs. Clark says, “She always seems to be tired. When she was small, I could never get her to sleep. Now all she wants to do is sleep. It’s all I can do to get her up for school each morning.”

Charlie Bitner

Charlie is an 86-year-old man who has recently been admitted to a long-term care facility. He tells his daughter that “even though I go to bed around 9 pm, I don’t fall asleep until after midnight and then I’m up twice to go to the bathroom and have a lot of trouble falling back to sleep.” His daughter has mentioned to the nurse that her father spends a lot of time napping during the day.

Omeara Family

Lydia Omeara, age 30, asks the nurse at the well-baby clinic whether she should let her infant twins sleep in bed with her and her husband. “They have their own beds, of course, but at night, when they get

up, they like to be in bed with us. Plus, I still breastfeed my babies, so having them nearby would really make it easier for me."

Learning Outcomes

After completing the chapter, you will be able to accomplish the following:

. Describe the functions of rest and sleep.
. Describe the physiology of sleep.
. Identify variables that influence rest and sleep.
. Describe nursing implications related to age-related differences in the sleep cycle.
. Perform a comprehensive sleep assessment.
. Describe common sleep disorders and associated assessment criteria.
. Diagnose actual and potential health problems and needs related to sleep that may be addressed through nursing intervention.
. Describe nursing strategies and interventions to promote rest and sleep.
. Plan, implement, and evaluate nursing care related to alterations in rest and sleep.

Nursing Concepts

Assessment
Clinical decision making/clinical judgment
Health promotion

Key Terms

circadian rhythms
enuresis
hypersomnia
insomnia
melatonin
narcolepsy
non–rapid eye movement (NREM)
sleep
obstructive sleep apnea (OSA)
parasomnias
rapid eye movement (REM) sleep
rest
restless legs syndrome (RLS)
sleep
sleep cycle
sleep deprivation
sleep hygiene
somnambulism

Rest and sleep are vital for life and health—a person's body needs both sleep and rest, and rest is a vital component of restorative sleep (Helvig et al., 2016; National Sleep Foundation [NSF], n.d.a). However, various factors may affect a person's ability to obtain adequate sleep and/or find time for essential periods of rest. Deficiencies in rest and/or sleep can have a negative impact on a person's mental, physiologic, and emotional health (Helvig et al., 2016; Medic et al., 2017; NIH, 2019). Rest and sleep are often used synonymously; however, a person can sleep and not feel rested and can rest without sleeping (Helvig et al., 2016).

This chapter provides the nurse with knowledge of the functions of rest and sleep, as well as the physiology of sleep and factors affecting rest and sleep. Suggestions for performing a sleep assessment are included. Sample interview

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

questions for a general sleep history are presented, along with information on sleep diaries and pertinent physical assessment data. The importance of analyzing these data is explained, and examples of potential health problems and needs related to rest and sleep are provided. Expected patient outcomes and specific nursing strategies for promoting rest and sleep are described. The concluding nursing care plan illustrates how the nurse's knowledge of rest and sleep, combined with skilled nursing interventions and caring, can resolve rest and sleep problems.

REST AND SLEEP

Rest is a basic need in health and illness (Helvig et al., 2016). **Rest** is a concept that is used in many disciplines; in this chapter, rest refers to a condition in which the body is in a decreased state of activity, with the consequent feeling of being refreshed.

Many factors affect a person's ability to rest. Adults juggling the demands of their job and family responsibilities often find little opportunity for rest and relaxation during the course of a day. Children involved in numerous extracurricular activities, as well as trying to excel academically, also do not have the opportunity to rest and relax during the day. Even when rest is possible, one's environment is not always conducive to physical and mental relaxation. Suggestions for preparing a restful environment and promoting relaxation are discussed later in the chapter.

Sleep is a state of rest accompanied by altered consciousness and relative inactivity. Sleep is part of what is called the sleep–wake cycle. Wakefulness is a time of mental activity and energy expenditure (Norris, 2019). Sleep is a period of inactivity and restoration of mental and physical function (Norris, 2019). It is a complex rhythmic state involving a progression of repeated cycles, each representing different phases of body and brain activity, and is crucial for physical, mental, and emotional well-being (Buysse, 2014). Although sensitivity to external stimuli is diminished during sleep as a result of diminished consciousness, this sensitivity can be reversed, as a person can be aroused by sensory or other stimuli (Norris, 2019).

The term *sleep health* has been proposed to express sleep as a positive, measurable attribute (Buysse, 2014, p. 12). Sleep health refers to a multidimensional pattern of multiple sleep characteristics, including sleep duration, continuity, timing, alertness, and satisfaction, that promotes physical and mental well-being (Hale et al., 2020).

Many people can fall asleep easily and remain asleep until the desired waking time. Conversely, others rarely fall asleep without a struggle; then when they do, sleep is fragmented. Insufficient sleep can seriously affect a person's physical and psychological health (see Physical and Psychological Effects of Insufficient Sleep). Consequently, nurses need to be vigilant in promoting good sleep health and detecting and addressing sleep disturbances. See the accompanying Reflective Practice display.

PHYSIOLOGY OF SLEEP

Two systems in the brainstem, the reticular activating system (RAS) and the bulbar synchronizing region, are believed to work together to control the cyclic nature of sleep. The RAS extends upward through the medulla, the pons, the midbrain, and into the hypothalamus; the bulbar synchronizing region is also located in the pons and medulla. It facilitates reflex and voluntary movements as well as cortical activities related to a state of alertness. The RAS comprises many nerve cells and fibers. The fibers have connections that relay impulses into the cerebral cortex and spinal cord.

During sleep, the RAS experiences few stimuli from the cerebral cortex and the periphery of the body. Wakefulness occurs when this system is activated with stimuli from the cerebral cortex and from periphery sensory organs and cells. For example, an alarm clock awakens us from sleep to a state of consciousness, in which we realize that we must prepare for the day. Sensations such as pain, pressure, and noise produce wakefulness by means of peripheral organs and cells.

The hypothalamus has control centers for several involuntary activities of the body, one of which concerns sleeping and waking. Injury to the hypothalamus may cause a person to sleep for abnormally long periods.

Various neurotransmitters are involved with the sleeping process. Norepinephrine and acetylcholine—in addition to dopamine, serotonin, and histamine—are involved with excitation. Gamma-aminobutyric acid (GABA) appears to be necessary for inhibition. However, research has yet to prove exactly how many of the biochemical changes and hormones function in sleep. **Melatonin**, a hormone, is thought to regulate the sleep–wake cycle and possibly circadian rhythms (see following discussion of circadian rhythms) (NSF, 2020a). It is also known that sleep and wake states are also characterized by distinct hormonal patterns that exert potential significant influences on metabolism and glucose homeostasis (Norris, 2019).

QSEN Reflective Practice: Cultivating QSEN Competencies

CHALLENGE TO ETHICAL AND LEGAL SKILLS

I was working in our well-baby clinic today when a mother, Lydia Omeara, asked my advice about letting her infant twins sleep in bed with her and her husband: "They have their own beds, of course, but at night,

when they get up, they seem to like to be in bed with us. Plus, I still breastfeed my babies, so having them nearby would really make it easier for me." She mentioned reading an article recently about this, noting that while this custom is usual in other countries, it had been discouraged until recently in the United States. According to the article, she said that it seems that more and more U.S. parents are doing this now. She asked for my advice, and I had no idea how to respond. Clearly, anything that resulted in better rest for the parents—who are up many times each night if the babies aren't sleeping well—would seem to be a good idea. However, I vaguely remembered learning that small children are at increased risk for sudden infant death syndrome (SIDS) in an adult bed. I needed to find the best way to respond to Mrs. Omeara.

Thinking Outside the Box: Possible Courses of Action

- Make up an answer: "Yes, it's OK" or "No way! What are you, crazy?"
- Refer her to a nurse with more experience.
- Tell her that I honestly don't know the answer, but I will find out more about this and then get back to her.

Evaluating a Good Outcome: How Do I Define Success?

- A decision is made about where the children sleep that protects them and promotes rest, health, and well-being for each member of the family.
- I learn more about the evidence for best practice to inform the best recommendation.
- I am faithful to my professional obligations to be knowledgeable about matters like this.

Personal Learning: Here's to the Future!

Since I don't have children myself and couldn't ever remember spending the night in my parents' bed or having a conversation with them about this, I certainly couldn't draw on personal experience in responding to this mother. In addition, we had never studied anything about this topic. I did remember a recent article in *Newsweek* magazine raising the issue, but I didn't remember this article proposing a scientifically-based recommendation. As a result, I did some research on this issue and learned that there are definitive recommendations for a safe infant sleeping environment from the American Academy of Pediatrics; these guidelines indicate that infants should sleep in the parent's room, close to the bed, but on a separate surface designed for infants, not in the parent's bed. I did my best to summarize the guideline and then I shared the guidelines with Mrs. Omeara so that she and her husband could make an informed decision.

This little experience has taught me a lot about the power of my profession to influence—literally—how people are born, live, and die. I want to have enough knowledge to help people make the best possible life choices, never leading them astray by virtue of my ignorance!

Amy Norris, Georgetown University

QSEN SELF-REFLECTION ON QUALITY AND SAFETY COMPETENCIES DEVELOPING KNOWLEDGE, SKILLS, AND ATTITUDES FOR CONTINUOUS IMPROVEMENT

How do you think you would respond in a similar situation? Why? What does this tell you about yourself and about the adequacy of your skills for professional practice? Do you agree with the criteria that the nursing student used to evaluate a successful outcome? Why or why not? What *knowledge, skills,* and *attitudes* do you need to develop to continuously improve quality and safety when caring for patients and their family like Lydia Omeara?

Patient-Centered Care: What information would be necessary for the nursing student to obtain from the patient to provide an overall picture of the family situation? How can you provide clear, reliable, and unbiased information to Ms. Omeara in a timely manner? What is the best way to communicate emotional support to Ms. Omeara as she struggles with making the right decision for her and her family?

Teamwork and Collaboration/Quality Improvement: What communication skills do you need to continue to function as a resource and advocate for your patient? Could collaboration with other nurses in the well-baby clinic result in a sleep history tool that you could use to assess Ms. Omeara's sleep needs and pattern?

Safety/Evidence-Based Practice: Can you identify any additional evidence in nursing literature that provides information related to the risk of SIDS when infants share a bed with their parents or other behaviors that increase risk? How do you think your response contributed to a safe environment for Ms. Omeara and her twins?

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

Informatics: What information should be electronically documented regarding your assessment of Ms. Omeara's sleep needs? Can you identify essential information that was provided in order for Ms. Omeara and her husband to make an informed decision?

Circadian Rhythms

Rhythmic biologic clocks are known to exist in plants, animals, and humans. Influenced by both internal and external factors, they regulate certain biologic and behavioral functions in humans. Some cycles are monthly, such as a person's menstrual cycle. **Circadian rhythms** are predictable fluctuations in processes that occur in repeated cycles of time, completing a full cycle every 24 hours (Norris, 2019). Fluctuations in a person's heart rate, blood pressure, body temperature, hormone secretions, metabolism, and performance and mood display circadian rhythms.

Sleep is one of the body's most complex biologic rhythms. Circadian synchronization exists when a person's sleep–wake patterns follow the inner biologic clock located in the hypothalamus. When physiologic and psychological rhythms are high or most active, the person is awake; when these rhythms are low, the person is asleep. Light and dark are powerful regulators of the sleep–wake circadian rhythm; when there is interference with the normal cycle, circadian disruption (chrono disruption) occurs. For example, nurses who work the night shift may routinely sleep from 2 PM to 8 PM, and peak physiologic activity may occur between 2200 and 0600 during work. Problems of desynchronization occur when sleep–wake patterns are frequently altered, and the person attempts to sleep during high-activity rhythms or to work when the body is physiologically prepared to rest. A person's individual biologic clock also responds to numerous influences such as occupational demands and social pressures.

Think back to **Charlie Bitner**, the older man living in a long-term care facility. The nurse would need to assess Mr. Bitner, gathering data about his circadian rhythm. This knowledge would be important in developing an individualized plan of care for the patient to promote adequate sleep.

Stages of Sleep

Research reveals that there are two major stages of sleep: non–rapid eye movement (NREM) sleep and rapid eye movement (REM) sleep. These stages have been studied and analyzed with the help of the electroencephalograph (EEG), which receives and records electrical currents from the brain; the electrooculogram (EOG), which records eye movements; and the electromyograph (EMG), which records muscle tone. This combination of diagnostic recordings is referred to as a sleep study or polysomnogram. It is a noninvasive, pain-free study usually conducted over one or two nights in a sleep study facility. Once a health care provider interprets the results, treatments may be recommended for any conditions detected (NSF, 2020c).

Non–Rapid Eye Movement Sleep

Non–rapid eye movement (NREM) sleep, which comprises about 75% to 80% of total sleep time, consists of four stages. Stages I and II, consuming about 5% and 50% of a person's sleep time, respectively, are light-sleep states. During these stages, the person can be aroused with relative ease. Stages III and IV, each representing about 10% of total sleep time, are deep-sleep states, termed delta sleep or slow-wave sleep. The arousal threshold (intensity of stimulus required to awaken) is usually greatest in stage IV NREM. Throughout the stages of NREM sleep, the parasympathetic nervous system dominates, and decreases in pulse, respiratory rate, blood pressure, metabolic rate, and body temperature are observed. Characteristics of the four stages of NREM sleep are summarized in Box 35-1.

Rapid Eye Movement Sleep

It is more difficult to arouse a person during **rapid eye movement (REM) sleep** than during NREM sleep. In normal adults, the REM state consumes 20% to 25% of a person's nightly sleep time. People who are awakened during the REM state almost always report that they have been dreaming. They can usually vividly recall their dreams even if they were absurd or have no sensible meaning for them. Everyone dreams.

During REM sleep, the pulse, respiratory rate, blood pressure, metabolic rate, and body temperature increase, whereas general skeletal muscle tone and deep tendon reflexes are depressed. REM sleep is believed to be essential to mental and emotional equilibrium and to play a role in learning, memory, and adaptation.

A person who is deprived of REM sleep for several nights generally will spend more time in REM sleep on successive nights. This phenomenon, termed REM rebound, allows the total amount of REM sleep to remain fairly constant over time. See Box 35-1 for characteristics of REM sleep.

Box 35-1 Characteristics of NREM and REM Sleep

NREM Sleep

Stage I

- The person is in a transitional stage between wakefulness and sleep.
- The person is in a relaxed state but still somewhat aware of the surroundings.
- Involuntary muscle jerking may occur and waken the person.
- The stage normally lasts only minutes.
- The person can be aroused easily.
- This stage constitutes only about 5% of total sleep.

Stage II

- The person falls into a stage of sleep.
- The person can be aroused with relative ease.
- This stage constitutes 50% to 55% of sleep.

Stage III

- The depth of sleep increases, and arousal becomes increasingly difficult.
- This stage composes about 10% of sleep.

Stage IV

- The person reaches the greatest depth of sleep, which is called *delta sleep.*
- Arousal from sleep is difficult.
- Physiologic changes in the body include the following:
  - Slow brain waves are recorded on an EEG.
  - Pulse and respiratory rates decrease.
  - Blood pressure decreases.
  - Muscles are relaxed.
  - Metabolism slows and the body temperature is low.
  - This constitutes about 10% of sleep.

REM Sleep

- Eyes dart back and forth quickly.
- Small muscle twitching, such as on the face
- Large muscle immobility, resembling paralysis
- Respirations irregular; sometimes interspersed with apnea
- Rapid or irregular pulse
- Blood pressure increases or fluctuates
- Increase in gastric secretions
- Metabolism increases; body temperature increases
- Encephalogram tracings active
- REM sleep enters from stage II of NREM sleep and re-enters NREM sleep at stage II: arousal from sleep difficult
- Constitutes about 20% to 25% of sleep

Sleep Cycle

Normally during a **sleep cycle**, a person passes consecutively through the four stages of NREM sleep. This pattern is then reversed, and the person returns from stage IV to stage III to stage II. Instead of re-entering stage I and awakening, the person enters into the REM stage of sleep, after which the person re-enters NREM sleep at stage II and returns to stages III and IV. A person awakened from sleep at any time will return to sleep by starting at stage I of NREM sleep. Figure 35-1 illustrates the normal sleep pattern of young adults.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

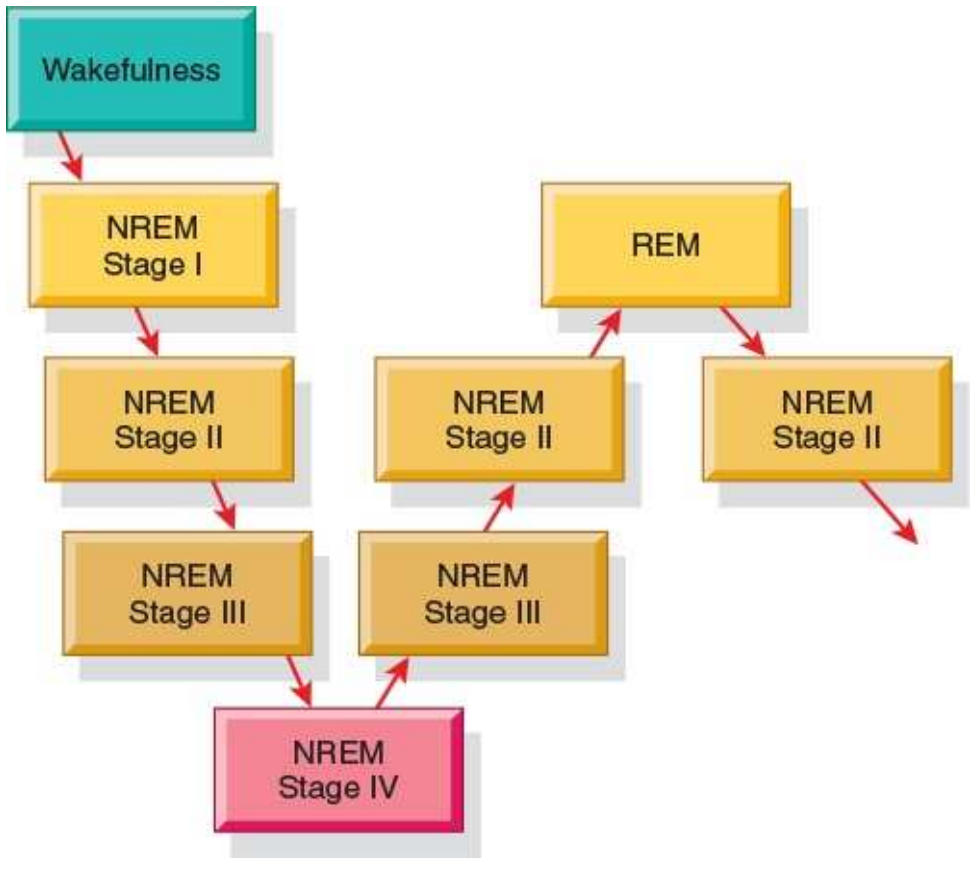

FIGURE 35-1. A single normal sleep cycle in a young adult. In the normal nocturnal pattern, the shaded cycle is repeated four or five times. Periods of REM sleep generally increase in duration; periods of deep sleep (stage IV) progressively decrease as morning approaches.

Consider **Charlie Bitner**, the long-term care resident described at the beginning of the chapter. When evaluating Mr. Bitner's sleep cycle, the nurse would need to keep in mind that each time Mr. Bitner awakes, his sleep cycle is starting all over again. Subsequently, he is experiencing light sleep, characteristic of sleep stages I and II.

Most people go through four or five cycles of sleep each night. On average, each cycle lasts about 90 to 110 minutes (Norris, 2019). The cycles tend to become longer as morning approaches. Ordinarily, more deep sleep occurs in the delta stage (NREM stages III and IV) in the first half of the night, especially if one is tired or has lost sleep. Variations in the sleep cycle occur according to age, as Figure 35-2 illustrates on page 1306.

REST AND SLEEP REQUIREMENTS AND PATTERNS

For no known reason, an average of 8 hours of sleep per night has been the accepted standard for adults, despite variations in individual requirements (see Box 35-2 on pages 1306–1307). No rigid formula exists for the regular intervals and duration of sleep. It is important, however, that each person follow a pattern of rest that maintains one's own well-being.

Despite individual variations, some generalities can be stated. On average, infants require 12 to 16 hours each day (including naps); toddlers, 11 to 14 hours (including naps); and preschoolers 10 to 13 hours (including naps) a day. School-aged children, ages 6 to 12 years, require from 9 to 12 hours of sleep, and teenagers 8 to 10 hours a day (American Academy of Sleep Medicine, 2016b; CDC, 2017).

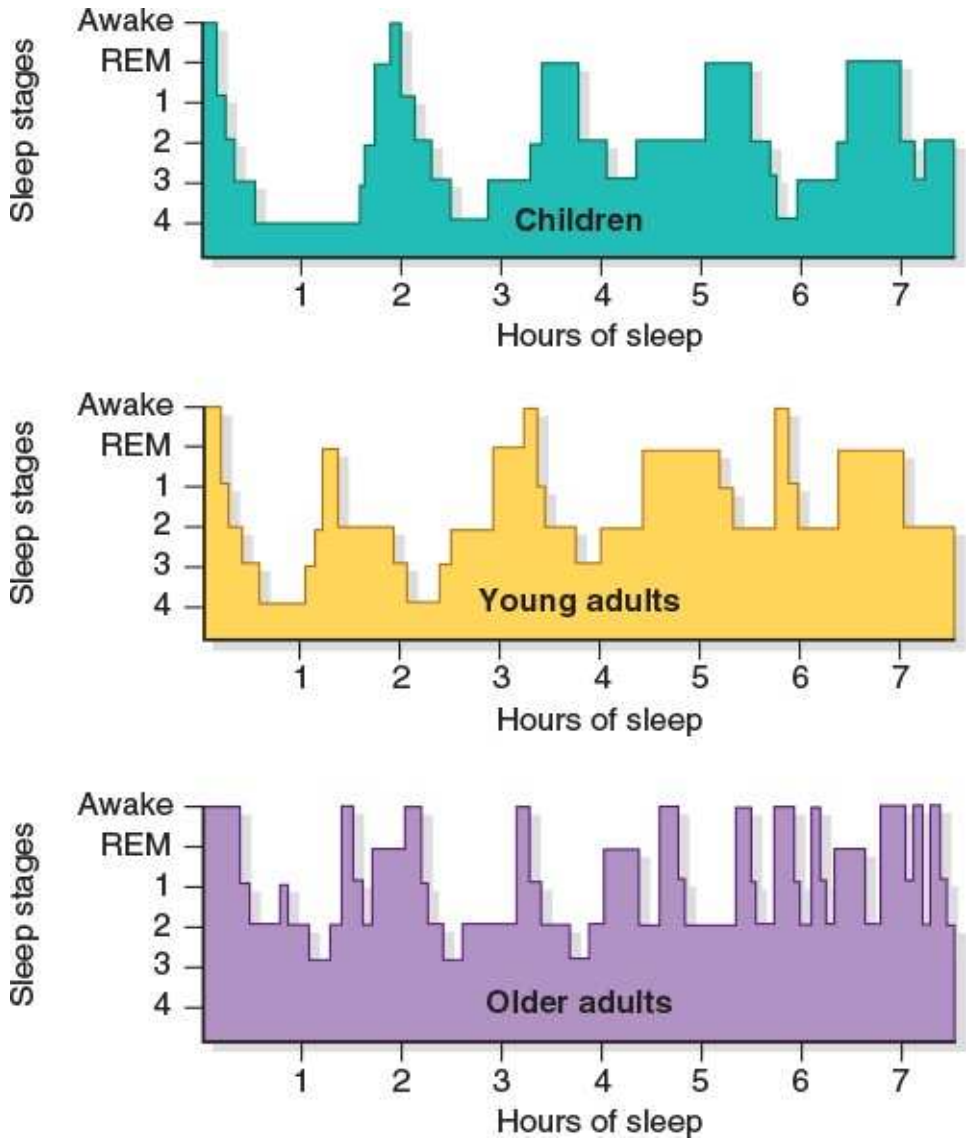

FIGURE 35-2. A comparison of developmental differences in NREM and REM cycles during nocturnal sleep for children, young adults, and older adults.

Recall **Jeanette Clark**, the mother of an adolescent girl who seems to want to sleep all the time. When discussing this issue with Mrs. Clark, the nurse would need to integrate information about the adolescent's developmental stage—that is, that adolescence is a period of tremendous growth, which requires an increased amount of sleep.

The recommended amount of sleep for adults is 7 or more hours (CDC, 2017). Those who are able to relax and rest easily, even while awake, often find that less sleep is needed, whereas others may find that more sleep is required to overcome fatigue. Fatigue can be considered a normal, protective body mechanism and nature's warning that sleep is necessary. Chronic fatigue, however, is abnormal and is often a symptom of illness.

Sleep patterns of older adults vary, but the optimal recommendation for this age group is 7 to 8 or 9 hours (CDC, 2017). They may sleep less, however, because of insomnia and medical conditions that interrupt their sleep, and the quality of their sleep changes.

Patterns of sleep periodicity appear to be learned. For example, most people learn to sleep at night and to be awake and work during the day. However, many night workers learn to sleep equally well during the day.

PHYSICAL AND PSYCHOLOGICAL EFFECTS OF INSUFFICIENT SLEEP

Many people have sleep disturbances that go undetected for years, progressively undermining their energy and destroying their sense of self. One third of U.S. adults report that they usually get insufficient sleep (CDC, 2020). Insufficient sleep in children may affect normal growth and development and could be a contributing factor in performance deficits and behavioral problems. Furthermore, short sleep duration in childhood is associated with an increased risk of obesity during childhood or later in life (CDC, 2018a). The NSF (n.d.b) has also identified a link between insufficient sleep and obesity in adults and children; adults and children who slept less than the recommended hours per night were more likely to be overweight. This sleep–weight link is possibly related to two hormones: leptin

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

and ghrelin (NSF, 2022a). Leptin signals the brain to stop eating, whereas ghrelin promotes continued eating. Research suggests that sleep deprivation lowers leptin levels and elevates ghrelin levels, thus increasing one's appetite. To compound the problem, the brain may interpret a drop in leptin as a sign of starvation. Unfortunately, the brain then signals the body to eat more while it simultaneously lowers the body's metabolic rate. When this happens, people are more likely to gain weight, even if food intake is decreased (Miller et al., 2015).

Box 35-2 **Developmental Patterns of Sleep**

Newborns and Infants

Sleep Pattern

- *Newborn:* Sleeps an average of 16 hr/24 hr; averages about 4 hours at a time.
- Each infant's sleep pattern is unique. On average, infants sleep 12 to 16 hours at night, with several naps during the day.
- Usually by age 8 to 16 weeks, an infant sleeps through the night.
- REM sleep constitutes much of the sleep cycle of a young infant.

Nursing Implications

- Teach parents to position infant on the back. This is the only safe sleeping position for infants younger than age 1 year. Sleeping in the prone position increases the risk for sudden infant death syndrome (SIDS).
- Advise parents that eye movements, groaning, grimacing, and moving are normal activities at this age.
- Encourage parents to have infant sleep in a separate area in the parents' bedroom rather than their bed.
- Caution parents about placing pillows, crib bumpers, quilts, stuffed animals, and so on in the crib because this poses a suffocation risk.

Toddlers

Sleep Pattern

- Need for sleep declines as this stage progresses. May require two naps during the day and end this stage sleeping 11 to 14 hours a night and napping once during the day.
- Toddlers may begin to resist naps and going to bed at night.
- They may move from crib to youth bed or regular bed at around age 2 years.

Nursing Implications

- Establish a regular bedtime routine (e.g., reading a story, singing a lullaby, saying prayers).
- Advise parents of the value of a routine sleeping pattern with minimal variation.
- Encourage attention to safety once child moves from crib to bed. If child attempts to wander out of room, a folding gate may be necessary across the door of the room.

Preschoolers

Sleep Pattern

- Children in this stage generally sleep 10 to 13 hours at night.
- The REM sleep pattern is similar to that of an adult.
- Daytime napping decreases during this period, and by the age of 5 years, most children no longer nap.
- This age group may continue to resist going to bed at night.

Nursing Implications

- Encourage parents to continue bedtime routines.
- Advise parents that waking from nightmares or night terrors (awakening screaming about 20 minutes after falling asleep) are common during this stage. Waking the child and comforting the child generally helps. Sometimes use of a night light is soothing.

School-Aged Children

Sleep Pattern

- Younger school-aged children may require 9 to 12 hours nightly, whereas older children in this stage may average 9 to 11 hours.
- Sleep needs usually increase when physical growth peaks.

Nursing Implications

- Discuss the fact that the stress of beginning school may interrupt normal sleep patterns.
- Advise that a relaxed bedtime routine is most helpful at this stage.
- Inform parents about child's awareness of the concept of death possibly occurring at this stage. Encourage parental presence and support to help alleviate some of the child's concerns.

Teenagers

Sleep Pattern

- Sleep needs of teenagers vary widely, but the average requirement is 8 to 10 hours. The growth spurt that normally occurs at this stage may necessitate the need for more sleep; however, the stresses of school, activities, and part-time employment may cause adolescents to have a restless sleep. Adolescents tend to go to bed later than younger children and adults, but early morning start times for high school frequently require an early awakening time. This can result in an average of only 7 to 7.5 hours of sleep a night.
- Many adolescents do not get enough sleep.

Nursing Implications

- Advise parents that their adolescents' complaints of fatigue or inability to do well in school may be related to not enough sleep. *Excessive daytime sleepiness (EDS)* may also make the teenager more vulnerable to accidents and behavioral problems.

Young Adults

Sleep Pattern

- The amount of sleep required is 7 to 9 hours.
- Sleep is affected by many factors: physical health, type of occupation, exercise. Lifestyle demands may interfere with sleep patterns.
- REM sleep averages about 20% of sleep.

Nursing Implications

- Reinforce that developing good sleep habits has a positive effect on health, particularly as a person ages.
- If loss of sleep is a problem, explore lifestyle demands and stress as possible causes.
- Suggest use of relaxation techniques and stress-reduction exercises rather than resorting to medication to induce sleep. Sleep medications decrease REM sleep, may be habit forming, and frequently lose their effectiveness over time.

Middle-Aged Adults

Sleep Pattern

- Total sleep time decreases during these years, with a decrease in stage IV sleep.
- The percentage of time spent awake in bed begins to increase.
- People become more aware of sleep disturbances during this period.

Nursing Implications

- Encourage adults to investigate consistent sleep difficulties to exclude pathology or anxiety and depression as causes.
- Encourage adults to avoid use of sleep-inducing medication on a regular basis.

Older Adults

Sleep Pattern

- An average of 7 to 8 hours of sleep is usually adequate for this age group.
- Sleep is less sound, and stage IV sleep is absent or considerably decreased. Periods of REM sleep shorten.
- Older adults frequently have great difficulty falling asleep and have more complaints of problems sleeping.
- Decline in physical health, psychological factors, effects of drug therapy (e.g., nocturia), or environmental factors may be implicated as causes of inability to sleep.

Nursing Implications

- A comprehensive nursing assessment and individualized interventions may be effective in the long-term care of this age group.
- Emphasize concern for a safe environment because it is not uncommon for older adults to be temporarily confused and disoriented when they first awake.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

- Use pharmacologic sleep aids with extreme caution because of declining physiologic function and concerns about polypharmacy.
- Encourage older adults to discuss sleep concerns with their health care provider.

People who suffer sleep difficulties caused by working night shifts or constantly changing work shifts may experience adverse effects, including anxiety, personal conflicts, loneliness, depression, gastrointestinal (GI) symptoms, increase in type 2 diabetes, hypertension, and higher rates of cardiovascular disease including strokes, and substance abuse (Nena et al., 2018; National Institute for Occupational Safety and Health [NIOSH], n.d.). A person who has experienced shortened sleep by just a few hours a night can have a reaction time similar to someone intoxicated with alcohol (NSF, 2022b).

Sleep loss that results in fatigue and decreased competence increases the risk of a sleep-related motor vehicle accident. The NSF (n.d.c) reports that 55% of Americans admitted driving while feeling drowsy during the past year and drowsy driving is implicated in at least 100,000 motor vehicle accidents a year. A large study of critical care nurses reported that 43% of the nurses stated that they fell asleep while stopped at a traffic light and 20% had a traffic accident or a near miss directly associated with their fatigue (Johnson, 2011).

In addition, studies of physicians' and nurses' work habits have concluded that shift work sleep disorders (SWSDs) from extended work schedules are a causative factor in a substantial number of adverse medical events and errors (Weaver et al., 2018; Witkoski Stimpfel, 2020). Fatigue and sleepiness can compromise patient safety and increase the risk for adverse events such as medication errors. Sleep deprivation and the resulting consequences of decreased alertness and ability to perform tasks competently are well documented. The Office of Disease Prevention and Health Promotion (ODPHP) (2020) recognizes that improved attention to sleep health promotes a safer environment for health care workers and their patients. Objectives related to sleep health identified in *Healthy People 2030* include increasing the proportion of adults who get sufficient sleep; increasing the proportion of high school students who get sufficient sleep; increasing the proportion of people with sleep apnea symptoms who get evaluated by a health care provider; reducing the rate of motor vehicle crashes due to drowsy driving; increasing the proportion of children who get sufficient sleep; and increase the proportion of infants who are put to sleep on their backs (ODPHP, 2020). The Joint Commission (2018) acknowledges the impact of fatigue on health care workers and urges greater attention to the issue, suggesting actions for health care facilities to reduce fatigue-related risks. These include:

- Assess work schedules and staffing to address extended work shifts and hours.
- Review hand-off processes and procedures to ensure safe transfer of information.
- Request staff input in designing work schedules to minimize staff fatigue.
- Develop and implement a fatigue management plan.
- Educate staff about sleep hygiene and the effects of fatigue on patient safety.
- Address staff concerns about fatigue.
- Encourage teamwork to support staff who work extended shifts.
- Keep the effects of fatigue in mind when reviewing adverse events.

FACTORS AFFECTING REST AND SLEEP

A variety of factors influence both the quality and quantity of sleep. These factors help inform the assessment process as well as identification of appropriate interventions related to enhancing rest and sleep.

Developmental Considerations

Variations in sleep patterns are related to age. Box 35-2 highlights these variations and associated nursing implications. Routine assessment of sleepiness or short sleep patterns in children is a first step in identifying the existence of a sleep problem and factors interfering with a child's sleep. With a growing body of evidence linking inadequate sleep with obesity and other health concerns in children, health care practitioners must ask about patterns of sleep and sleep habits in children and discuss these issues with parents.

Many people ages 65 years and older report difficulty falling asleep, early awakening or waking frequently during the night, napping, or not feeling rested after a night's sleep (Hedges & Gotelli, 2020). Older adults often need more time to fall asleep and are less able to cope with changes in their usual sleep patterns compared to younger people. Many older adults nap during the day, which often results in sleeping fewer hours at night. Chronic illnesses in older adults may also affect their sleep patterns. For instance, many older men have enlargement of the prostate gland, which may cause them to awaken throughout the night to use the bathroom.

Motivation

A desire to be wakeful and alert helps overcome sleepiness and sleep. For example, a tired person may be wakeful and alert when at a party or when attending an interesting play or concert. The opposite is also true: When there is minimal motivation to be awake, sleep generally follows. For example, a student who is bored and disinterested in a lecture or class may doze during the lecture.

Culture

A person's cultural beliefs and practices can influence rest and sleep. Although developmental stages are similar, children's bedtime rituals, sleeping position and place, and pattern of sleep may vary based on culture. Methods to enhance or foster sleep may also be culturally influenced. A cultural orientation toward privacy and quiet makes sleep difficult in a busy special care unit. Sensitivity to a patient's culture must be included in the plan of care for preparing the patient for an evening's sleep.

Think back to **Mrs. Omeara**, the mother of infant twins. She is wondering whether she should let her twins sleep in her and her husband's bed. The nurse should investigate the family's cultural background to determine any influences it may have on the patient's question. The nurse would then use this information to develop an individualized, culturally considerate plan of care for dealing with this question

Lifestyle and Habits

Various lifestyle factors can affect a person's ability to sleep well. People working a shift other than the day shift must reorganize their priorities, or sleep difficulties may occur. Based on the circadian cycle, the body prepares for sleep at night by decreasing the body temperature and releasing melatonin (a natural chemical produced at night that decreases wakefulness and promotes sleep). Working the night shift disrupts this natural process and can result in loss of sleep and other adverse effects (see Physical and Psychological Effects of Insufficient Sleep). Developing a sleep pattern is especially difficult if the work shift changes periodically. Nurses and others who work long hours and varying shifts have difficulty finding time to exercise, which can promote weight gain. The NIOSH (2020) offers information to educate nurses and their managers about the health and safety risks associated with shift work and long work hours and a training program to increase knowledge about personal behaviors and workplace systems to reduce associated risks.

The duration and quality of sleep can be affected by watching some types of television shows, participating in stimulating outside activities, and taking part in activity or exercise within 3 hours of the person's normal bedtime. A person's ability to relax from work-related pressures and to put aside home stresses are also important factors in the ability to fall asleep. Nurses who role model good health behaviors are more effective teachers. Use the Promoting Health 35-1 display for yourself before using it with others.

Physical Activity and Exercise

Activity and exercise increase fatigue and, in many instances, promote relaxation that is followed by sleep. It appears that physical activity increases both REM and NREM sleep. Moderate exercise is a healthy way to promote sleep, but exercise that occurs within a 3-hour interval before normal bedtime can hinder sleep. The fatigue that results from normal work activities or exercise is believed to contribute to a restful sleep, whereas excessive exercise or exhaustion can decrease the quality of sleep.

Remember **Jeanette Clark**, the mother of the adolescent girl who seems to be sleeping all the time. As part of the health promotion teaching plan, the nurse would need to explain to Mrs. Clark about the significant changes occurring during adolescence. In addition to this stage being a period of rapid growth, it is also a time of increased activity—physically, emotionally, and socially. All of these may be affecting her daughter's sleep patterns.

Dietary Habits

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

There is some evidence supporting a sleep moderating effect of the dietary amino acid L-tryptophan in promoting sleep (Binks et al., 2020). A small protein-containing snack (a source of tryptophan) before bedtime has been recommended for patients with insomnia. However, as nutritionists have studied the effects of various foods on mood, new information has emerged. Carbohydrates make tryptophan more available to the brain. This explains why meals heavy in carbohydrate content tend to cause drowsiness. Combining foods that are high in tryptophan with healthy, complex carbohydrates improves sleep. Therefore, a small protein- and carbohydrate-containing snack such as peanut butter on toast or cheese and crackers about an hour before bed may be more effective (Binks et al., 2020; Sleep Foundation, 2020a).

Promoting Health 35-1

REST AND SLEEP

Use the assessment checklist to determine how well you are meeting needs for rest and sleep. Then develop a prescription for self-care by choosing appropriate behaviors from the list of suggestions.

Assessment Checklist

☐ almost always ☐ sometimes ☐ almost never

☐ ☐ ☐ 1. I feel rested and refreshed when I get up in the morning.
☐ ☐ ☐ 2. I have energy to carry out normal activities of daily living.
☐ ☐ ☐ 3. I understand the normal changes in sleep and rest requirements and patterns that occur with aging.
☐ ☐ ☐ 4. I set aside time for quiet recreation and restful activities each day.

Self-Care Behaviors

1. Follow a regular routine for bedtime and morning awakening.
2. Accept individual differences in need for sleep.
3. Use relaxation exercises to relax before bedtime, especially if feeling stressed.
4. Avoid caffeine, smoking, and alcohol before bedtime.
5. Adjust bedcoverings, room temperature, and lighting to your preferences.
6. Eat a small protein and carbohydrate snack before going to bed.
7. Be aware of the potential dangers of sleeping pills.
8. Use some part of each day for quiet, enjoyable activities such as crafts, hobbies, reading, watching television, listening to music, and visiting with friends.
9. Incorporate periods of regular exercise into each week.

Alcoholic beverages, when used in moderation, appear to induce sleep in some people. However, large quantities have been found to limit REM and delta sleep. Initially, alcohol consumption may help to induce sleep, but once the alcohol is cleared from the body, sleep is fragmented and disrupted often (Sleep Foundation, 2020b). Alcohol also interferes with entering deeper stages of sleep, which may result in feelings of fatigue upon wakening despite having spent an adequate amount of time in bed (Sleep Foundation, 2020a). Most recommendations to promote effective sleep state that alcohol and products containing alcohol should be avoided in the evening to promote better sleep habits.

Caffeine is a central nervous system stimulant. For many people, beverages containing caffeine interfere with the ability to fall asleep. Caffeine is thought to interfere with the action of adenosine, which is a compound found in every cell in the body. It binds to adenosine receptors in the brain, thus preventing the adenosine from entering nerve cells and causing drowsiness. Caffeine consumption should be avoided too close to bedtime as its effect may persist for several hours (Sleep Foundation, 2020b). Examples of beverages containing caffeine include coffee, tea, energy drinks, and most cola drinks. Chocolate also contains caffeine.

Smoking

Exposure to tobacco smoke is associated with poorer sleep quality (Zandy et al., 2020). Nicotine has a stimulating effect; smokers usually have a more difficult time falling asleep. They are more easily aroused once asleep and may describe themselves as light sleepers. Avoiding nicotine in any substance close to bedtime is suggested as part of good sleep hygiene practices (Sleep Foundation, 2020d). People usually report improved sleep patterns after discontinuing nicotine use.

Total withdrawal from smoking may be associated with temporary sleep disturbances. Patients who stop smoking often have more daytime sleepiness and report significantly more restlessness at night. Whether this is a short-term effect or is related to nicotine's effect on the central nervous system is uncertain.

Environmental Factors

Most people sleep best in their usual home environments. Sleeping in a strange or new environment tends to influence both REM and NREM sleep. People accustomed to sleeping in a noisy environment, such as a busy large city, actually have a hard time falling asleep in an area that is extremely quiet. By turning on soothing music or a fan or other background noise, the person may actually be able to rest in the new environment (Sleep Foundation, 2020c). Likewise, if a patient is accustomed to sleeping in a quiet environment, a room next to a high-traffic area, such as the nurse's desk, may not be the best place for this patient to rest.

Psychological Stress

Psychological stress, such as from illness and various life situations, tends to disturb sleep. In general, psychological stress affects sleep in two ways: (1) the person experiencing stress may find it difficult to obtain the amount of sleep needed; and (2) REM sleep decreases in amount, which tends to add to anxiety and stress.

Consider **Mrs. Omeara**, the mother described in the beginning of the chapter and in the Reflective Practice display. The nurse would need to gather additional information about Mrs. Omeara's current situation to determine if any stressors might be affecting her ability to obtain adequate rest and sleep. Areas to address may include her typical daily activities, amount of time spent caring for each child, employment, and amount of assistance and support from others. In addition, the nurse would need to investigate the reasons underlying Mrs. Omeara's question about the babies sleeping in the parents' bed.

Illness

Illness, a physiologic as well as a psychological stressor, influences sleep. Certain illnesses are more closely related to sleep disturbances than others. For example:

- Gastric secretions increase during REM sleep. Many people with gastroesophageal reflux disease (GERD) awaken at night with heartburn or pain (NSF, 2020b). They find that using antacids to neutralize stomach acidity often relieves discomfort and promotes sleep.
- Certain epilepsy seizures are associated with certain stages of sleep; sleep deprivation is also associated with activation of seizures in some patients with epilepsy (Lanigar & Bandyopadhyay, 2017).
- Liver failure is associated with insomnia, excessive daytime sleepiness, and a reversal in day–night sleeping habits (disturbance of circadian rhythmicity) (Bruyneel & Sersté, 2018).
- Hypothyroidism is associated with sleep disturbances as a result of trouble tolerating cold at night and joint or muscle pain that disrupts sleep (Sleep Foundation, 2020c). Hyperthyroidism may result in difficulty sleeping due to arousals from nervousness or irritability, night sweats, or frequent urges to urinate (Sleep Foundation, 2020c). Thyroid disease may also be associated with restless legs syndrome (RLS) (see discussion on p. 1315), which may lead to significant sleep disruption (Sleep Foundation, 2020c).
- End-stage renal disease (ESRD) disrupts nocturnal sleep and leads to excessive daytime sleepiness. Patients with ESRD who receive dialysis also have a higher incidence of RLS (discussed later in the chapter) (Maung et al., 2016).

Medications

Health care practitioners must also take into account the effect that drugs used to treat health care problems may have on sleep. Drugs that can affect sleep include benzodiazepines, amphetamines, and antidepressants. Diuretics, antiparkinsonian drugs, some antidepressants and antihypertensives, steroids, decongestants, caffeine, and asthma medications are seen as additional common causes of sleep problems.

Chronotherapeutics is a growing field of study that involves the strategic use of time in the treatment of disease and administration of medications (Zaki et al., 2019). Researchers have determined that certain treatments for disease are more effective when circadian rhythms are taken into account. For example, an unequal dosing schedule including a greater intake of bronchopulmonary drugs and bronchodilators in the evening may be more effective in preventing asthma attacks that commonly occur at night during sleep (Zaki et al., 2019). The timing of antihypertensive medication administration may need to be adjusted to provide peak protection during early-morning hours, when heart attacks are more common (Hermida et al., 2019). Cancer chemotherapy appears to be less toxic when administered at certain times of the day (Mohammadi, 2016). Paying attention to biologic rhythms may influence drug tolerance and medication

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

effectiveness, and reduce adverse effects, including those related to rest and sleep.

COMMON SLEEP DISORDERS

A nurse who interviews a patient to obtain a sleep history needs to understand common sleep disturbances to recognize significant data. The most recent classification of sleep disorders categorized by the International Classification of Sleep Disorders (ICSD) includes six major categories of disorders (American Academy of Sleep Medicine, 2014):

- Insomnia
- Sleep-related breathing disorders
- Central disorders of hypersomnolence
- Circadian rhythm sleep–wake disorders
- Parasomnias
- Sleep-related movement disorders

The more common sleep disorders are insomnia, sleep-related breathing disorders, circadian rhythm sleep–wake disorders, and parasomnias. A brief description of these disturbances follows, with the major focus on specific symptoms associated with the sleep disorder, as well as a brief discussion of possible treatments.

Insomnia

Insomnia is the most common sleep disorder (Hedges & Gotelli, 2020). **Insomnia** is characterized by difficulty falling asleep, intermittent sleep, or difficulty maintaining sleep, despite adequate opportunity and circumstances to sleep (American Academy of Sleep Medicine, 2014; Wilson et al., 2019). People experiencing insomnia report excessive daytime sleepiness (Wilson et al., 2019). As many as 30% to 35% of adults in the United States complain of insomnia (American Academy of Sleep Medicine, 2015). Older adults, women, people under stress, and people with certain health and mental health problems, such as depression are more likely to experience insomnia (American Academy of Sleep Medicine, 2015). Many cases of insomnia are related to disruptions in circadian rhythms. This sleep disorder can also occur during periods of stress; in situations involving some change in the normal environment such as shift work; as a result of pain, discomfort, or limited mobility; and as a result of the side effects of medications. Common medications that may result in insomnia include those taken for hypertension and cardiovascular disease, cold and allergies, attention-deficit hyperactivity disorder (ADHA), and depression (American Academy of Sleep Medicine, 2015).

Daytime consequences of insomnia include reports of feeling tired, lethargic, and irritable during the day. Difficulty concentrating is also a common manifestation. Older adults who experience insomnia while in an acute care setting may manifest delirium as a symptom of sleep deprivation (Hedges & Gotelli, 2020). It is a challenge for health care providers to understand the effects of age-related changes on sleep and be alert for the potential complications associated with insomnia in this growing population.

Insomnia may be a short-term or chronic in nature. Chronic insomnia is frequently listed as the motivating factor for a visit to a sleep disorder clinic. A growing number of health conditions have been associated with chronic insomnia. They include obesity; type 2 diabetes; psychiatric disorders such as depression; and cardiovascular disorders such as heart failure, stroke, hypertension, and myocardial infarction (heart attack) (CDC, 2018a; CDC, 2018b; Javaheri & Redline, 2017).

Nonpharmacologic approaches may be attempted initially to resolve the insomnia. Refer to the Teaching About Rest and Sleep discussion on page 1326. The misuse of alcohol or caffeine can have an adverse effect on sleep; stopping these behaviors may reduce or eliminate the insomnia. Cognitive behavioral therapy (CBT) is a safe, effective means of managing chronic insomnia and may include cognitive therapy, relaxation training, stimulus control therapy, or sleep restriction therapy (American Academy of Sleep Medicine, 2019; Brem, 2015; Chung et al., 2018). CBT is recommended as a first-line treatment of insomnia (Wilson et al., 2019). CBT involves meeting with a therapist and working through maladaptive sleep beliefs. It may also include biofeedback, additional relaxation techniques, and sleep hygiene measures (see Teaching About Rest and Sleep on page 1326). When used in conjunction with these other complementary therapies, CBT can be very successful (Brem, 2015). If, however, nonpharmacologic measures prove ineffective, pharmacologic treatment may be necessary. Refer to the Using Medications to Promote Sleep discussion on page 1325.

Sleep-Related Breathing Disorders

There are several sleep-related breathing disorders. The discussion here will focus on the more common OSAs. **Obstructive sleep apnea (OSA)** is a potentially serious sleep disorder in which the throat muscles intermittently relax and block the airway during sleep, causing breathing to repeatedly stop and start (Mayo Foundation for Medical Education and Research [MFMER], 2020b). OSA is further delineated as OSA (adult) and OSA (pediatric).

Adult OSA is characterized by five or more predominantly obstructive respiratory events (the absence of breathing [apnea] or diminished breathing efforts [hypopnea] or respiratory effort-related arousals) during sleep, accompanied by excessive daytime sleepiness, fatigue, insomnia, loud snoring, observed apnea, and/or gasping for air during sleep (MFMER, 2020b). Adults suffering from OSA may also present with associated health disorders (hypertension,

coronary artery disease, atrial fibrillation, congestive heart failure, stroke, diabetes, cognitive dysfunction, or mood disorder) (American Academy of Sleep Medicine, 2014). OSA (adult) may be diagnosed based on a frequency of obstructive respiratory events that occur at a rate of >15 events per hour, even in the absence of associated symptoms or health disorders alone (American Academy of Sleep Medicine, 2014).

OSA (adult) is a common disorder, caused by recurrent collapse of the upper airway during sleep (Fig. 35-3). Breathing may cease for 10 to 20 seconds and possibly as long as 2 minutes. During long periods of apnea, the oxygen level in the blood drops, the pulse usually becomes irregular, and the blood pressure often increases. This decrease in ventilation and associated physiologic response activates the fight-or-flight response of the sympathetic nervous system and the sleeper startles and awakens (Simmons & Pruitt, 2012). This pattern may repeat 5 to 30 times or more each hour (MFMER, 2020b).

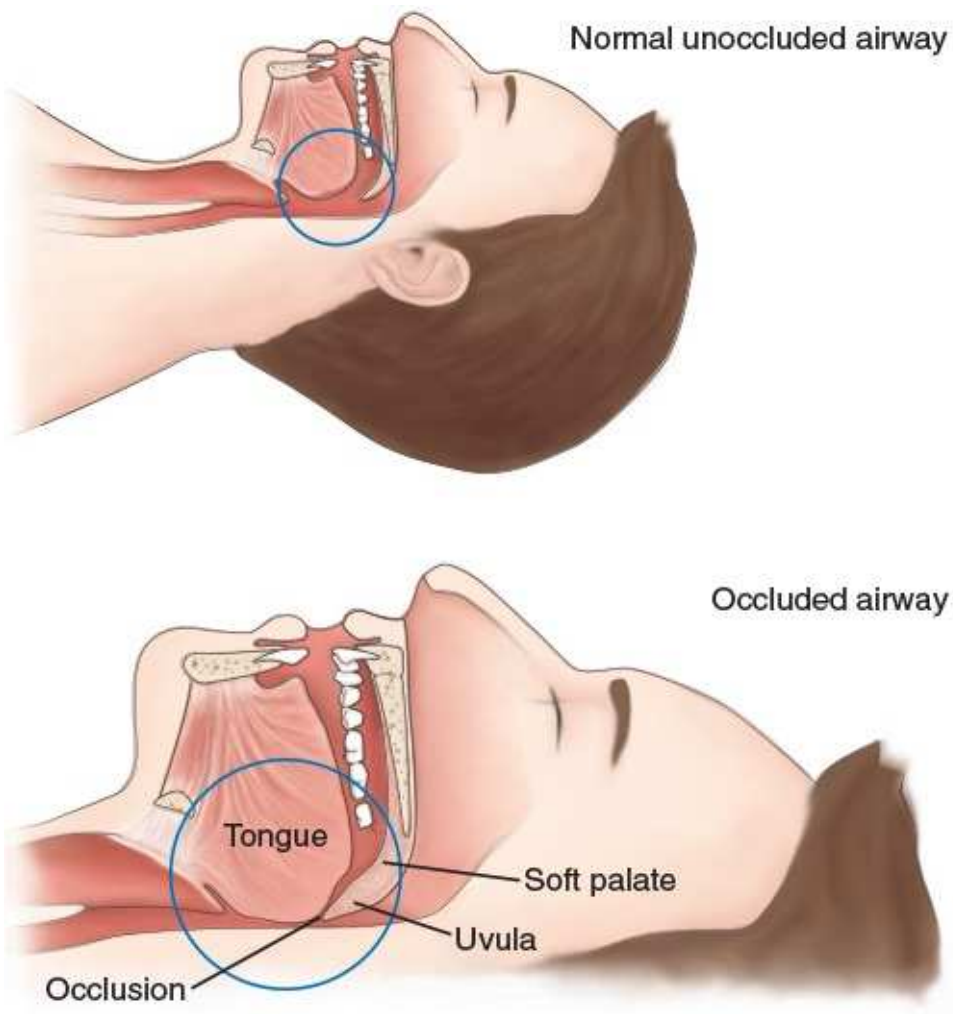

FIGURE 35-3. Obstructive sleep apnea occurs when the airway is occluded due to recurrent collapse of the upper airway. Normally, the airway remains open during sleep (see insets).

The incidence of OSA (adult) increases with age, obesity, large neck size, male, and family history and is associated with cardiovascular risk factors, cardiovascular disease, depression, increased risk of motor vehicle accidents, and increased mortality (American Academy of Sleep Medicine, 2016a; MFMER, 2020b; Norris, 2019).

Clinical information and nocturnal polysomnography can confirm the diagnosis of sleep apnea. This overnight sleep study also includes a video recording of sleep awakenings and movements. Cardiopulmonary monitoring of the arterial oxygen saturation and an electrocardiogram (ECG) to detect any cardiac arrhythmias can also assist in the diagnosis of OSA.

Adults with OSA may become irritable during the day, fall asleep during monotonous activities, have difficulty concentrating, and exhibit slower reaction times. Alcohol, tobacco, and sleeping pills increase the breathing disruption that occurs in sleep apnea and therefore should be avoided.

The definitive treatment of moderate or severe OSA involves use of a continuous positive airway pressure machine (CPAP). CPAP is noninvasive and consists of a mask connected to an air pump that is worn during sleep. This device delivers positive air pressure that holds the airway open. It can significantly improve the manifestations of OSA, but adherence and inconsistent use of the CPAP device is an issue for many patients. Patients may discontinue use of CPAP because of a sensation of claustrophobia, discomfort exhaling against air inflow, or dryness and skin irritation. Some patients who are unable to tolerate use of CPAP may be able to use a bilevel positive airway pressure (BPAP) machine (Hess et al., 2021; MFMER, 2020b). BPAP adjusts the air pressure delivered, providing more pressure when the patient inhales and less when the patient exhales. The decreased expiratory pressure may make exhalation more comfortable than with CPAP (Hess et al., 2021).

Mild OSA can be managed with a custom-made oral appliance (OA) that is used to enlarge the oropharynx by either advancing the mandible or keeping the tongue in a forward position (Hess et al., 2021). These hard, plastic devices are fitted by a dentist or orthodontist based on a mold of the patient's mouth. If a person is unable to tolerate CPAP, an OA is an alternative treatment, but OA are not considered first-line therapy for severe sleep apnea (Hess et al., 2021). OA may also be used with CPAP.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

If medical treatment methods fail, several surgical procedures may be suggested to manage sleep apnea. Surgery is not without risks and poses significant postoperative issues for the patient. People who opt for these procedures need continued support and comprehensive teaching, including coping strategies, for the immediate postoperative period.

Pediatric OSA is a sleep disorder in which a child's breathing is partially or completely blocked repeatedly during sleep due to a narrowing or blockage of the upper airway during sleep. OSA (pediatric) is defined by the presence of one of these findings: snoring, labored/obstructed breathing, **enuresis** (urinating during sleep), or daytime consequences (hyperactivity or other neurobehavioral problems, sleepiness, fatigue) (American Academy of Sleep Medicine, 2014). Unlike adults, children with OSA are more likely to have behavioral problems than daytime sleepiness (MFMER, 2020a). A common underlying cause in children is enlargement of the adenoids and tonsils (MFMER, 2020a; Nierengarten, 2018). Obesity/overweight is also a risk factor in children as well as increased risk in children with neuromuscular disease, craniofacial dysmorphology, and certain genetic syndromes (Nierengarten, 2018).

Children and adolescents with symptoms of OSA, including snoring, should have a physical examination, polysomnography, overnight oximetry, and an electrocardiogram to confirm diagnosis (MFMER, 2020a; Marcus et al., 2012). Severe complications affecting a child's growth, cognitive development and behavior can occur if this disorder is untreated or ignored (MFMER, 2020a). Options for treatment in children include weight loss if obesity is present, adenotonsillectomy (removal of tonsils and adenoids), CPAP, BPAP, oral appliances, or intranasal corticosteroids (Marcus et al., 2012; MFMER, 2020a).

Central Disorders of Hypersomnolence

These disorders are characterized by excessive daytime sleepiness (hypersomnolence) that is not attributable to another sleep disorder, specifically those that result in disturbed sleep (e.g., sleep-related breathing disorders) or abnormalities of circadian rhythm (American Academy of Sleep Medicine, 2014).

Idiopathic **hypersomnia** is characterized by constant or recurrent episodes of extreme sleepiness, particularly during the day. A person may sleep for 10 or more hours at night and take naps during the day and still feel sleepy (NSF, n.d.). When they awake, they are often disoriented, irritated, restless, and have slower speech and thinking processes. Some people may have a genetic predisposition to hypersomnia. It appears most often in adolescents and young adults. Although not usually life threatening, hypersomnia can have some serious consequences, such as motor vehicle accidents that occur because of drowsiness or falling asleep while driving. These attacks may occur indefinitely (NSF, n.d.).

Treatment of hypersomnia is symptomatic in nature. Stimulant drugs may prove effective, or in some cases, antidepressants may be prescribed. Attention to diet (avoidance of alcohol and caffeine) and behavioral changes (avoidance of night work and social activities later in the evening) may offer some relief from such episodes. Additional interventions may include encouraging naps whenever possible and maintenance of a regular sleep schedule (NSF, n.d.).

Narcolepsy is a chronic neurologic disorder characterized by excessive daytime sleepiness and frequent overwhelming urges to sleep or inadvertent daytime lapses into sleep. Some people with narcolepsy also experience cataplexy, the sudden, involuntary loss of skeletal muscle tone lasting from seconds to 1 or 2 minutes (Norris, 2019). Additional symptoms include the presence of hallucinations or sleep paralysis (National Institute of Neurological Disorders and Stroke [NINDS], 2019b). A person with narcolepsy can literally fall asleep standing up, while driving a car, in the middle of a conversation, or while swimming. People with narcolepsy tend to fall asleep quickly, find it difficult to wake up, sleep fewer hours than others, and sleep restlessly. Symptoms usually appear in susceptible people during adolescence or early adulthood and are usually lifelong; symptoms may improve with treatment but never completely resolve (National Heart Lung and Blood Institute [NHLBI], n.d.a.; NINDS, 2019b).

Narcolepsy is caused by the brain's inability to regulate sleep–wake cycles and may have a genetic component (NINDS, 2019b; Norris, 2019). Many people with narcolepsy have been shown to have an unusually high rate of a specific human leukocyte antigen subtype and low hypocretin level has also been shown to be a possible contributor (NHLBI, n.d.a; Norris, 2019). Hypocretin is a neurotransmitter in the brain that causes alertness and wakefulness. It is unknown at this time what causes this low hypocretin level (American Academy of Sleep Medicine, 2014). Undiagnosed, a person with narcolepsy is potentially dangerous to self and others. In some countries, a person with a diagnosis of narcolepsy is not permitted to drive a motor vehicle. A sleep study is important to confirm the diagnosis of narcolepsy. At present, there is no cure. However, medications that restore alertness allow near-normal functioning for most patients.

A central nervous system stimulant (e.g., modafinil) that causes wakefulness may be used to control narcolepsy. Additional medications such as methylphenidate (a stimulant) and tricyclics and SSRI (antidepressants) have proved effective in treating narcoleptic symptoms (NINDS, 2019b). People using such drugs should take them faithfully because with discontinuation of use, the uncontrollable desire to sleep returns. In addition to medications, behavioral therapies should be implemented to help to control the symptoms of narcolepsy (NINDS, 2019b).

Circadian Rhythm Sleep–Wake Disorders

Circadian rhythm sleep–wake disorders are characterized by a chronic or recurrent pattern of sleep–wake rhythm disruption primarily caused by an alteration in the internal circadian timing system or misalignment between the internal

circadian rhythm and the sleep–wake schedule desired or required; a sleep–wake disturbance (e.g., insomnia or excessive sleepiness); and associated distress or impairment, lasting for a period of at least 3 months (except for jet lag disorder) (American Academy of Sleep Medicine, 2014; Wilson et al., 2019). There are several disorders within this group of sleep disorders, with the most common being shift-work disorder and jet-lag disorder.

Shift-work disorder results from working on a schedule outside the traditional daytime workday (9:00 AM to 5:00 PM) that goes against the body's natural circadian rhythm (Cleveland Clinic, 2017a; Pacheco, 2020a). A constant or recurrent pattern of sleep interruption caused by difficulty adjusting to the different sleep and wake schedule results in excessive sleepiness during work and insomnia when trying to sleep between shifts (Wilson et al., 2019). Other symptoms may include ongoing tiredness, general feeling of discomfort or uneasiness, mood disorder, GI problems, and decreased sex drive (Cleveland Clinic, 2017a). Many industries and other occupations and professions rely on shift work, including nursing. The work schedule of shift workers may prevent attainment of sufficient sleep (Pacheco, 2020a). Shift workers are more likely to sleep fewer than 6 hours on workdays and experience drowsy driving at least once a month (Pacheco, 2020a). Not all shift workers experience sleep issues, but approximately 10% to 40% of shift workers experience symptoms of the disorder, including excessive sleepiness or insomnia (Cleveland Clinic, 2017a). In addition, shift work has been linked to problems with physical and mental health, performance, accidents, work-related errors, increased irritability or mood problems, and safety (Cleveland Clinic, 2017a; Nena et al., 2018; Pacheco, 2020a; Weaver et al., 2018).

Jet-lag disorder results from a conflict between the pattern of sleep and wakefulness between the internal biologic clock and that of a new time zone (Cleveland Clinic, 2020). This temporary disorder occurs as a result of travel across two or more time zones, producing difficulty adjusting and functioning optimally in the new time zone. Symptoms of jet lag include general tiredness, difficulty staying alert, an unwell feeling or discomfort, mood disturbance, and a change in appetite and other GI function (Cleveland Clinic, 2020; MFMER, 2020c).

Treatment for circadian rhythm sleep–wake disorders varies based on the type of disorder and the degree to which it affects a person, and usually includes a combination of interventions. Behavior therapy includes maintaining regular sleep–wake times, avoiding naps, keeping to a regular exercise routine, and avoiding caffeine, nicotine, and stimulating activities within several hours of bedtime (Cleveland Clinic, 2020). Light therapy helps ease the transition to a new schedule or time zone. It involves exposing the patient's eyes to an artificial bright light that simulates sunlight for a specific and regular amount of time during the time the person should be awake; exposure to sunlight can also be used to regulate the sleep–wake cycle (Cleveland Clinic, 2020; MFMER, 2020c; Wilson et al., 2019). Chronotherapy requires a commitment on the part of the patient to act over a period of weeks to progressively advance or delay the time of sleep for 1 to 2 hours per day. Over time, this results in a shift of the sleep–wake cycle (Cleveland Clinic, 2020). Medications such as melatonin (Wilson et al., 2019), modafinil (stimulant) or caffeine may also be used to adjust and maintain the sleep–wake cycle (Cleveland Clinic, 2020; MFMER, 2020c).

Parasomnias

Parasomnias are episodes or behaviors that occur during arousals from REM sleep or partial arousals from NREM sleep that disturb the patient or others (Cleveland Clinic, 2017b; Wilson et al., 2019). Parasomnias occur in both children and adults but are more common in children (DePietro, n.d.). Although parasomnias are commonly outgrown before adulthood, safety and prevention of injury are paramount concerns. These sleep disorders can occur rarely or on a regular basis. Examples of parasomnias include:

- ***Somnambulism*** or *sleepwalking* may range from sitting up in bed to walking around the room or the house to walking outside the house. The automatic behavior can also include behaviors which are very familiar to the patient, such as dressing, washing, or arranging objects in the house (Wilson et al., 2019). The sleepwalker is unaware of his environment and is unresponsive to other people.
- *REM Sleep Behavior Disorder (RBD)* is characterized by dramatic "acting out" and/or violent dreams during REM sleep (Cleveland Clinic, 2017b). While experiencing the dream episode, the sleeper can moan and thrash around in the bed, possibly causing harm to a bed partner or themselves (Wilson et al., 2019).
- *Sleep terrors/night terrors* are more common in children and occur during the deepest stages of sleep. Typical behavior involves waking up screaming, signs of intense fear, sitting up in bed accompanied by increased heart rate or breathing, sweating, and being unresponsive to comforting (Cleveland Clinic, 2017b; Wilson et al., 2019). They may appear to be awake and reasonable but are unable to communicate when they awaken from a sleep terror.
- *Nightmare disorder* involves frightening dreams that are vivid and disturbing. They occur more frequently in children and represent a normal developmental process.
- *Sleep enuresis* is urinating during sleep or bedwetting. Primary bedwetting occurs when a child at least 5 years old has never regularly stayed dry during sleep for 6 straight months (Pacheco, 2020b). It is more common in males. Secondary bedwetting occurs when a child or adult had earlier stayed dry for at least 6 straight months and then began bedwetting at least twice a week for a period of at least 3 months (American Academy of Sleep Medicine, n.d.). Secondary bedwetting can occur at any age and may be related to other health issues, such as a urinary tract problem, chronic constipation, OSA, social or psychological stress, or inability to concentrate urine, as in sickle cell disease or some forms of diabetes (American Academy of Sleep Medicine, n.d.). Children with secondary bedwetting have often recently faced a strong social or mental stress, such as parental divorce, physical or sexual abuse, or neglect (American

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

Academy of Sleep Medicine, n.d.).

- *Sleep paralysis* is a brief state of involuntary immobility occurring on waking from a night's sleep or a nap, and may be accompanied by dreams (which may be of a frightening kind) (Wilson et al., 2019).
- *Sleep-related eating disorder* occurs when a person eats and drinks while sleeping but has no recollection of eating in the morning. It can occur during sleepwalking, and those affected can gain weight and experience injury either from cooking in their sleep or eating potentially dangerous raw food or inedible or toxic substances, such as coffee grounds, cleaning solutions or cigarette butts (Cleveland Clinic, 2021). They may not be easily awakened or redirected during an episode and may exhibit signs of sleep disruption during waking hours.

There is little good evidence for treatment of parasomnias (Wilson et al., 2019). Parasomnias may be treated by improving sleep habits, including maintaining a regular sleep schedule; good sleep hygiene, and obtaining an adequate amount of sleep. Medication may be used to control symptoms based on the frequency and severity of the events (Wilson et al., 2019). It is important to safeguard against harm to the patient; locking of window and doors and sleeping on the ground floor may be considered. Interventions to increase the safety of a bed partner and children in the home should be considered as well (Wilson et al., 2019).

Sleep-Related Movement Disorders

There are several sleep-related movement disorders, which are characterized by physical movements during sleep. These movements may be irresistible or involuntary, occur during sleep or periods of rest and frequently result in insomnia and daytime fatigue (Kaiser Permanente, n.d.a). Some of the disorders in this group include sleep-related leg cramps and bruxism (grinding or clenching of the teeth), and restless legs syndrome (Kaiser Permanente, n.d.a).

Restless legs syndrome (RLS), also known as Willis–Ekbom disease (WED), is a common sleep-related neurologic disorder that affects approximately 7% to 10% of the people in the United States, including children and adults (NSF, 2020d; Restless Legs Syndrome Foundation, 2020). Abnormalities in the neurotransmitter dopamine have been associated with RLS (CDC, 2020). RLS involves involuntary movement of the legs when the body is at rest (NSF, 2020d). Patients with RLS cannot lie still and report unpleasant creeping, crawling, itching, aching, burning, throbbing, pulling, or tingling sensations and pain and discomfort in the legs (NSF, 2020d; RLS Foundation, 2020. Occasionally, RLS can occur in the arms, face, or torso. Patients describe an irresistible urge to move the legs when these sensations occur, usually during the evening and night, which may lead to kicking and/or the need to move around or pace, resulting in loss of sleep (CDC, 2020). Symptoms usually affect both sides of the body but can alternate between the left and right leg or occasionally occur only on one side of the body (NSF, 2020d). Women are at greater risk of having RLS, although both men and women can develop the condition, and it can begin at any age; research indicates that there is a genetic component to the disorder (NSF, 2020d). Additional risk factors include the use of antinausea medications and antidepressants, iron deficiency, renal disease, nerve damage, pregnancy, and rheumatoid arthritis or osteoarthritis. The use of alcohol, nicotine, and caffeine may also increase the risk for RLS (NSF, 2020d). This disorder has no specific diagnostic test and no known cure.

Nonpharmacologic measures to prevent or alleviate this discomfort include massaging the legs, walking, doing knee bends, and moving or gently stretching the legs. Research continues into additional treatment options, but the following may prove effective (Klingelhoefer et al., 2016):

- Avoiding high intake of caffeine and alcohol before bedtime
- Promoting good sleep habits (quiet, comfortable, cool sleeping environment; keeping regular bed and wake hours)
- Walking and stretching, massaging the affected limbs
- Using relaxation techniques; biofeedback and yoga may also relieve symptoms (see the accompanying Promoting Health Literacy display on page 1316).

Several medications may be used if symptoms are clinically significant with associated impairment of nighttime sleep, daytime alertness, and quality of life (Klingelhoefer et al., 2016). Medication to help correct the underlying dopamine abnormality combined with medication to promote sleep continuity may be prescribed (CDC, 2020). In general, the dosage is kept as low as possible and is administered as a single dose in the evening; medications recommended to treat RLS include ropinirole, pramipexole dihydrochloride, gabapentin enacarbil, and rotigotine transdermal system (Klingelhoefer et al., 2016). The Restless Legs Syndrome Foundation (http://www.rls.org) is a support group available for the millions of people with this disorder who experience chronic sleep loss.

Sleep Deprivation

Sleep deprivation describes the cumulative effect of a person not having sufficient sleep, a decrease in the amount, consistency, or quality of sleep. It may result from decreased REM sleep or NREM sleep. There are many causes, including the presence of a sleep disorder, such as insomnia, sleep apnea, or RLS, inadequate sleep behaviors, and insufficient total sleep time (Refer to the discussions related to common sleep disorders in this chapter). Manifestations of sleep deprivation progress from irritability and impaired mental abilities to a total disintegration of personality. Sleep deprivation may result in daytime fatigue and decreased alertness; impaired learning, focusing, memory, and reactions; trouble controlling emotions and behavior; difficulty interpreting other people's emotions and reactions; and feelings of

worry, frustration, and anxiety (NHLBI, n.d.b). Children who are sleep deficient may have different reactions of deprivation, with resulting over activity, behavior issues, and difficulty paying attention as well as mood swings, anger, impulsivity, or lack of motivation (NHLBI, n.d.b). Sleep deficiency is associated with increased risk of injury, such as automobile accidents and fatalities, aviation accidents, and accidental falls and related fractures (NHLBI, n.d.b).

Partial sleep deprivation may result in loss of concentration, inattention, and impaired information processing, and poses serious safety risks. Excessive daytime sleepiness, a form of partial sleep deprivation, impairs performance at times when people need to be alert. The strange environment of the hospital, physical discomfort and pain, the effects of medications, and the need for 24-hour nursing care may also contribute to sleep deprivation in hospitalized patients (Delaney et al., 2018; Grimm, 2020).

Promoting Health Literacy

IN PATIENTS WITH RESTLESS LEGS SYNDROME

Patient Scenario

Mary Weymouth is a 40-year-old person who has an appointment to see her primary health care provider because of a "strange sensation in her legs that is keeping her awake at night." When asked by the nurse to further describe her symptoms, Mary explains that she has this feeling that "something is crawling up her lower leg." She keeps moving her leg from side to side until she finally just gets out of bed and walks around for a while. She states that movement seems to "make it better" but this does not work all the time. Sometimes, she also gets "pretty severe cramping pain" that can last several hours. Mary relates that this has been happening 2 or 3 nights a week for at least 1 month and she finds that she is "very sleepy" the following day. At times when she is at work, she said that she finds herself starting to "nod off" and is afraid that someone might notice, and she could lose her job. She's tried drinking a few glasses of wine at night to relax her and has also occasionally taken "some Tylenol PM" to see if that will help her sleep through the night. Nothing seems to help. After the health care provider examined Mary, he asked if anyone in her family had similar symptoms. Mary remembered that her mother used to tell her that she sometimes had "nervous legs" at night. The health care provider reviews her history and tells Mary that her symptoms indicate that she has restless legs syndrome (RLS). At this time, he prefers not to prescribe medication for her but wants her to try some nonpharmacologic measures to see if they ease her symptoms. As Mary is making another appointment, she tells the nurse that "she doesn't know how much longer she can manage without a good night's sleep most nights. I may just have to give Tylenol PM another try."

Nursing Considerations: *Tips for Improving Health Literacy*

Provide Mary with some specific information about measures that may ease her symptoms of RLS and allow her to get a restful sleep. Recommend that she avoid alcohol, caffeine, and any OTC sleeping medications because they contain antihistamines that may aggravate the symptoms of RLS. Encourage her to participate in and incorporate into her daily life regular, moderate physical activity to promote better sleep at night. Explain to Mary that there is no specific diagnostic test for RLS, but if her symptoms are not relieved by these other measures, there is medication that the health care provider might prescribe. Also, give her information about the online resource that is specifically for patients with RLS. When Mary returns for her follow-up appointment, she needs to be prepared to ask her health care provider the following questions:

- What is my main problem? Can anything else be associated with RLS?
- What else do I need to do?
- Why is it important for me to do this?
- What can you do if you prescribe a medication, but it does not help with my symptoms?

What additional measures can you take to help increase health literacy in this patient? What other measures would be helpful if Mary did not speak English, could not read, or had other learning deficits?

As mentioned earlier in this chapter, recent research has indicated the possibility of a causal relationship between sleep deprivation and obesity, altered healing, depression, diabetes, and cardiovascular conditions. However, sleep deprivation clearly produces changes in physical and mental functioning, supporting the belief that sleep is essential for well-being. Whether it occurs as a result of a disorder or is due to voluntary sleep curtailment, sleep deprivation has wide-ranging negative consequences for human health and well-being (American Sleep Association [ASA], n.d.a). See also the earlier section, Physical and Psychological Effects of Insufficient Sleep.

The primary treatment of sleep deprivation is to increase total sleep time (ASA, n.d.a). Interventions are directed at the cause of deprivation for the individual patient and should also address improving sleep habits. Daytime naps may be

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

beneficial but should be limited to earlier in the afternoon and, for adults, be no longer than 20 minutes to avoid troubles falling asleep at night (NHLBI, n.d.b). Napping in preschool-age children is normal and promotes healthy growth and development (NHLBI, n.d.b). Refer to the discussion of interventions to promote rest and sleep in the following sections.

Recall **Charlie Bitner**, the long-term care facility resident complaining of sleep problems. From the patient's statements, the nurse would identify that Mr. Bitner is at risk for developing sleep deprivation. Therefore, the nurse would work with Mr. Bitner to establish measures that would promote effective sleep patterns.

Unfolding Patient Stories: Edith Jacobson • Part 2

Recollect Edith Jacobson from Chapter 31, who is 85 and hospitalized for surgical repair of a left hip fracture. Are risk factors present for her to develop disordered sleep patterns or a lack of adequate sleep? How can insufficient sleep affect her physical and psychological health? What nursing interventions can promote adequate rest and sleep while Edith is hospitalized?

Care for Edith and other patients in a realistic virtual environment: *vSim for Nursing* (thepoint.lww.com/vSimFunds). Practice documenting these patients' care in DocuCare (thepoint.lww.com/DocuCareEHR).

NURSING PROCESS FOR REST AND SLEEP

Assessing

Sleep status can have a significant impact on health and a patient's ability to cope with illness. Nursing assessment of a patient's sleep and rest habits and status includes pertinent patient history and physical assessment. Sleep studies may be prescribed by an advanced practice professional and completed as part of the data collection process.

Rest and Sleep Nursing History

Health care providers in all settings should incorporate questions about sleep into routine health assessment. Interview questions help identify the patient's sleep–wakefulness patterns, the effect of these patterns on everyday functioning, the presence of factors that may be affecting the patient's sleep, the patient's use of sleep aids, and the presence of sleep disturbances and contributing factors. If the patient's sleep is adequate and poses no problems, the sleep history may be brief. At a minimum, ask the following questions of a patient (Weber & Kelley, 2018:

- Do you feel you are getting enough sleep?
- Do you feel rested when you awaken?
- How much sleep do you get each night?
- What do you do to help you fall asleep?
- Do you find it difficult to stay awake during the day?

When the patient's response to any of the interview questions indicates a potential problem, open-ended questions may be used to gather more data (Focused Assessment Guide 35-1).

Assess the patient's usual times for retiring and waking, bedtime rituals, and preferences regarding sleep

environment so that these can be incorporated into the plan of care, if possible. Patients in hospitals or other care facilities often receive fragmented sleep. Their sleep may be disrupted by routine care measures, noise in the environment, and lighting (see the accompanying Nursing Advocacy in Action display). Paying attention to small matters can make the difference between a patient's having a good night of sleep or no sleep.

Focused Assessment Guide 35-1

REST AND SLEEP

Factors to Assess	Questions and Approaches
Usual sleep–wakefulness pattern: Recent changes	Do you set an alarm and hit "snooze" before getting up? How many hours of sleep do you usually get in a day?
Usual sleeping and waking times	Do you wake up earlier in the morning than you would like and find it difficult to fall back asleep? Have there been any recent changes in your usual sleep–wake patterns? If yes, describe them and tell me if they are causing any problems for you. Do you usually go to bed and wake up about the same time each day?
Number of hours of undisturbed sleep	How have you been sleeping? Do you have any difficulty falling asleep? Do you wake up frequently during the night? Do you dream at night? Are your dreams frightening?
Quality of sleep	How much sleep do you think you need to feel rested?
Number and duration of naps	Do you take naps throughout the day?
Effect of sleep pattern on everyday functioning	In what way does the sleep you get each day affect your everyday living? Has this sleep disturbance caused any change in your sex life?
Energy level (ability to perform activities of daily living)	Do you feel rested and ready to start the day when you wake up? Are there times during the day or certain activities when you feel especially tired? What happens when you don't get enough sleep? Are you having difficulty concentrating?
Sleep aids	What do you do to relax before you get ready for bed?
Means of relaxing before bedtime	Describe what you usually do to help yourself fall asleep.
Bedtime rituals Sleep environment	Tell me how you like your room (lights, noises, ventilation, position of door, temperature) and bed (mattress, pillows, blankets) when you are sleeping.
Pharmacologic aids	Do you take any medications to help you sleep? Are you taking any medicine at all?
Sleep disturbances and contributing factors	Tell me about your sleep problem.
Nature of the sleep disturbance	How often does it occur?
Onset of disturbance	Are you doing anything differently now that might be causing the problem?
Causes (physical, psychosocial, medicine related)	Do you wake up gasping for air? Do you snore?
Severity	Do you recall changing your position frequently during the night?
Symptoms	What have you been doing to deal with the problem?
Interventions attempted and results	How effective were these measures?

Nursing Advocacy in Action

PATIENT SCENARIO

Maria was born premature. After surgery on her bowel, she was placed on the transplantation list for a new liver and small bowel and started on total parenteral nutrition. She is now 9 months old but has spent the last 4 weeks in the hospital with fungemia, a fungus infection spread throughout the bloodstream. Her single mother, Ms. Gomez, practically lives at the hospital and in recent days has annoyed the nurses with her complaints about the nursing care. Her English is limited, but she is able to express her annoyance at the many times Maria is awakened during the night for treatment and care. "Why can't the nurses do several things at once so Maria can at least get a few hours of uninterrupted sleep?!" Recently the nurses complained to the medical director, and he informed Ms. Gomez that if she doesn't stop interfering with Maria's care, the doctors will take Maria off the transplantation list. The nurse giving you the report repeats this story and tells you "not to take any complaints or grief from the mom." When you meet Ms. Gomez and listen to her story, you admire her love for Maria and willingness to advocate for her. You also sense the mother's frustration with the system. She asks you tearfully, "They can't take Maria off the list, can they? I am only trying to be a good mother." Ms. Gomez appears to have no family or other support network.

IMPLICATIONS FOR NURSING ADVOCACY

How would you respond if you were the nurse assigned Maria as a patient? Talk with your classmates and experienced nurses about the questions that follow.

- Is it fair to say that Ms. Gomez is being threatened for trying to advocate for her baby? If you elect to

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

advocate for Maria and her mother, what practical steps can you take to remedy this situation?
- What is it reasonable to expect of a student nurse, graduate nurse, and an experienced nurse in this situation?
- What advocacy skills are needed to effectively respond to this challenge?

When a sleep disturbance is noted, ask about the following when obtaining the history:

- The nature of the problem
- The cause of the problem
- The related signs and symptoms
- When the problem began and how often it occurs
- How the problem affects everyday living
- The severity of the problem and whether it can be treated independently by nurses or needs to be referred to another health care professional
- How the patient is coping with the problem and the success of any treatments attempted

Think back to **Lydia Omeara**, the mother of twin infants who was asking about allowing the infants to sleep in their parents' bed. The nurse would need to obtain a sleep history from Mrs. Omeara to ascertain both her and her husband's sleep patterns. This information would be helpful in assisting Mrs. Omeara and her husband in making a decision about allowing the children to sleep in their parents' bed.

Assistance from the patient's bed partner may be needed to aid in data collection and provide more accurate information regarding the patient's sleep patterns. The patient's record may also contain pertinent information (e.g., a history of illnesses that influence sleep).

Sleep Diary

A sleep diary or log provides more specific data on the patient's sleep–wakefulness patterns over a period of time. It is completed over a period of time and provides information and insight about these patterns, possibly indicating activities and behaviors that affect the quality and quantity of sleep. In general, the diary is kept for 1 or 2 weeks and typically includes the total number of hours of sleep per day, the number of undisturbed hours of sleep, number of awakenings, and other details (Ibáñez et al., 2018). There are many versions of sleep diaries, and the information to be documented may include:

- Time patient retires
- Time patient tries to fall asleep
- Approximate time patient falls asleep
- Time of any awakenings during the night and when sleep was resumed
- Time of awakening in the morning
- Presence of any stressors the patient believes are affecting their sleep
- A record of any food, drink, or medication the patient believes has positively or negatively influenced their sleep (include time of ingestion)
- Record of physical activities—type, duration, and time
- Record of mental activities—type, duration, and time
- Record of activities performed 2 to 3 hours before bedtime, bedtime rituals, changes in sleep environment
- Presence of any worries or anxieties the patient believes are affecting their sleep

Sleep diaries are also available as mobile apps (Ibáñez et al., 2018) and offer the advantage of reducing the time needed for data entry and scoring (Tonetti et al., 2016).

It is helpful if the patient has a bed partner who can assist with the diary. The patient needs to understand that the diary is simply a diagnostic tool. If keeping the diary causes too much stress for the patient and further interferes with

the ability to sleep restfully, it should be discontinued. A sample diary is available from the National Sleep Foundation.

Remember **Jeanette Clark**, the mother of the adolescent girl who seems to be sleeping all the time. Having Mrs. Clark's daughter complete a sleep diary might be helpful in obtaining a better picture of what is happening and helping rule out other causes for the daughter's increased fatigue and sleeping. These underlying causes could be wide ranging, including such conditions as depression, physical illness, or increased activity or schoolwork.

Sleep Screening Tools

There are additional questionnaire screening tools that can be used to assess sleep disturbances and the quality of sleep. Some examples include:

- Epworth Sleepiness Scale
- Pittsburgh Sleep Quality Index (PSQI)
- STOP-Bang Questionnaire (OSA)
- Stanford Sleepiness Scale

Physical Assessment

The findings in the physical assessment may either confirm that the patient is getting sufficient rest to provide energy for the day's activities or validate the existence of a sleep disturbance that is decreasing the quantity or quality of sleep. Key findings include energy level (presence of physical weakness, fatigue, lethargy, or decreased energy), facial characteristics (narrowing or glazing of eyes, swelling of eyelids, decreased animation), or behavioral characteristics (yawning, rubbing eyes, slow speech, slumped posture). Physical data suggestive of potential sleep problems (e.g., obesity, enlarged neck, deviated nasal septum) may also be noted.

If the nurse or a bed partner can observe the patient sleeping, other sleep characteristics to assess include restlessness, sleep postures, and sleep activities such as snoring or leg jerking (RLS). Snoring is caused by an obstruction to airflow through the nose and mouth. Other than disturbing others in the same bedroom, snoring is not ordinarily a sleeping disorder. However, loud snoring or snoring accompanied by apnea can present a problem. When snoring changes from the characteristic sawing-wood sound to a more irregular silence followed by a snort, this indicates obstructive apnea. As mentioned earlier in the discussion of obstructive sleep apnea (OSA), snoring in children needs to be evaluated as a possible indication of OSA.

Additional Methods to Assess Sleep

There are several medical examinations and testing that can be done at a sleep clinic to assess sleep, sleep breathing, and sleep brain patterns to aid in evaluating sleep disturbances (Weber & Kelley, 2018).

The most used device to self-assess sleep is the smartphone (Ibáñez et al., 2018). Smartphones contain a microphone, camera, and an accelerometer (detects motion and determine tilt of the phone), and these features can be used to monitor sleep. As a result, many mobile apps have been developed and made available to assess sleep and support sleep self-management. Expert reviews have been completed and report high performance and reliability of these apps, but there is a lack of scientific validation studies to support clinical value and use (Choi et al., 2018; Ibáñez et al., 2018).

Diagnosing Actual or Potential Health Problems and Needs

An assessment of a patient's rest and sleep status may lead to the identification of one or more actual or potential health problems and needs related to rest and sleep. Following the formulation of the actual or potential health problems and needs, the nurse communicates findings to other nursing and health care professionals through the use of written and spoken word. The written actual or potential health problem or need becomes a permanent part of the patient's health record. Examples of health problems and needs with related etiology and signs and symptoms can be found in the Examples of Actual or Potential Health Problems and Needs: Rest and Sleep on page 1320.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

Outcome Identification and Planning

Rest and sleep are essential components of well-being. Planning for patient care, especially in a health care facility, involves planning and collaborating with the patient to identify suitable goals in relation to rest and sleep. Nursing measures are directed toward the achievement of the following patient outcomes. The patient will:

- Maintain a sleep–wake pattern that provides sufficient energy for the day's tasks
- Demonstrate self-care behaviors that provide a healthy balance between rest and activity
- Identify stress-relieving rituals that enable the patient to fall asleep more easily
- Demonstrate decreased signs of sleep deprivation
- Verbalize feeling less fatigued and more in control of life activities

Implementing

In most cases, sleep problems are not the primary reason for a patient's interaction with the health care system. A key to detecting a patient's sleep problems is the use of appropriate communication skills while displaying a nonjudgmental, caring attitude. Patients who believe the nurse is generally concerned about their well-being are not reluctant to discuss their sleep concerns or problems. In order to correct a sleep problem, the patient needs to believe that the nurse cares and will provide help to promote rest and sleep. Interventions that promote good sleep and sleep hygiene are important in maintaining health. **Sleep hygiene** is a set of behaviors or habits that may influence sleep quality (ASA, n.d.; Jansson-Fröjmark et al., 2019). Sleep hygiene involves the use of behaviors to facilitate sleep and avoidance of behaviors that interfere with sleep (Sleep Foundation, 2020d). Nursing care involves collaborating with the patient to identify suitable measures related to sleep hygiene and to promote rest and sleep.

Examples of Actual or Potential Health Problems and Needs

REST AND SLEEP

Actual or Potential Health Problems and Needs	Possible Etiologic Factors	Potential Signs and Symptoms
Impaired sleep	Worries about family and lack of destressing rituals	• "At least 4 or 5 nights a week, I lay in bed awake for 3 or 4 hours before I finally fall asleep. Sometimes it is 2:00 or 3:00 in the morning, and I'm still awake worrying about the kids. I've tried getting up and reading or paying my bills, but even that doesn't make me sleepy." • Reports problem falling asleep for past 6 months; is widowed and very concerned about two teenage sons. Never sleeps until both sons are home. States she does nothing special to relax. Feels her worries are "her business"—no support person with whom she shares these. • Reports lack of energy and fatigue, difficulty completing activities of daily living.
Risk for impaired sleep	Noise of hospital environment and need for periodic treatments Frequent naps Post-surgical pain	—
Sleep deprivation	Frequent rotations of work shifts and overtime Inadequate sleep hygiene	• New graduate nurse, 24 years old, who has been working on a busy medical floor for 6 months; rotates 11–7 and 7–3 shifts; recently a problem with staffing has necessitated frequent rotations and often volunteers (two or three times a week) for overtime.

• "I don't know what is wrong with me. I'm so tired anymore and don't feel at all like myself. All I want to do when I'm off is to sleep—but often I can't fall asleep when I lay down and often fall asleep when I should be awake. I can't concentrate. Please help!"

QSEN EVIDENCE-BASED PRACTICE

It is important for the nurse to be able to identify evidence reports and guidelines related to appropriate and effective interventions to promote rest and sleep to support patients' health and well-being.

Preparing a Restful Environment

A comfortable bed (mattress and pillow) helps promote rest and sleep. The bottom linen should be tight and clean. The upper linen, while secure, should allow freedom of movement and should not exert pressure, especially over the legs and feet. Good body alignment is conducive to relaxation. For patients who must assume unusual positions because of their illness, ingenuity and skill are necessary to minimize muscle strain and discomfort. For example, patients who must sleep with their head and torso elevated to aid breathing should be well supported in a manner that relieves muscle strain.

A quiet and darkened room with privacy and a comfortable temperature promotes relaxation (ASA, n.d.b; NHLBI, n.d.b). Light-blocking curtains and/or an eye mask may be helpful in preventing light from interrupting sleep (Sleep Foundation, 2020d). In a strange environment, unfamiliar noises may be sources of distraction. Although some of these sounds are difficult to control, make every effort to reduce disturbances and to promote relaxation and sleep. Ear plugs or a fan or other background noise may be helpful in blocking disturbing noises (ASA, n.d.b; Sleep Foundation, 2020d; Sleep Foundation, 2020c). Many health care facilities have made attempts to transform their patient care areas into quieter settings that facilitate rest and sleep. Refer to the discussion related to minimizing sleep disturbances in health care settings on p. 1322.

Focus on the Older Adult

AGE-RELATED CHANGES AND NURSING STRATEGIES FOR REST AND SLEEP

Age-Related Changes	Nursing Strategies
Initiation of Sleep	
• Decreased physical activities	• Encourage patient to engage in some type of physical activity, such as walking or water aerobics.
• Tired and fatigued throughout day • Depression • Polypharmacy	• Discourage napping throughout day. • Arrange for assessment for depression and treatment. • Review medications that patient is taking and assess for any side effects of sleep pattern disturbances.
Maintaining Sleep	
• Nocturia • Sleep-related movement disturbances (e.g., RLS)	• Decrease fluids during the evening. • Take diuretics in the morning or early evening. • Discuss problems with health care provider.

The temperature of the room, the amount of ventilation, and the amount of bed covering are matters of individual choice. Meet the patient's wishes when at all possible. Many older adults cannot sleep if they feel cold. Thermal blankets or comforters, insulated bed socks, cotton flannel sheets, leg warmers, long underwear, and a cap help patients stay warm and promote comfort and sleep. Refer to Focus on the Older Adult for additional suggestions.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

Recall **Charlie Bitner**, the older man living in a long-term care facility. The nurse would work with Mr. Bitner to ensure that his sleeping area is as comfortable and restful as possible. Making sure that he is warm enough, dimming the lights, closing the door (as appropriate), and minimizing disturbances outside his room would be key.

Promoting Bedtime Rituals

A comfortable pre-bedtime routine can promote good sleep (ASA, n.d.b). Many people have bedtime rituals to help them relax and promote sleep. Reading, listening to soft music, light stretching, relaxation exercises, talking to a family member, meditation or quite time, and praying are common before-sleep activities that can help put a person at ease and make it easier to fall asleep (ASA, n.d.b; Sleep Foundation, 2020d). Children may take a favorite doll, stuffed toy, or blanket to bed; listen to a bedtime story; kiss everyone good night; and say prayers before bed (Fig. 35-4). Readiness for sleep follows a personal hygiene routine for many people, such as brushing teeth, washing hands and face, voiding, or taking a warm bath or shower. Snacks are acceptable and are important elements in the bedtime rituals of many children and adults. Refer to the discussion below and to the previous discussion of dietary habits on page 1309.

FIGURE 35-4. A bedtime routine helps promote sleep in children.

To promote relaxation and sleep, be alert to the patient's bedtime rituals and observe them as much as possible. Include these rituals in the patient's plan of care so that all health personnel can observe them.

Teaching **Mrs. Omeara** about the importance of bedtime rituals for her twin infants may promote the children's sleep. In addition, the nurse would need to reinforce the need for Mrs. Omeara's bedtime rituals to ensure that the sleep she obtains is restful.

Offering Appropriate Bedtime Snacks and Beverages

A light snack is acceptable (NHLBI, n.d.b; Sleep Foundation, 2020d); going to bed hungry may interfere with sleep. As discussed earlier in the chapter, combining foods that are high in tryptophan with healthy, complex carbohydrates improves sleep (Binks et al., 2020; Sleep Foundation, 2020b). As a result, there appears to be justification for offering a snack that contains a protein and a carbohydrate before bedtime, if this is allowed in the patient's treatment regimen. Large, heavy or spicy meals within a few hours of bedtime may produce a bad night's sleep and should be avoided (NHLBI, n.d.b; Sleep Foundation, 2020d).

Recommend that the patient take fluids during the day but avoid excessive fluid intake before bedtime to prevent the need to use the bathroom during the night. Alcoholic beverages later in the evening should be avoided because they may interrupt the normal sleep cycle and interfere with deep sleep (Sleep Foundation, 2020b). For most patients, consumption of beverages containing caffeine should be reduced or avoided for at least 4 to 5 hours before bedtime; effects of caffeine can last as long as 8 hours (ASA, n.d.b; NHLBI, n.d.b; Sleep Foundation, 2020d).

Refer also to the previous discussion of dietary habits on page 1309.

Promoting Relaxation and Comfort

We can relax without sleeping but sleep rarely occurs until we are relaxed. Stress, anxiety, discomfort, and pain occur in relation to or as result of many health problems and interfere with a person's ability to relax, rest, and sleep. Numerous nonpharmacologic nursing interventions have been shown to be effective in alleviating stress and anxiety as well as pain and discomfort. A backrub, soft music, gentle noise, a warm bath, and face washing are nursing measures that may be used to help patients relax (Macnamara et al., 2018; Yeager, 2019). The use of guided imagery, visual imagery and aromatherapy have also been suggested as interventions to support relaxation, reduce pain, and improve sleep (Cheraghbeigi et al., 2019; Macnamara et al., 2018; Yeager, 2019). The technique for back massage is described in Skill 36-1 (on pp. 1377–1380). Nonpharmacologic interventions to aid in relaxation, and decrease discomfort and pain, including distraction and relaxation techniques, are described in Chapters 29, 36, and 43 and should be considered when planning nursing care to improve patient well-being and sleep.

Respecting Normal Sleep–Wake Patterns

A consistent sleep schedule, including sleep–wake regularity, is beneficial in achieving good sleep (ASA, n.d.b; Chung et al., 2018; Sleep Foundation, 2020d). Make every effort to allow patients to experience their normal period of sleep. In many instances, insisting that all patients retire and awaken at specific times is not necessary. For example, is there a good reason to wake a patient at 0700 if the patient ordinarily sleeps until 0800? The patient's normal napping habits should also be followed when possible. Sleep during morning naps consists primarily of light NREM and possibly REM sleep. Napping later in the evening when a person's sleep drive increases is comprised of more deep sleep, which may disrupt the person's ability to fall asleep at night (Pacheco, 2020c). With this knowledge, help patients plan napping periods that best fit their needs and interfere the least amount with nighttime sleeping. Additional information about napping is provided in the previous discussion related to sleep deprivation on page 1315.

Minimizing Sleep and Rest Disturbances in Health Care Settings

Factors associated with sleep disturbance in health care environments include light; noise made by health care staff, health care equipment/machines, and other patients; and care interactions (Delaney et al., 2018; Grimm, 2020; Hedges et al., 2019; Trossman, 2018). Studies have demonstrated that excessive noise on patient care units interferes with sleep and that these noise-related disruptions can increase patient anxiety, length of stay, and blood pressure; decrease oxygen saturation; increase pain and discomfort; diminish immune responses; and delay wound healing as well as having other negative effects (Crawford et al., 2018; Delaney, 2016; Reuter-Rice et al., 2020; Trossman, 2018; Wallis et al., 2019). Behavioral manifestations such as disorientation, restlessness, and irritability are also possible consequences, particularly in older adults (Hedges & Gotelli, 2020; Trossman, 2018). Patient surveys consistently report that noise and sleep deprivation are among the top concerns during admittance to a hospital or other health care facilities (Adatia et al., 2014; Anderson, 2012; Dobson et al., 2019; Fillary et al., 2015; Oleksy & Schlesinger, 2019). Environmental factors impacting a good night's sleep are not limited to acute care settings; residents in long-term care settings can encounter challenges in obtaining adequate sleep as well (Ellmers et al., 2013; Steiner et al., 2020). Although some of these sounds are difficult to control, make every effort to reduce disturbances and to promote relaxation and sleep. Many health care facilities have made attempts to transform their patient care areas into quieter settings that facilitate rest and sleep (Trossman, 2018; Winterbottom et al., 2020). Attention to design features with a focus on eliminating environmental noise, use of noise monitors, providing patients with private rooms, and formal quiet times (quiet hours) on units all are aimed at creating a more supportive environment that is conducive to good sleep (Hedges et al., 2019; Tabas et al., 2019; Winterbottom et al., 2020).

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

In an ICU and other settings, sleep is even further challenged by the level of light in the patient care areas as well as continuous exposure to light (Grimm, 2020; Trossman, 2018). Nighttime light can range from a level similar to that at twilight and peak at a level brighter than lighting in some television studios (Dave et al., 2015).

35-1 Focused Critical Thinking Guide

SLEEP

You have just arrived on the unit and checked your clinical assignment. You have two patients today and about 30 minutes before preconference. Your routine is to review their charts for pertinent information, go and introduce yourself to them, and take their morning vital signs before preconference. With 10 minutes to spare, you visit your second patient and find that he is sound asleep. Remembering that he had a fractured hip repaired 2 days ago and that the night nurse had stated in his note that the patient was restless and awake until 0400, you are reluctant to awaken him. On the other hand, at your midterm conference your instructor commented that you need to improve your organizational skills. If you don't have your vital signs recorded until after preconference, then breakfast arrives, doctors make rounds, and you're that much further behind in your morning care and documentation. When you look at the last set of vitals documented in the patient's EHR from midnight, you note the vital signs were within normal limits. You're attempting to reconcile several things—the importance of these morning vital signs, the patient's need for sleep, and your need to accomplish your tasks on time and receive a good evaluation. What should you do?

1. Identify goal of thinking

Determine whether it is more important to awaken your patient for morning vital signs or let him sleep at least until after your preconference.

2. Assess adequacy of knowledge

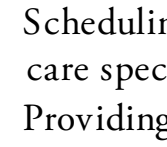
Pertinent circumstances: Your patient had major surgery 2 days ago, did not have a restful night, but is sleeping peacefully now. You realize that his vital signs can be an important indicator of a complication. You also need to accomplish your tasks in a timely and organized manner.

Prerequisite knowledge: To make your decision, you need knowledge about his postoperative condition and assessment data that indicate he is recovering or developing a complication. You are aware that sleep is vital to promote tissue repair, physical recovery, and mental well-being. You also need to review the tasks that you need to accomplish this morning and decide how and if priorities could be shifted.

Room for error/time constraints: Will a delay in taking vital signs cause injury to this patient? You are not planning to omit this task but just questioning whether to postpone it and allow the patient to have some additional sleep.

3. Address potential problems

Waking your patient for vital signs may be disturbing for him and interfere with his need for rest. A decision to postpone morning vital signs might also cause several problems. If the patient has developed a complication, such as an infection, his elevated temperature may go undetected for at least another hour. By the time you come out of preconference, the patient may be eating his breakfast, which further delays recording of vital signs. You perceive that you are already falling behind on your schedule and are really intent on completing your responsibilities on time today.



4. Consult helpful resources

Before you make your decision, you should check the patient's health record and note whether the previous set of vital signs were within normal limits. The primary nurse and your instructor may also help you sort through your priorities in this situation.

5. Critique judgment/decision

You have two choices here. If you wake your patient and take his vital signs, you are disturbing him when he is sleeping soundly, risking the fact that he may be angry with you, but you are on schedule for the day's activities. By postponing his vital signs at least until after postconference, you provide additional rest for the patient but know that you are already behind schedule and worry that your instructor will view you as disorganized. After reviewing your options and checking his EHR again, you decide to allow him to sleep and plan to take them as soon as possible after your preconference. During preconference, when your instructor reviews your priorities for the day, she comments positively that you have individualized care based on your particular patient's needs at the moment. In your mind, you determine that the vital signs are your next priority and will take minimal time, and you should still be able to complete care and documentation in a competent manner and on time.

The scheduled nursing care can also be a source of disturbances to a patient's ability to achieve rest and sleep (Lampron & Copeland, 2019). Many patients report being awakened to take sleeping pills and are roused in the early morning to prepare for breakfast long before it is served. Consider these common complaints when developing the patient's plan of care; whenever possible, schedule nursing care to avoid unnecessary disturbances and to promote rest and sleep. Provide care during periods when the patient is normally awake. When this is not feasible, avoid awakening the patient during REM sleep, when the rapid eye movements can be observed. Because a patient's need for sleep is important, examine priorities for nursing care with the goal of decreasing staff interruptions (Dobson et al., 2019; Graham et al., 2021). For example, consider whether checking a vital sign or carrying out a particular nursing measure is more important than the patient's sleep (refer to the Focused Critical Thinking Guide 35-1).

Technology Alert

A sleep headband that actively cancels exterior sounds has been developed for use with patients to decrease environmental noise and promote sleep. The headband monitors a patient's vital signs and wirelessly transmits results to a central nursing station. The device consists of thin headband with two earpieces, a small plastic case that contains a wireless transmitter, pulse oximetry and thermometer sensors, and an auxiliary jack to enable optional playing of music (Vincensi et al., 2016).

Nursing interventions to manage factors associated with sleep disturbances in the health care environment to facilitate rest and sleep for patients should be based on individual patient needs and preferences and include:

- Maintaining a brighter room environment during daylight hours and reducing patients' light exposure during the night (Grimm, 2020; Trossman, 2018; Winterbottom et al., 2020).
- Decreasing the volume on alarms, telephones, and limiting staff conversations (Goeren et al., 2018; Grimm, 2020; Oleksy & Schlesinger, 2019
- Closing doors to patient rooms (Antonio, 2020).
- Bundling of care, scheduling and grouping care activities together so as not to awaken or disturb patients multiple times for interventions that can safely be postponed for a short time (Dobson et al., 2019; Graham et al., 2021; Grimm, 2020; Trossman, 2018).
- Medicating for pain as indicated and prescribed (Dobson et al., 2019).
- Keeping the room cool and providing sheets and blankets to the patient's comfort level (Dave et al., 2015; Dobson et al., 2019).
- Scheduling a quiet time, a period of rest overnight, in which patients are not awakened unless their condition or care specifically requires it (Graham et al., 2021; Lampron & Copeland, 2019).
- Providing ear plugs and/or eye masks, if requested and as appropriate (Antonio, 2020; Tabas et al., 2019). See the accompanying Research in Nursing display.

Additional interventions to minimize noise levels have been implemented at some health care facilities. These initiatives include innovative use of communication technology to target noise reduction, and campaigns titled "Shhh" (Silent Hospitals Help Healing), "Hush" (Help Us Support Healing), and institution of "Quiet Time" (Goeren et al., 2018; Hedges et al., 2019). It is difficult to guarantee rest and a good night's sleep during admission to a health care facility but recognizing and listening to patients' concerns are critical to delivery of thoughtful person-centered care.

Research in Nursing

Bridging the Gap to Evidence-Based Practice

Earplugs and Eye Masks and Quality of Sleep in the Cardiac Care Unit

Sleep is essential for the well-being of a person. Many physiologic, psychological, and environmental factors contribute to sleep disruption for patients in health care settings, and particularly for patients in intensive care units (ICUs).

Related Research

Tabas, E. E., Khodadadi, F., Sarani, H., Saeedinezhad, F., & Jahantigh, M. (2019). Effect of eye masks, earplugs, and quiet time protocol on sleep quality of patients admitted to the cardiac care unit: A clinical trial study. *Medical Surgical Nursing Journal*, *8*(3), e98762. https://doi.org/10.5812/msnj.98762

This quasi-experimental study aimed to compare the impact of applying eye masks and earplugs and the implementation of a quiet time (QT) protocol on the sleep quality of patients in the cardiac care unit of a hospital. Patients who met the eligibility criteria (n = 135) were assigned to three groups (n = 45 each) based on admission to the CCU. Participants were sequentially assigned first to the control group (usual care), the eye mask and earplugs group, and then the QT protocol group. The subjects were studied over 3 days after admission. The morning after the first night, the participants' sleep quality was measured using the Verran and Snyder-Halpern Sleep Scale

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

(VSH). The VSH assesses the mental response of hospitalized adults to sleep and perceptions of the previous night's sleep, with questions divided into two domains: sleep effectiveness and sleep disturbance. On the second and third nights, the eye mask and earplugs and QT protocol were implemented for each group, respectively. The morning after the second and third nights, the participants' sleep quality was measured again. Results indicated the control group had scores indicating poor sleep quality, and the earplug and eye mask group had scores indicating decreased sleep disturbance and increased sleep efficacy. The mean score of sleep disturbance after the intervention was significantly different between the control and the two intervention groups (p = .001). The mean score of sleep efficacy was higher in the eye mask and earplugs group than the control group (p = .002). Patients' sleep quality improved after applying earplugs and using eye masks. Implementation of the QT protocol was effective in reducing sleep disturbance. The researchers concluded earplugs and eye mask are appropriate nonpharmacologic interventions to promote quality of sleep among CCU patients and nurses should use these tools to help reduce environmental factors which disturb patients' sleep.

Relevance to Nursing Practice

It is difficult to always completely control environmental factors in health care settings that may interfere with a patient's ability to sleep. Sleep is an important consideration in supporting patients' well-being and health. Nurses should consider strategies to incorporate into patient care to promote quality sleep. Earplugs and eye masks could be used as a sleep intervention for patients when appropriate.

Using Medications to Promote Sleep

Medications may be prescribed as part of the plan of care to address disturbances in sleep. A thorough health history, drug history, and sleep history, as well as assessment of stress and coping patterns and any underlying medical conditions, are required prior to the use of medications to induce or maintain sleep. The underlying cause for the sleep disturbance must be determined; nonpharmacologic interventions should be tried first or in combination with pharmacologic therapy (Adams et al., 2019; Singh, 2016). Refer also to the discussion in the previous sections, as well as the Insomnia and Teaching About Rest and Sleep sections on pages 1326 and 1327.

When sleep disturbances cannot be managed by other means, medications may be prescribed (pharmacotherapy) to be used in combination with other therapies and interventions (Neubauer et al., 2018). Medications approved for use to induce sleep and maintain sleep include benzodiazepine-receptor agonists, a melatonin-receptor agonist, a selective histamine-receptor antagonist, and an orexin/hypocretin receptor antagonist (Neubauer et al., 2018; Reynolds & Adams, 2019). There are some other non–insomnia-indicated medications that are sometimes prescribed "off label" for sleep enhancement and include antidepressants, anxiolytics, antipsychotics, and antihypertensives; however, these medications have not been evaluated for efficacy or safety in subjects with insomnia (Neubauer et al., 2018). The characteristics of the most commonly prescribed sleep aids are highlighted in Box 35-3. Use of medication to treat sleep disturbances in older adults should be limited if possible; when prescribed, medication use and adverse effects should be reviewed frequently (Reynolds & Adams, 2019). It is important for the nurse and patient to know and understand the action and potential adverse effects of any prescribed medication to ensure responsible administration.

Sleep medications are often prescribed on an as needed (PRN) basis. Administer these medications only when indicated and always with the full knowledge of their limitations. Provide thorough patient education about these medications. In addition, help patients develop other self-care strategies, including developing healthy sleep and lifestyle behaviors. Use alternative nonpharmacologic measures to promote sleep when appropriate. Over-the-counter (OTC) sleep medications most often contain antihistamines and should only be used on a short-term basis because of the potential for adverse effects and their lack of effectiveness over a lengthy time period (Neubauer et al., 2018).

Some patients use complementary health approaches (CHAs) that include melatonin or hypnotic herbs. Evidence suggests melatonin can be of assistance in addressing select circadian rhythm sleep–wake disorders, for which insomnia may be a primary symptom. However, evidence is conflicting in regard to the use of melatonin at bedtime for the treatment of insomnia (Neubauer et al., 2018; Reynolds & Adams, 2019). Hypnotic herbal therapies include valerian and Pacific valerian (Fontaine, 2019). Nervines are another type of herb that have a mild effect on sleep and include passionflower, lemon balm, skullcap, and gotu kola (Yarnell, 2015). Complementary therapies are also used in combination, such as melatonin, passionflower, and lemon balm, and have been shown to be effective in treating mild-to-moderate insomnia (Lemoine et al., 2019). Herbs and other complementary health approaches may offer ways to improve sleep; it is important to include questions about use of these agents as part of a nursing assessment related to sleep, as some patients may not consider OTC herbs or other CHAs to be medication.

Box 35-3 Commonly Prescribed Pharmacologic Sleep Aids

Pharmacodynamic	Generic Name	Indications	Potential Side

Category	Example Medication		Effects
Benzodiazepine receptor agonists, nonbenzodiazepines	zaleplon, eszopiclone, and zolpidem tartrate	Patients experiencing difficulty with sleep onset and maintenance, difficulty returning to sleep after awakening during the night	Somnolence, cognitive impairment, dizziness, fatigue, anterograde amnesia, parasomnias, confused behaviors Rebound insomnia may occur with abrupt discontinuation or intermittent use
Selective melatonin receptor agonist	ramelteon	Facilitates the onset of sleep but is not intended for sleep maintenance	
Orexin receptor antagonists	suvorexant	Insomnia characterized by difficulty with sleep onset and/or sleep maintenance	
Selective histamine receptor antagonist	doxepin	Patients experiencing difficulty with sleep maintenance	

Source: Neubauer, D. N., Pandi-Perumal, S. R., Spence, D. W., Buttoo, K., & Monti, J. M. (2018). Pharmacotherapy of insomnia. *Journal of Central Nervous System Disease*, *10*, 1–7. https://doi.org/10.1177/1179573518770672; Reynolds, A. C., & Adams, R. J. (2019). Treatment of sleep disturbance in older adults. *Pharmacy Practice and Research*, *49*, 296–304. https://doi.org/10.1002/jppr.1565

Remember **Charlie Bitner**, the older man living in the long-term care facility. Nonpharmacologic measures would be helpful to promote sleep. Having Mr. Bitner consume a warm beverage before bedtime, listen to soft music, or receive a backrub may promote relaxation, thereby eliminating the need for and/or enhancing the effectiveness of the prescribed sleep medication.

Teaching About Rest and Sleep

A well-informed person is better able to cope with distressing situations. Teach patients and their families about the nature of rest and sleep and their importance to well-being, as the lack of sufficient and/or quality sleep affects not just the brain, but also the entire body (see Physical and Psychological Effects of Insufficient Sleep).

Also teach patients about normal variations in sleep patterns and common measures to promote relaxation and sleep (Teaching Tips 35-1). Review the patient's lifestyle and environment to identify possible changes to enhance sleep hygiene. Sleep hygiene suggestions include the following:

- Restricting the intake of caffeine, nicotine, and alcohol, especially later in the day
- Avoiding mental and physical activities after 5 PM that are stimulating
- Avoiding daytime naps
- Eating a light carbohydrate/protein snack before bedtime
- Avoiding high fluid intake in the evening so as to minimize trips to the bathroom during the night
- Sleeping in a cool, dark room

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

- Eliminating use of a bedroom clock
- Taking a warm bath before bedtime
- Trying to keep the sleep environment as quiet and stress-free as possible

Stimulus-control therapy is a CBT and works to reassociate the bed with sleepiness instead of awakening. Stimulus control therapy involves using the bedroom for sex and sleep only (Chawla et al., 2018). People with insomnia who have problems initiating sleep should go to bed only when sleepy and stay in the bedroom for only 15 to 20 minutes. If after this time they cannot fall asleep, they should leave the room, do something relaxing until sleepy, and return only when they feel sleepy. Getting up at the same time every day, no matter what time the person fell asleep, and refraining from napping during the day are recommended (Chawla et al., 2018).

Sleep restriction is another CBT and is designed to eliminate prolonged middle of the night awakenings. Sleep restriction initially restricts the time spent in bed, with subsequent steps gradually increasing the time spent in bed, limiting the time in bed to actual sleep time (Stanford Health Care, n.d.). It is thought that excessive time in bed may result in fragmented sleep, which may exacerbate the insomnia. A sleep diary helps to determine sleep patterns (Kaiser Permanente, n.d.b). The focus of sleep restriction is to avoid naps and early bedtimes and actually change the way a person sleeps. The initial time in bed is usually the average nightly total sleep time over the past week, with the minimum time not less than 5 to 5.5 hours (Kaiser Permanente, n.d.b; Stanford Health Care, n.d.). For example, if the average sleep time for a person is 6 hours, the person should be in bed for only 6 hours; after a week or so, there will be a marked decrease in time spent awake in the middle of the night. Then, the time spent in bed is gradually increased by 15 to 30 minutes if wakefulness in the middle of the night remains minimal. Increases may occur at weekly intervals, as long as 85% of the time spent in bed is spent sleeping (Stanford Health Care, n.d.). The procedure continues until no further extension is necessary because the person is sleeping better at night and feeling good during the day (Kaiser Permanente, n.d.b).

Teaching Tips 35-1

REST AND SLEEP

Health Topic	Teaching Tip	Why Is This Important?
Activity	• Find an activity that can be done daily and involves physical exertion, such as walking. • Do not participate in any physical activities right before bedtime.	• Sleep is easier to obtain if some physical activity has been completed. • Many people find it hard to rest and sleep right after a physical activity.
Nutrition	• Avoid food, beverages, or over-the-counter (OTC) medications that contain caffeine in the evening. • Eat a light dinner. • Eat a light protein and carbohydrate-containing snack at bedtime if hungry.	• Caffeine is a stimulant and may prolong the time it takes to fall asleep. • Eating a large meal before bedtime may produce heartburn, delaying sleep. • A small protein-containing snack (a source of tryptophan) combined with a carbohydrate (makes tryptophan more available to the brain) before bedtime has been recommended to improve sleep.
Sleep patterns	• Keep to usual waking time every day, even if previous night's bedtime was later than usual or sleep was restless. • Get out of bed if unable to fall asleep within 30 minutes and go into another room.	• Keeping the same pattern helps the body's circadian rhythms. • By using the bedroom for only sleep and sexual activity, the mind begins to associate this room with sleep.

Relaxation therapy involves any type of relaxation, such as progressive muscle relaxation, imagery training, or meditation. Not all relaxation methods are beneficial for all patients. Relaxation therapy and biofeedback are discussed in detail in Chapter 43.

Discuss the plan of care with the patient to make sure that the patient deems it acceptable. If a sleep disorder becomes a problem and common nursing measures are inadequate, the nurse may need to refer the patient to an advanced health care provider with the expertise to help the patient address their sleep concerns.

Evaluating

Evaluate the effectiveness of the plan of care to promote rest and sleep by determining whether the patient has met the individualized expected outcomes specified in the plan. See Nursing Care Plan 35-1 for Mr. Bitner.

Nursing care is considered effective if the patient is able to:

- Verbalize feeling rested or having had a restful night's sleep
- Identify factors that interfere with or disrupt the normal sleep pattern
- Use techniques that promote sleep and provide a restful environment
- Concentrate and function effectively during waking hours
- Eliminate behaviors related to sleep deprivation

REFLECTIVE PRACTICE LEADING TO PERSONAL LEARNING

Remember that the goal of reflective practice is to look at an experience, understand it, and learn from it. As you begin to develop use of and expertise in providing care to support patients' rest and sleep, reflect on your experiences—successes and failures—in order to improve your practice. How can you do it better next time? What did you learn today that can help you tomorrow? Begin your reflection by paying close attention to the following while performing interventions related to rest and sleep and providing nursing:

- How confident are you that the data you reported and recorded accurately communicates the status of the patient? How successfully have you communicated who this patient and family/caregivers are to the interdisciplinary team?
- Were you aware of any cultural and/or ethnic beliefs or practices that may have influenced the patient's rest and sleep practices? Were you aware of any stereotypes or prejudices that might have negatively influenced encounter? If so, how did you address these?
- How did you prioritize the data you collected? What patterns in the data did you identify? What knowledge from your learning, personal experience, and intuition did you use to make decisions and develop your plan of care?
- Did you need to modify the plan of care related to promoting rest and sleep as a result of ongoing assessments? Did you think of better interventions to produce the expected outcomes?
- As you concluded your care, did the patient/family/caregivers know your name, and know what to expect of you and nursing? Did the patient sense that you are respectful, caring, and competent to provide care?

Perhaps the most important questions to reflect on are: Are your patients and their families better for having had *you* share in the critical responsibility of being a part of their health care team? Are your patients now receiving thoughtful, person-centered, prioritized, holistic, evidence-based treatment and care because of your efforts?

Nursing Care Plan for *Mr. Bitner 35-1*

Mr. Bitner is an alert, widowed, 86-year-old man who was admitted to a long-term care facility 2 months ago. He is ambulatory and performs most of his own care. His admitting medical diagnoses include diabetes mellitus and hypertension. He adds to this list "a touch of arthritis." His daughter complains to the charge nurse that her father seems to be spending more and more time during the day napping and that he says he does not sleep well at night. A comprehensive sleep assessment of Mr. Bitner after his daughter's expression of concern reveals the following data:

- *Sleep–wakefulness pattern:* Patient goes to bed between 2000 and 2100 and gets out of bed between 0700 and 0800 because the staff are getting his roommate out of bed at this time. Patient states he never falls asleep before midnight because he always watched the late news at home. He usually wakes twice during the night to void and often cannot go back to sleep. During the day, patient is frequently observed dozing in his chair. If not discouraged, he returns to his room midmorning and afternoon for a 1-hour nap.
- *Effect of sleep pattern on everyday living:* Patient states: "I'm always tired. I don't seem to have much energy anymore." Patient has not socialized yet with other residents and, without strong encouragement, does not

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

participate in group activities. From his point of view, the patient states that life holds little reason for him to be awake. "I worked for the railroad for almost 50 years and I never overslept once."

- *Sleep aids:* Patient denies ever using medication to fall asleep. States he often relaxed at home in the evening with a couple of beers. Patient likes a dim light on during the night so that he can find the bathroom easily and likes his bedroom door ajar. He sleeps with two blankets and is often still cold.
- *Sleep disturbances and contributing factors:* Patient states: "Ever since my wife died, I'm just not getting enough sleep, and since I came here it's worse. I don't know why I don't fall asleep when I go to bed or why I wake up so much. It sure makes the nights long." Patient has no regular periods of exercise and drinks black coffee with every meal as well as one or two diet colas in the evening.

ACTUAL OR POTENTIAL HEALTH PROBLEMS AND NEED

Impaired sleep

Etiology: new sleep environment and schedule, evening caffeine intake, and insufficient meaningful daytime activity

Signs/Symptoms: difficulty falling asleep and remaining asleep

EXPECTED OUTCOME

By the next monthly assessment, 1/20/25, the patient will:

- Identify a routine hour of sleep and maintain retiring to bed at that time

NURSING INTERVENTIONS	RATIONALE	EVALUATIVE STATEMENT
Assess advisability of re-establishing Mr. Bitner's usual retiring pattern of going to bed after the 11 PM news. Assess how patient spends the time from the evening meal to 2300—explore relaxing alternatives with him. Investigate possibility that Mr. Bitner and his roommate might become social partners.	Strengthens the natural rhythm of his sleep–wake cycle. Elimination of evening naps will facilitate his falling asleep more easily.	1/18/25 Outcome met. Patient does not go to bed until after the news and has been observed talking with his roommate. *Recommendation:* Continue to develop evening activities with him—he finds that the time after supper "drags." *M. LeBon, RN*

EXPECTED OUTCOME

By the next monthly assessment, 1/20/25, the patient will:

- Report that he falls asleep within 1 hour of getting into bed

NURSING INTERVENTIONS	RATIONALE	EVALUATIVE STATEMENT
Continue to assess how long it takes patient to fall asleep after getting into bed.	In older adults, stage I time is increased.	1/18/25 Outcome partially met. Three or four nights a week, he falls asleep within 30 minutes of going to bed. States he really misses comfort of his wife. *Revision:* Investigate patient's sense of loss and need for touch. May be a good candidate for pet therapy program. *M. LeBon, RN*
Explore with patient means to relax before falling asleep—deep breathing, imagery, prayer.	Activities that calm and relax the person prepare the body for sleep.	
Teach the importance of using the bed only as a place to sleep. Advise patient when he cannot sleep to get out of bed and to go to another room, such as the common room, where he can	This maintains the bed as a powerful stimulus for sleep and helps to prevent "conditioned" insomnia ("Well, here I am in bed now and I know sleep won't come").	

perform some monotonous activity (watching television, listening to radio).		
EXPECTED OUTCOME	By the next monthly assessment, 1/20/25, the patient will: • Decrease nighttime awakenings to one, after which he returns to a sound sleep	
NURSING INTERVENTIONS	**RATIONALE**	**EVALUATIVE STATEMENT**
Assess and manipulate factors that contribute to nighttime awakenings: • Need to void (time of day diuretic is taken, amounts of fluid intake in the evening) • Roommate's wakefulness, snoring, or need for care • Uncomfortableness in strange environment • Comfort (e.g., temperature)	Individualizing the patient's bedtime environment and meeting comfort needs (warmth, soft light, and so forth) promote sleep onset and maintenance.	1/18/25 Outcome partially met. Nighttime awakenings vary from none to three nightly. See previous revision. *M. LeBon, RN*
Teach patient how, on awakening, to concentrate on breathing until he falls back to sleep.	This uses the power of relaxation and positive thinking to facilitate return to sleep.	
EXPECTED OUTCOME	By the next monthly assessment, 1/20/25, the patient will: • Identify a preferred physical activity and participate on a routine basis	
NURSING INTERVENTIONS	**RATIONALE**	**EVALUATIVE STATEMENT**
Assess whether patient understands the relation between daily exercise and his ability to sleep.	Regular exercise throughout the day is known to increase physical fatigue and to promote sleep. Exercise or stimulating activities immediately before retiring interfere with sleep's onset.	1/20/25 Outcome met. Patient has become an enthusiastic participant in exercise sessions —attends daily. *M. LeBon, RN*
Determine how his exercise needs can best be met (i.e., through a group program or an individualized program of walking or other program).	Exercise program must be individualized based on physical state and interests of patient.	
Use positive verbal reinforcement to communicate to patient that someone cares that he is using positive means to remedy his sleep disturbance and increase his well-being.	Activity provides the opportunity for socialization and improvement of a self-image. Positive reinforcement promotes continued participation.	
Encourage patient's daughter to go for walks with him when she visits and to question him about his exercise program.	Communications and interaction with family members helps the older adult to maintain self-esteem and to feel valuable and loved.	
EXPECTED OUTCOME	By the next monthly assessment, 1/20/25, the patient will:	

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

- Verbalize an understanding of appropriate foods to avoid to enhance sleep. Substitute caffeine-free beverages for coffee and cola at supper and evening snack

NURSING INTERVENTIONS	RATIONALE	EVALUATIVE STATEMENT
Assess patient's willingness to substitute caffeine-free beverages for coffee and cola.	Caffeine is a stimulant that can cause difficulty sleeping.	1/20/25 Outcome met. Patient verbalizes an understanding of the importance of caffeine-free beverages at dinner and before bedtime. Patient now drinks decaffeinated coffee with meals and milk in the evening. Dislikes caffeine-free sodas. *M. LeBon, RN*
Consult with dietary department and his daughter about options. Experiment with options until his preferences are determined.	Caffeine-free versions of beverages are often available and can be used based on patient acceptance.	
Gradually reduce his caffeine intake, especially from evening meal onward. Offer a protein and carbohydrate evening snack.	The combination of a protein and carbohydrate snack appears to promote sleep.	

SAMPLE DOCUMENTATION

12/20/25 Nursing

Family conference to discuss Mr. Bitner's sleep disturbance—initiated by daughter's concern. Present were Mr. Bitner and his daughter (A. Jelner), K. Behner (social worker), W. Quing (activity director), and M. LeBon (primary nurse). Primary nurse presented findings from comprehensive sleep assessment: Actual Health Problem: Impaired sleep as a result of Mr. Bitner's new sleep environment and schedule, evening caffeine intake, and insufficient meaningful daytime activity.

Discussion centered on strategies to help Mr. Bitner develop interests in the center, including possibilities for increased physical exercise, decrease his evening caffeine intake (daughter to bring noncaffeinated sodas), and re-establish usual retiring and waking times. See plan of care. Patient's progress will be evaluated at next monthly assessment, 1/20/25.

M. LeBon, RN

DEVELOPING CLINICAL REASONING AND CLINICAL JUDGMENT

. Interview three adults of varying ages (young, middle, older) about their sleep and rest patterns, using the Focused Assessment Guide in this chapter. Explore the special problems experienced by each of the adults, the efficacy of the self-help measures they use to cope, and helpful nursing interventions.
. Interview three practicing nurses who are recent graduates. Using the Focused Assessment Guide in the text, ask them: if they are getting adequate rest, what factors are compromising their rest (e.g., working double or rotating shifts), how any lack of rest is affecting their practice, and what self-help measures they have used or would be appropriate. Discuss with your classmates the issue of practicing nurses with sleep alterations, the factors that place nurses at risk for sleep alterations, and what students can learn or actions to take to lower their risk.

PRACTICING FOR NCLEX

. A nurse on a postpartum unit is teaching new parents about newborn safety and sleep patterns. Which comment from a parent indicates further teaching is required?

a. "I can expect my newborn to sleep an average of 16 to 24 hours a day."

b. “Eye movements or groans during my baby’s sleep is an emergency.”
c. “It is essential that I place my infant on their back to sleep.”
d. “I will not place pillows or blankets in the crib to prevent suffocation.”

. A nurse observes involuntary muscle jerking in a sleeping patient. What action will the nurse take next?
a. No action is necessary; this is normal in stage 1 sleep.
b. Report the neurologic deficit to the health care provider.
c. Lower the temperature in the patient’s room.
d. Awaken the patient, as this is an indication of night terrors.

. A nurse working the night shift is watching the monitors on a telemetry unit and observes a slight increase in a patient’s vital signs during sleep. Which of these points will the nurse correlate to changes in vital signs? Select all that apply.
a. They are aware of his surroundings at this point.
b. They are in delta sleep at this time.
c. It would be most difficult to awaken them at this time.
d. This is most likely an NREM stage.
e. This stage constitutes around 20% to 25% of total sleep.
f. The muscles are relaxed in this stage.

. A nurse working in a sleep lab observes the developmental factors that may affect sleep. Which statements accurately describe these variations? Select all that apply.
a. REM sleep constitutes much of the sleep cycle of a preschool child.
b. By age 8 years, most children no longer take naps.
c. Sleep needs usually decrease when physical growth peaks.
d. Many adolescents do not get enough sleep.
e. Total sleep decreases in adults with a decrease in stage IV sleep.
f. Sleep is less sound in older adults, and stage IV sleep may be absent.

. A nurse is providing education in a senior center on sleep and sleep hygiene in older adults. What teaching point will the nurse include?
a. Drinking a cup of regular tea at night induces sleep.
b. Using alcohol moderately promotes a deep sleep.
c. Eating a bedtime snack high in tryptophan and carbohydrates improves sleep.
d. Exercising right before bedtime can hinder sleep.

. As part of interprofessional rounds, a nurse in a skilled facility assesses for sleep deficits. Patients with which health problems would the team identify as higher risk for sleep disturbances? Select all that apply.
a. Uncontrolled hypothyroidism
b. Anxiety
c. GERD
d. HIV
e. Arthritis
f. Urinary tract infection

. A nurse is providing discharge teaching for patients regarding their medications. For which patients would the nurse recommend actions to promote sleep? Select all that apply.
a. Patient taking iron supplements for anemia
b. Patient with Parkinson’s disease who is taking dopamine
c. Older adult taking diuretics for congestive heart failure
d. Child taking antibiotics for an ear infection
e. Patient taking antidepressants
f. Patient taking low-dose aspirin prophylactically

. A nurse in a pediatric unit notes a school-aged child snores and appears to have labored breathing during sleep. Which assessment question could the nurse ask the patient or parents?
a. “Do you have trouble sleeping?”
b. “Have you missed a lot of school due to not feeling well?”
c. “Have you been wetting the bed lately?”
d. “Do you have a history of high blood pressure?”

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

. At an annual health and wellness visit, the parent of an adolescent reports a teacher's concerns that their child is sleepy at school during class time. Which information will the nurse share with the parent and child? Select all that apply.

a. Adolescents typically need 8 to 10 hours of sleep each night.
b. Demands on the adolescent's time causes them to sleep longer hours.
c. Insufficient sleep can lead to daytime sleepiness.
d. Adolescents require reduced sleep in the teen years.
e. The adolescent could benefit from a sleep study for insomnia.

. A nurse recommends that a patient with a sleep disorder keep a sleep diary. Which data will the nurse ask the patient to document? Select all that apply.

a. Daily mental activities
b. Daily physical activities
c. Morning and evening body temperature
d. Daily measurement of fluid intake and output
e. Presence of anxiety or worries affecting sleep
f. Morning and evening blood pressure readings

. A nurse in a rehabilitation facility develops a plan to help promote patients' sleep. What interventions will the nurse include in the plan? Select all that apply

a. Maintain a consistent bedtime and time to awaken.
b. Drink two or three glasses of water at bedtime.
c. Have a large snack at bedtime.
d. Take a sedative-hypnotic every night at bedtime.

. A nurse is caring for an older adult who is having trouble falling asleep at night. What nursing interventions are appropriate for this patient? Select all that apply.

a. Assess the patient for depression.
b. Discourage napping during the day.
c. Decrease fluids during the evening.
d. Administer diuretics in the morning.
e. Encourage the patient to engage in some type of physical activity.
f. Assess medication for side effects of sleep pattern disturbances.

. A nursing student is caring for an older adult with arthritis who states she did not sleep well and was "up all night to use the bathroom." To help promote sleep, the student plans to discuss re-timing which medication with the primary nurse?

a. Furosemide (diuretic) 10:00 AM, 10:00 PM
b. Melatonin 9:00 PM
c. Acetaminophen 10:00 AM, 10:00 PM
d. Artificial tears every 8 hours, 8:00 AM, 2:00 PM, 8:00 PM

. A nurse caring for patients on a surgical unit should implement which recommendation to promote sleep? Select all that apply

a. Keep the room light dimmed during the day.
b. Maintain a cool temperature in the room for sleep.
c. Keep the door of the room open for fresh air.
d. Offer a hypnotic to patients on a regular basis.
e. Offer pain medication prior to sleep, as needed.
f. Provide earplugs if the patient agrees.

. A nurse caring for patients in a long-term care facility is implementing interventions to help promote sleep in older adults. Which is the best action for these patients?

a. Increase physical activities during the day.
b. Encourage short periods of napping during the day.
c. Increase fluids during the evening.
d. Dispense diuretics during the afternoon hours.

. A patient experiencing menopause tells the nurse at the medical clinic that she would like to try a CAH hormonal sleep aid like her friend uses. What information can the nurse give the patient?

a. Melatonin, an over-the-counter hormonal sleep aid, has varied effectiveness.

b. Lavender is a hormonal scented sleep aid.
c. Lorazepam, a naturally occurring benzodiazepine, is recommended for sleep.
d. Valerian is a natural hormonal sleep aid.

. After reporting an adult patient's loud snoring and changes in vital signs occurring overnight the patient's health care provider, a nocturnal polysomnography study is prescribed. What teaching will the nurse provide about this test?
a. This is a blood test, taken in the evening to evaluate leptin and ghrelin.
b. The patient is monitored overnight to evaluate for sleep apnea.
c. A patient is evaluated for leg jerking and awakenings during the night.
d. Adults, rather than children, can be diagnosed with this test.

ANSWERS WITH RATIONALES

. **b.** Eye movements, groaning, grimacing, and moving are normal activities at this age; no emergency exists. Newborns sleep an average of 16 to 24 hours a day. Infants should be placed on their backs for the first year to prevent SIDS. Parents should be cautioned about placing pillows, crib bumpers, quilts, stuffed animals, and other items in the crib as they pose a suffocation risk.

. **a.** Involuntary muscle jerking occurs in stage I NREM sleep and is a normal finding. No further actions are needed for this patient.

. **c, e.** This scenario describes REM sleep. During REM sleep, it is difficult to arouse a person, and the vital signs increase. REM sleep constitutes about 20% to 25% of sleep. In stage I NREM sleep, the person is somewhat aware of surroundings. In stage IV NREM sleep (delta sleep), the muscles are relaxed, whereas small muscle twitching may occur in REM sleep.

. **d, e, f.** Many adolescents do not get enough sleep due to the demands of school, activities, and part-time employment. Total sleep time decreases during adult years, with a decrease in stage IV sleep. Sleep is less sound in older adults, and stage IV sleep is absent or considerably decreased. REM sleep constitutes much of the sleep cycle of a young infant, and by the age of 5 years, most children no longer nap. Sleep needs usually increase when physical growth peaks.

. **c.** The nurse would teach that having a small bedtime snack high in tryptophan and carbohydrates improves sleep. Regular tea contains caffeine and increases alertness. Large quantities of alcohol limit REM and delta sleep. Physical activity within a 3-hour interval before normal bedtime can hinder sleep.

. **a, b, c.** A patient who has uncontrolled hypothyroidism tends to have a decreased amount of NREM sleep, especially stages II and IV. Worries and anxiety can interfere with sleep, as can pain. A patient who has GERD may awaken at night with heartburn pain. Being HIV positive, taking corticosteroids, and having a urinary tract infection does not usually change sleep patterns.

. **b, c, e.** Drugs that decrease REM sleep include barbiturates, amphetamines, and antidepressants. Diuretics, antiparkinsonian drugs, some antidepressants and antihypertensives, steroids, decongestants, caffeine, and asthma medications are seen as additional common causes of sleep problems.

. **c.** OSA (pediatric) is defined by the presence of snoring, labored/obstructed breathing, enuresis, or daytime consequences (hyperactivity or other neurobehavioral problems, sleepiness, fatigue). Adults, children, and adolescents with symptoms of OSA, including snoring, should have polysomnography to confirm the diagnosis. Although OSA may cause insomnia, this is not the primary diagnosis in this case. Narcolepsy is a condition characterized by excessive daytime sleepiness and frequent overwhelming urges to sleep or inadvertent daytime lapses into sleep. Hypertension is a consequence of OSA in adults.

. **a, c.** Adolescents require 8 to 10 hours of sleep nightly; however, demands on their time cut into the needed sleep. Insufficient sleep can lead to daytime sleepiness.

. **a, b, e.** A sleep diary includes mental and physical activities performed during the day and the presence of any anxiety or worries the patient may be experiencing that affect sleep. A record of fluid intake and output, body temperature, and blood pressure is typically kept in the graphic record.

. **a.** Keeping a consistent bedtime and awakening schedule, even when up late, helps promote sleep. Drinking two or three glasses of water at bedtime will probably cause the patient to awaken during the night to void. A large snack may be uncomfortable right before bedtime; instead, a small protein and carbohydrate snack is recommended. Taking a sedative–hypnotic every night disturbs REM and NREM sleep, and sedatives also lose their effectiveness quickly.

. **a, b, d, e, f.** For patients who are having trouble initiating sleep, the nurse should arrange for assessment for depression and treatment, discourage napping, promote activity, and assess medications for sleep disturbance side effects. Limiting fluids and administering diuretics in the morning are appropriate interventions.

. **a.** It is best to administer diuretics in the morning or early evening to prevent nocturia. Melatonin promotes sleep and rest. Acetaminophen can relieve arthritis pain and help promote rest. Artificial tears, used for dry eyes, will not affect sleep.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

- **b, e, f.** The nurse should keep the room cool and provide earplugs and eye masks if desired. The nurse should maintain a bright room environment during daylight hours and dim lights in the evening, keeping the door of the room closed to keep out extraneous noise. Sleep aid medications should only be offered as prescribed with the knowledge that they can become habit forming.
- **a.** In order to promote sleep in the older adult, the nurse should encourage daily physical activity such as walking or water aerobics. The nurse discourages napping during the day, decreases fluids at night, and dispenses diuretics in the morning (or early evening when necessary).
- **a.** Melatonin, used as a complementary or alternate to traditional pharmacologic agents, is a hormone thought to regulate the sleep–wake cycle. Valerian is an herb; lavender is a plant used for aromatherapy and relaxation. Benzodiazepines are pharmacologic medications used to decrease anxiety and promote sleep and relaxation.
- **b.** Polysomnography is an overnight sleep study to determine if an individual has sleep apnea and treatment. Leptin and ghrelin are hormones that regulate nutritional intake. Leptin signals the brain to stop eating, whereas ghrelin promotes continued eating. Research suggests that sleep deprivation lowers leptin levels and elevates ghrelin levels, increasing appetite; however, this does not help diagnose sleep apnea. Jerking legs in the early stage of sleep is expected. Both adults and children can benefit from diagnosis of sleep apnea with this test.

Comfort and Pain Management

Carla Potter

Carla is a 72-year-old adult who has a history of type 2 diabetes and associated diabetic neuropathy. She reports pain in her lower extremities that is at times sharp but, is generally dull. She also reports that she has relatively new periods of numbness and tingling. Carla is becoming increasingly worried that this constant pain is going to take over her life. She reports that an increase in stress and anxiety seems to be making the pain even worse.

Sheree Lincoln

Sheree, a 42-year-old woman who has just undergone abdominal surgery, returns to the medical-surgical unit. Patient-controlled analgesia (PCA) is prescribed. Approximately 2 hours after returning from surgery, the patient reports unresolved pain. Assessment reveals that she has not been using the PCA device.

Xavier Malton

Xavier, a 5-year-old boy diagnosed with ulcerative colitis, is in the bathroom with his mother. He suddenly grabs his belly while on the toilet and starts to scream, “Something hurts really bad!” His

mother pulls the emergency call bell. He is doubled over in pain and can't get off the toilet. After being assisted back to his bed and receiving the relatively small dose of pain medication prescribed by the provider, Xavier continues to scream for half an hour while curled up in a fetal position on his bed. "The pain is so bad; it will never go away!"

Learning Outcomes

After completing the chapter, you will be able to accomplish the following:

. Describe specific elements in the pain experience.
. Compare and contrast acute (nociceptive) and chronic (neuropathic, nociplastic) pain.
. Identify factors that may affect a person's pain experience.
. Obtain a complete pain assessment using appropriate interviewing and physical assessment skills.
. Explain the relationship between pain and other areas of human functioning.
. Use a holistic approach to pain management that considers a multimodal approach to the pharmacologic management of pain and includes nonpharmacologic methods.
. Collaborate with the interprofessional team to develop, implement, and evaluate effective, individualized, evidence-based pain management regimens.
. Use teaching and counseling skills to empower patients to direct their own pain management programs.

transmission
visceral pain

Current reports indicate that 20.4% of adults in the United States experience chronic pain. High-impact chronic pain, chronic pain that frequently limits work, social, self-care, and recreational activities, impacts 7.4% of adults in the United States (Dahlhamer et al., 2018; Zelaya et al., 2020). Urbanization affected reports of chronic pain, with adults in rural areas experiencing the greatest percentage of chronic pain (28.1%) and high-impact chronic pain (10.9%). Older age, race, Hispanic origin, and biological sex also influence the percentage of adults who report chronic pain (Zelaya et al., 2020). When both direct (medical expenses) and indirect (missed days of work) costs are considered, the total financial impact of the use and misuse of alcohol, nicotine, and illicit (illegal) drugs, plus the misuse of prescribed drugs is more than $700 billion annually (National Institute on Drug Abuse, 2020). Additional costs of unrelenting, inadequately treated pain include physiologic, psychological, and social effects such as social isolation, disability and lost work productivity or advancement, change in the distribution of household chores, lower level of marital satisfaction, decrease in quality of life, limitations in performing complex activities, and feelings of fear, anxiety, depression, self-judgment, pain invalidation, stigmatization, and demoralization (Dahlhamer et al., 2018; Nicola et al., 2021; Suso-Ribera et al., 2020). Physiologic effects of pain include hyperglycemia, increased cardiac workload, immune system dysfunction, altered coagulation, gastrointestinal (GI) ileus, urinary retention, decreased lung volume, and fatigue (Hinkle et al., 2022; Karch, 2020).

Scientists and clinicians have united in their efforts to ensure that pain management is a high priority in our health care system. New advances in understanding and treating pain have focused on the possibility of safely managing most human pain. Hospital policies are required to include a comprehensive pain assessment that is consistent with the patient's scope of care, treatment, services, age, condition, and ability to understand. Hospitals must also reassess and respond to pain based on their established reassessment criteria. Hospitals can refer the patient for treatment of pain or employ pharmacologic and nonpharmacologic approaches that are patient-specific, consider the provider's clinical judgment, include a risk–benefit analysis, and comply with processes required for monitoring and education (The Joint Commission, 2021). Effective January 1, 2018, standards for hospitals from The Joint Commission (2017) specifically require hospitals to:

- **Identify pain assessment and pain management, including safe opioid prescribing, as an organizational priority:** involves a leader/leadership team; provides nonpharmacologic pain treatment modalities; provides staff and licensed independent practitioners educational resources, programs, and consultation services; identifies opioid treatment programs; facilitates practitioner and pharmacist access to the Prescription Drug Monitoring databases; and acquires equipment needed to monitor patients who are at high risk for adverse outcomes associated with opioid treatment
- **Actively involve the organized medical staff in leadership roles in organization performance improvement activities to improve quality of care, treatment, and services and patient safety:** medical staff participates in the establishment of protocols and quality metrics; and reviews performance improvement data
- **Assess and manage the patient's pain and minimize the risks associated with treatment:** employs accurate screening and assessment tools that are readily available and used appropriately; screens patients for pain during emergency department encounters and upon admission; treats the patient's pain or refers them for treatment; develops pain treatment plans based on evidence-based practices and patient involvement that considers the patient's condition, past medical history, treatment options, pain management goals; involves the patient in pain management treatment planning through the development of realistic expectations and goals, evaluation process, and education on pain management; monitors patients identified as high risk for adverse outcomes related to opioid treatment; reassesses and responds to the patient's pain through evaluation and documentation of response to pain, progress toward pain management goals, side effects, and risk factors for adverse events; and educates patients and families on discharge plans related to pain management including plan, side effects, impact on activities of daily living, and safe storage, use,

and disposal of opioids

QSEN Reflective Practice: Cultivating QSEN Competencies

CHALLENGE TO ETHICAL AND LEGAL SKILLS

While in my pediatrics rotation a local hospital, I was caring for Xavier Malton, a 5-year-old boy diagnosed with ulcerative colitis (UC), a form of inflammatory bowel disease (IBD). Suddenly, at the end of this relatively quiet shift, the emergency call bell alarm sounded. I realized that the call was coming from Xavier's bathroom. As I ran the 10 ft to his room, thoughts of him bleeding internally or perforating his bowel ran through my head. I got there at the same time his nurse did, only to discover that his mother had pulled the alarm because her son had suddenly grabbed his belly while on the toilet and had started screaming that something was "hurting really, really bad." He was so doubled over in pain that he could not even get off the toilet. Having Crohn disease myself (another form of IBD), I knew that the pain this boy was experiencing was excruciating and not imagined.

With help from Xavier's mother, his nurse and I got Xavier back into bed. We reviewed his chart only to learn Xavier did not have a PRN prescription for pain medication. We called the provider, who was hesitant to prescribe any pain medication. Pain is not unusual with UC, so the provider encouraged us to implement alternative methods of pain management such as distraction. We clearly presented Xavier's case and, based on our repeated recommendation, the provider agreed to prescribe pain medication, but only a very small dose. We immediately administered the pain medication, got Xavier as comfortable in bed as possible, and planned to routinely reassess his pain.

Although we had hoped the pain medication would relieve or at least alleviate some of his pain, Xavier continued to scream, curled up in a fetal position on his bed. I had to briefly leave the room, and even from across the hallway, I could hear him screaming that the pain was "so bad" and that it would "never go away."

Thinking Outside the Box: Possible Courses of Action

- I could give up and try not to care since this system clearly is not committed to meeting comfort needs, but this means abandoning my patient(s).
- I could be persistent about advocating for this patient until his pain is relieved, continuing to contact and work with key members of the interprofessional team to achieve pain relief for my patient.
- I could consult with a colleague who I respect regarding the best way to accomplish the goal of pain relief, since I don't want to alienate caregivers with whom I will need to continue to work.

Evaluating a Good Outcome: How Do I Define Success?

- Patient's pain is relieved and patient reports feeling comfortable.
- Colleagues are newly committed to the responsibility of *everyone* to adequately manage pain.
- My working relationships with other professional caregivers are not compromised by my advocacy for this patient.
- My personal and professional integrity remains intact.

Personal Learning: Here's to the Future!

Forty-five minutes after our shift had ended, Xavier's nurse and I were still following the provider around, basically demanding that she reassess the patient and prescribe additional pain medication for him. Finally, she performed a reassessment and prescribed a narcotic for pain management. Unfortunately, the narcotic she ordered was in short supply in the hospital. We spent the next 15 minutes tracking some down. Although it took more time than we had hoped, we did give Xavier additional pain medication, which, ultimately, did relieve his pain and allow him to fall asleep. However, we left the hospital almost an hour and a half after our shift had ended, time that was lost to Xavier and time for which we would not receive compensation.

Transforming the culture of health care is a daunting task. Demanding an unacceptable situation be remedied requires an absolute belief in the rights of the patient. The situation was indeed unacceptable—no child should be left to suffer. Interprofessional collaboration is challenging when members of the team have differing viewpoints. The nurse should be able to confidently and competently provide assessment data and a recommendation for the plan of care. This promotes safe, high-quality patient care and allows for the entire team to advocate for the patient. Any RN facing a situation that has the potential to transform the culture of health care for the better has the responsibility to take advantage of that situation, no matter

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

what the perceived or actual professional risk. I would recommend that any RN in a similar situation take the same steps that Xavier's nurse and I did. Do not be afraid to challenge others who you think are wrong. Be confident in your opinions. Refuse to back down. Remember that you may be the only one who can ensure that your patient's needs are met. Always advocate for high-quality care; never settle for less.

Tracey Sara Miller, Georgetown University

QSEN SELF-REFLECTION ON QUALITY AND SAFETY COMPETENCIES DEVELOPING KNOWLEDGE, SKILLS, AND ATTITUDES FOR CONTINUOUS IMPROVEMENT

How do you think you would respond to or approach this situation? Why? What does this tell you about yourself and about the adequacy of your skills for professional practice? Do you agree with the criteria that the nursing student used to evaluate a successful outcome? Why or why not? What *knowledge, skills,* and *attitudes* do you need to develop to continuously improve quality and safety when caring for patients like Xavier?

Patient-Centered Care: What assurances should be given to Xavier and his mother about pain relief and control? What is the best way to communicate emotional support and a commitment to providing pain relief to Xavier and his mother? How could you involve Xavier's mother as a partner in coordinating Xavier's pain management?

Teamwork and Collaboration/Quality Improvement: What communication skills do you need to continue to function as an advocate for your patients? What strategies might be appropriate to ensure that you function as a valued member of the health care team? Can you think of other ways to communicate with team members regarding individual patients' responses to pain?

Safety/Evidence-Based Practice: Is there anything more you could have done to facilitate timely pain relief for Xavier? When are nonpharmacologic methods of pain relief most appropriate and effective? How do you think your response affected the situation? What evidence in nursing literature provides guidance for decision making regarding responses to pain and misconceptions about the pain experience?

Informatics: What information should be electronically documented regarding your assessment of the presence and severity of Xavier's pain? Can you identify other essential information that must be available in Xavier's electronic record to support safe patient care from the entire health care team?

- **Collect data to monitor its performance:** includes types of interventions and effectiveness
- **Compile and analyze data:** identifies areas that need change to increase safety and quality for patients; and monitors the use of opioids for safe use

A person in pain often experiences the pain as an all-consuming reality and wants only one intervention—pain relief. If pain relief were as simple as rubbing a back or administering a prescribed analgesic, the nurse's task would be easy. However, no two people experience pain exactly the same way. Differences in individual pain perception and response to pain, as well as the multiple and diverse causes of pain, require the nurse to use highly specialized knowledge and abilities to promote comfort and to relieve pain. The most essential of these are the nurse's knowledge and understanding that the patient's pain is real, the willingness to become involved in the patient's pain experience, and competence in developing effective pain management regimens. (See the accompanying Reflective Practice box for an example.)

Although pain is often all-consuming for patients, it can be missed or misjudged easily because it is intangible. As a result, it is often easier to overlook or minimize a patient's poorly communicated pain than it is to ignore a dressing that needs to be changed, the need for assistance with walking, or the routine administration of a prescribed medication. Nurses must draw upon empathy and sensitivity when caring for patients experiencing pain. In addition, when addressing pain, nurses should ensure they are implementing active interventions that extend beyond the assessment of pain, and include interventions focused on treating and managing pain. Carefully consider your interventions when developing a care plan focused on pain: *You must do more than assess to impact change*, especially with pain.

This chapter discusses the pain experience and factors that influence it. A detailed guide to assessing pain is presented, along with numerous examples of actual and potential problems, and specific nursing strategies for promoting comfort and assisting patients to achieve pain management goals. The Evolving Case at the end of the chapter illustrates the application of clinical judgment to promote pain management and patient comfort.

EXPERIENCE OF PAIN

Pain is an elusive and complex phenomenon. Despite its universality, its exact nature remains a mystery. It is one of the

human body's defense mechanisms that indicate the person is experiencing a problem. Margo McCaffery offers the classic definition of pain that is probably of greatest benefit to nurses and their patients, "Pain is whatever the experiencing person says it is, existing whenever the experiencing person says it does" (1968, p. 95). This definition rests on the belief that the only one who can be a real authority on whether, and how, a person is experiencing pain is that person. Health care providers must respect the patient's description of the pain because it is a personal experience. The International Association for the Study of Pain (IASP) recently updated their 1979 definition of pain as "An unpleasant sensory and emotional experience associated with, or resembling that associated with, actual or potential tissue damage" (Raja et al., 2020, p. 1976). They expound on this definition with the following notes (p. 1978):

- Pain is always a personal experience that is influenced to varying degrees by biological, psychological, and social factors.
- Pain and nociception are different phenomena. Pain cannot be inferred solely from activity in sensory neurons.
- Through their life experiences, individuals learn the concept of pain.
- A person's report of an experience as pain should be respected.
- Although pain usually serves an adaptive role, it may have adverse effects on function and social and psychological well-being.
- Verbal description is only one of several behaviors to express pain; inability to communicate does not negate the possibility that a human or a nonhuman animal experiences pain.

Consider **Xavier Malton**, the 5-year-old boy with ulcerative colitis who suddenly develops acute pain. The nurse appreciates that Xavier is indeed experiencing pain because of his screaming that something hurts. Furthermore, his pain is validated by his body posture and inability to get off the toilet.

Gate Control Theory of Pain

Many theories have attempted to explain the mechanism of pain. However, the **gate control theory**, originally proposed by Melzack and Wall in 1965, provides the most practical model regarding the concept of pain. It describes the transmission of painful stimuli and recognizes a connection between pain and the projection of pain information to the brain (Norris, 2020). The theory states that small nerve fibers conduct excitatory pain stimuli toward the brain, exaggerating the effect of the arriving impulses through a positive feedback mechanism. Large nerve fibers appear to inhibit the transmission of pain impulses from the spinal cord to the brain through a negative feedback system (Melzack & Wall). There is a transmission mechanism that is believed by some to be located in substantia gelatinosa cells in the dorsal horn of the spinal cord. This serves as the gate. Only a limited amount of sensory information can be processed by the nervous system at any given moment. When too much information is sent through, certain cells in the spinal column interrupt the signal as if closing a gate (Pasero & McCaffery, 2011). One concrete example of this is when a person rubs the site of an injury that has just occurred. This stimulation of the large fibers, which are largely inactive when the small-fiber activity is increased, can decrease the level of pain experienced by the person (Melzack & Wall). Figure 36-1 illustrates the gate control theory of pain.

Other factors thought to have an impact on the opening and closing of this gate are past experiences, the cultural and social environment, personal expectations, beliefs about pain, the emphasis placed on pain, and emotions. For example, a positive mood, distraction, or relaxation can work to close the gate; fear and anxiety have been shown to open the gate, thus increasing the pain experienced. Understanding gate theory can positively impact on a patient's development of skills that help in their self-management of chronic pain (LeFort et al., 2021). Although not everyone accepts the gate control theory, it appears to explain why mechanical and electrical interventions, or heat and pressure may provide effective pain relief. Nursing measures, such as massage or a warm compress to a painful lower back area, stimulate large nerve fibers to close the gate, thus blocking pain impulses from that area. Teaching self-management techniques that activate closing the gate may also minimize the experience of pain for patients (LeFort et al., 2021).

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

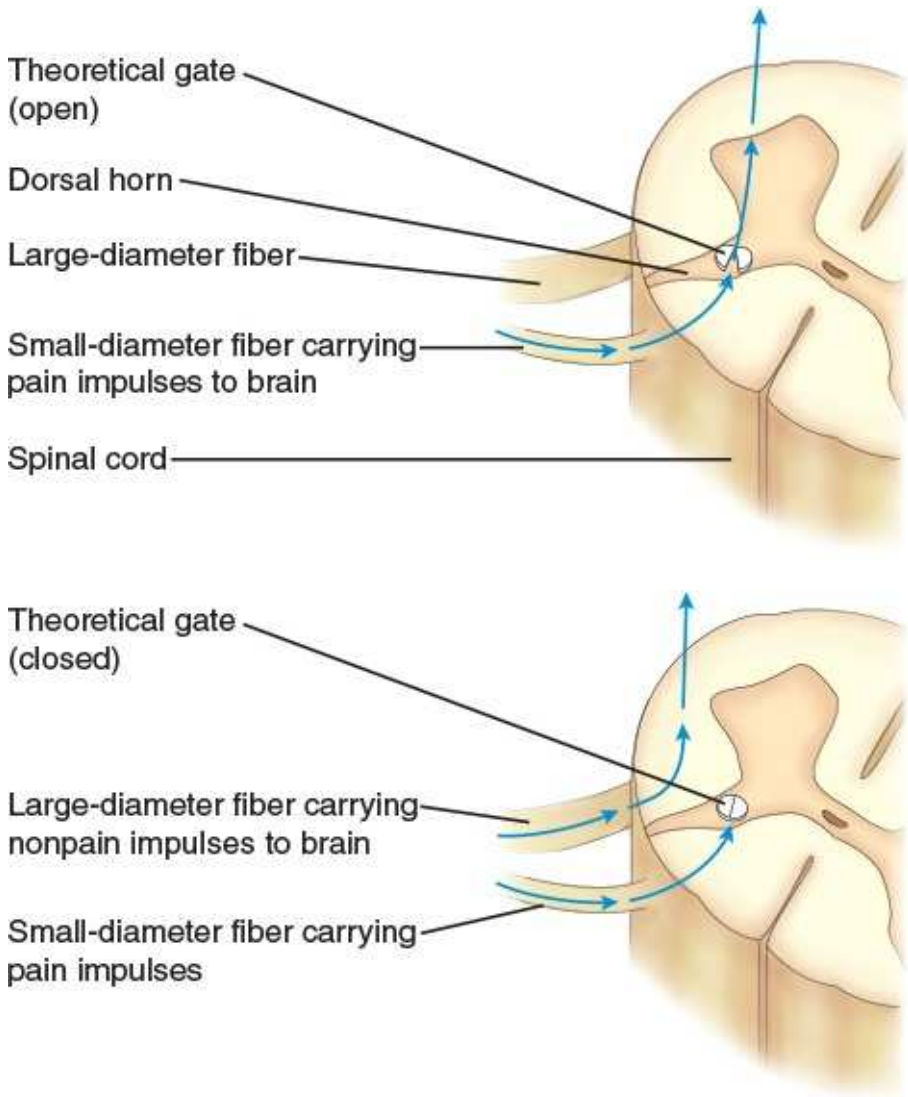

FIGURE 36-1. An illustration of the gate control theory of pain.

Theoretical models that explore pain also consider pain receptors, patterns of activity, the brain's role in managing inputs, and neurohormonal control of pain. There is no universally accepted explanation for the physiologic experience of pain. The mechanisms and pathways of pain are complex and continue to be explored (Norris, 2020).

Pain Process

The four specific physiologic processes involved in nociception (the ability to feel painful stimuli) include transduction, transmission, perception, and modulation of pain (Pasero & McCaffery, 2011). Nociceptive pain is initiated by nociceptors that are activated by injury to the peripheral tissue and is representative of the normal pain process (Norris, 2020).

Transduction

The activation of pain receptors is referred to as **transduction**. It involves conversion of painful stimuli into electrical impulses that travel from the periphery to the spinal cord at the dorsal horn. The **nociceptors**, or peripheral receptors, respond selectively to mechanical, thermal, and chemical stimuli that are noxious (Norris, 2020). In addition, when the threshold of perception for pain has been reached and when there is injured tissue, it is believed that the injured tissue releases chemicals that excite or activate nerve endings. For example, a damaged cell releases histamine, which excites nerve endings. Lactic acid accumulates in tissues injured by lack of blood supply and is believed to excite nerve endings, causing pain, or to lower the threshold of nerve endings to other stimuli (e.g., heat or pressure). The prolonged effect of pain stimuli acting on the central nervous system (CNS) can lead to sensitization, meaning that the threshold for activation of pain is lowered. At that point, even harmless stimuli can trigger pain; pain signals are faster and feel more intense.

Other substances are also released that stimulate nociceptors or pain receptors. These include bradykinin, prostaglandins, and substance P:

- Bradykinin, a powerful vasodilator that increases capillary permeability and constricts smooth muscle, plays an important role in the chemistry of pain at the site of an injury even before the pain message gets to the brain. It also triggers the release of histamine and, in combination with histamine, produces the redness, swelling, and pain typically observed when inflammation is present.
- Prostaglandins are important hormone-like substances that send additional pain stimuli to the CNS.
- Substance P, a neuropeptide, sensitizes receptors on nerves to feel pain and also increases the rate at which nerves fire.

Prostaglandins, substance P, and serotonin (a hormone that can act to stimulate smooth muscles, inhibit gastric secretion, and produce vasoconstriction) are **neurotransmitters**, substances that either excite or inhibit target nerve cells.

Receptors in the skin and superficial organs are incapable of responding selectively. However, mechanical, thermal, chemical, and electrical agents may stimulate them. Friction from bed linens and pressure from a cast are mechanical

stimulants. Sunburn and cold water on a tooth with caries are thermal stimulants. An acid burn is the result of a chemical stimulant. The jolt of a static charge is an electrical stimulant (Norris, 2020; Pasero & McCaffery, 2011).

Transmission of Pain Stimuli

Pain sensations from the site of an injury or inflammation are conducted along pathways to the spinal cord and then on to higher centers. These pathways are clearly defined in certain areas but are still somewhat unclear in other areas. The overall process is known as **transmission**. No specific pain organs or cells exist in the body. Rather, an interlacing network of undifferentiated free nerve endings receives painful stimuli. Free nerve-ending pain receptors include the afferent (those fibers carrying impulses from the pain receptors toward the brain) fast-conducting A-delta–fibers and the slow-conducting C-fibers. The larger A-delta–fibers transmit acute, well-localized pain that is typically elicited by mechanical or thermal stimuli. The smaller C-fibers convey diffuse, longer-lasting pain that is triggered by chemical stimuli or persistent mechanical or thermal stimuli (Norris, 2020). It is estimated that there are several million of these nerve endings in the body, often embedded in the layers of the skin and in some internal tissues, such as the joint surfaces. In the deeper tissues of the body, the pain receptors are diffusely but unevenly spread (Pasero & McCaffery, 2011).

A protective pain reflex is responsible for withdrawal of an endangered tissue from a damaging stimulus. Sensory impulses travel over A-fibers through the dorsal root ganglion to the dorsal horn of the spinal cord. At this point, the sensory nerve impulse synapses with a motor neuron, and the impulse is carried along efferent nerve pathways back to the site of the painful stimulus in a reflex arc. This results in an immediate muscle contraction intended to withdraw/remove the injured body part from the source of the pain. As a concrete example, think about the reaction that occurs when a hot stove is touched. Figure 36-2 (on page 1342) illustrates the transmission of the pain sensation, the initiation of the protective reflex response, and conscious awareness of the location, intensity, and quality of the pain after the impulse reaches the cortex (Pasero & McCaffery, 2011).

Perception of Pain

The **perception** of pain involves the sensory process that occurs when a stimulus for pain is present. It includes the person's interpretation of the pain. The **pain threshold** is the "minimum intensity of a stimulus that is perceived as painful" (IASP, 2021). Adaptation may affect this perception of pain. For example, when a person's hand is immersed in warm water, a sensation of pain eventually occurs as the water is heated. However, the person can tolerate a higher temperature as water is gradually heated to the pain level than if the hand had been plunged into hot water without any preparation. Other factors that may impact perception, interpretation, and response to pain will be discussed later in this chapter.

Modulation of Pain

The process by which the sensation of pain is inhibited or modified is referred to as **modulation**. The sensation of pain appears to be regulated or modified by substances called neuromodulators. These **neuromodulators** are endogenous opioid compounds, meaning they are naturally present, morphine-like chemical regulators in the spinal cord and brain. They appear to have analgesic activity and alter the perception of pain. These endogenous opioid compounds are believed to produce their analgesic effects by binding to specific opioid receptor sites throughout the CNS, blocking the release or production of pain-transmitting substances. Both pain and stress appear capable of activating the endogenous opiate system.

Endorphins and enkephalins are opioid neuromodulators. **Endorphins** are produced at neural synapses at various points along the CNS pathway. They are powerful pain-blocking chemicals that have prolonged analgesic effects and produce euphoria. It is suggested that endorphins may be released when certain measures are used to relieve pain, such as skin stimulation and relaxation techniques, and when certain pain-relieving drugs are used. The endorphin, dynorphin, has the most potent analgesic effect. However, many questions remain about endorphins.

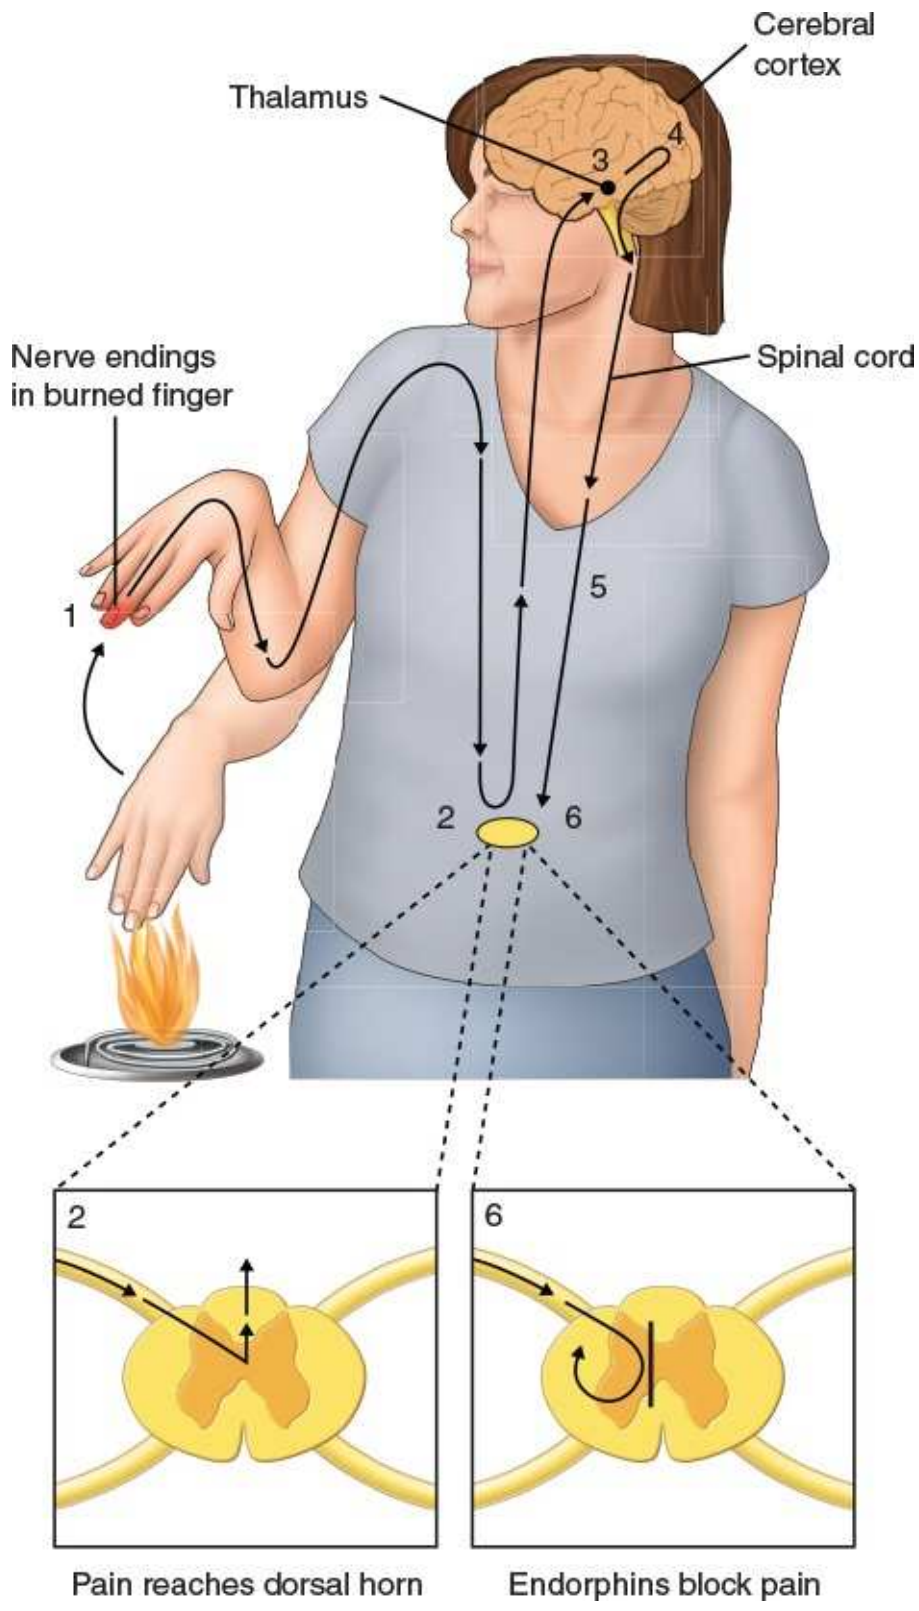

FIGURE 36-2. Pain sensation and relief. (*1*) Pain's path begins as a message and is received by nerve endings in a burned finger. (*2*) The pain signal from the burned finger travels as an electrochemical impulse along the length of the nerve to the dorsal horn on the spinal cord, a region that runs the length of the spine and receives signals from all over the body. (*3*) The message is relayed to the thalamus, a sensory center in the brain where sensations such as heat, cold, pain, and touch first become conscious. (*4*) It then travels on to the cortex, where the intensity and location of pain are perceived. (*5*) Pain relief begins as a signal from the brain and descends by way of the spinal cord. (*6*) In the dorsal horn, chemicals such as endorphins are released to diminish the pain message from the injured finger.

Enkephalins, which are widespread throughout the brain and dorsal horn of the spinal cord, are considered less potent than endorphins. **Enkephalins** are thought to reduce pain sensation by inhibiting the release of substance P from the terminals of afferent neurons (Norris, 2020; Pasero & McCaffery, 2011).

Types of Pain

Pain may be classified according to its duration, its localization/location, or its etiology.

Duration of Pain

Perhaps the most common distinction involves the duration of pain. **Acute pain** is generally rapid in onset and varies in intensity from mild to severe. It is protective in nature. In other words, acute pain warns the person of tissue damage or organic disease and triggers autonomic responses such as increased heart rate, the fight-or-flight response, and increased blood pressure (Jungquist et al., 2017; Norris, 2020). After its underlying cause is resolved, acute pain disappears. It should end once healing occurs. Causes of acute pain include a pricked finger, sore throat, or surgery.

Chronic pain is maladaptive pain that persists or is recurrent for more than 3 months. When classified as chronic *primary* pain, the chronic pain itself is considered the disease—this includes diagnoses such as fibromyalgia or back pain. Chronic pain is classified as *secondary* when the chronic pain results from cancer, surgery or trauma, an issue in the nervous system (neuropathic), headache or orofacial issues, visceral (organ) conditions, or musculoskeletal diseases (Treede et al., 2019). Chronic pain presentation varies greatly and can include pain that is continuous, pain that is episodic with periods of **remission** (disease is present, but the person does not experience pain) and **exacerbation** (the symptoms reappear), or pain that is recurring and contains elements of both chronic and acute pain (Norris, 2020; Treede

et al., 2019).

Patients have difficulty describing chronic pain because it may be poorly localized. The patient presentation will vary from person to person, which makes completing an accurate, objective assessment challenging for health care professionals. In addition, the misconceptions and personal biases of caregivers can adversely affect the management of patients with chronic pain. Chronic pain takes a toll on the person experiencing pain and may result in depression, anger, frustration, sleep and appetite disturbances, and dependency. Chronic secondary pain that is associated with a disease process, such as cancer, is more likely to be viewed as valid, while chronic primary pain that is not well defined may be misinterpreted or dismissed by health care providers. Health care providers who have experienced chronic pain or struggled through the experience with a loved one may have a special awareness of its debilitating, destructive nature. Improved classification and diagnostic coding (related to reimbursement) of chronic pain lends credibility to the consideration of chronic pain a stand-alone health condition, which positively impacts on the ability of patients to receive effective pain management (Treede et al., 2019).

Nurses need an awareness of their own personal feelings toward pain (especially chronic pain) and the factors that affect pain if they are to assess and manage their patient's pain creatively and effectively. See Promoting Health 36-1 for a checklist of behaviors to foster one's self-awareness of comfort needs and pain.

Localization/Location of Pain

Pain can also be categorized according to whether it is generalized or localized (IASP, 2021). **Cutaneous pain** (superficial pain) usually involves the skin or subcutaneous tissue. A paper cut that produces sharp pain with a burning sensation is an example of cutaneous pain. Deep **somatic pain** is diffuse or scattered and originates in tendons, ligaments, bones, blood vessels, and nerves. Strong pressure on a bone or damage to tissue that occurs with a sprain causes deep somatic pain. **Visceral pain**, or splanchnic pain, is poorly localized and originates in body organs in the thorax, cranium, and abdomen. Visceral pain is one of the most common types of pain produced by disease, and occurs as organs stretch abnormally and become distended, ischemic, or inflamed (Norris, 2020). A reflex contraction or spasm of the abdominal wall, called guarding, may occur as a protective mechanism to prevent additional trauma to underlying structures. A person automatically tenses the abdomen when an acute abdominal pain condition is present. This prevents underlying tissues and organs from being palpated or touched.

Promoting Health 36-1

COMFORT

Use the assessment checklist to determine how well you are meeting comfort needs. Then, develop a prescription for self-care by choosing appropriate behaviors from the list of suggestions.

Assessment Checklist

☐ almost always ☐ sometimes ☐ almost never

☐☐☐ 1. Obtain a medical evaluation when acute or chronic pain is present.

☐☐☐ 2. Respect pain as the body's means of signaling that all is not well.

☐☐☐ 3. Control stress in the environment.

☐☐☐ 4. Avoid excessive fatigue.

☐☐☐ 5. Implement stress reduction or diversionary behaviors when pain is present.

☐☐☐ 6. Maintain awareness of personal preconceived notions that affect my perception of pain in others.

Self-Care Behaviors

1. I seek medical attention when pain persists.
2. I am aware of my usual behavioral responses to pain.
3. I use stress reduction techniques regularly.
4. I sleep well at night.
5. I have a positive outlook about my present situation.
6. I am aware of how to use distraction strategies to deal with pain.
7. I have a self-care management regimen I use if pain requires intervention.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

Think back to **Sheree Lincoln**, the woman who has had abdominal surgery. Sheree was most likely experiencing visceral pain prior to surgery when her internal organs were undergoing injury, and the pain was vague and poorly localized. However, the postoperative pain she is experiencing now is more likely somatic pain because, although it may still be deep pain, it is now localized to the injury and incision site.

Pain can originate in one part of the body but be perceived in an area distant from its point of origin. This is known as **referred pain**. For example, pain associated with a myocardial infarction (heart attack) frequently refers to the neck, shoulder, chest, or arms (often the left arm). Referred pain is transmitted and perceived at a site different from the originating location but is referred to a place innervated by the same spinal segment. Figure 36-3 (on page 1344) illustrates areas to which pain from various organs is usually referred.

Etiology

Pain also is classified by its cause, which can be highly varied. Cancer-related pain and pain associated with end of life or palliation is generally considered separate from the following general pain classifications, and guidelines for treatment are specific to those types of pain. **Nociceptive pain** is initiated by nociceptors that are activated by actual or threatened damage to nonneural tissue and is representative of the normal pain process (IASP, 2021; Norris, 2020). **Nociceptors** are the peripheral somatosensory nerve fibers that transduce and encode noxious stimuli (IASP, 2021). Nociceptive pain is different from **neuropathic pain**, which is pain caused by a lesion or disease of the peripheral or central somatosensory nervous system (IASP, 2021; Norris, 2020; Raja et al., 2020). The exact cause of neuropathic pain is unknown, but it can originate either peripherally (e.g., phantom leg pain) or centrally (e.g., pain from spinal cord injury). Neuropathic pain can be of short duration but frequently is chronic. It is often described as burning, electric, tingling, or stabbing. Allodynia is an unexpected pain response that occurs after the introduction of a stimulus that is not normally known to provoke pain. Other characteristics of this pain include hyperalgesia, in which there is an increased pain response to a normally painful stimulus, and hyperesthesia, in which there is an increase in the level of sensitivity to a stimulus (IASP, 2021). Numerous pain syndromes have been identified that produce neuropathic pain. Several common examples are included in Table 36-1 (on page 1344).

In addition to nociceptive and neuropathic pain, patients may experience a combination of those two types of pain (mixed) or may have pain that is real but has no clear evidence of actual or threatened tissue damage. Pain that is not classified as nociceptive or neuropathic in nature is referred to as **nociplastic pain** and is addressed in the classification of chronic primary pain (Raja et al., 2020). Appropriate treatment of these syndromes is often delayed as a result of misdiagnosis, and they can prove difficult to treat. Nursing can play an important role in their early detection.

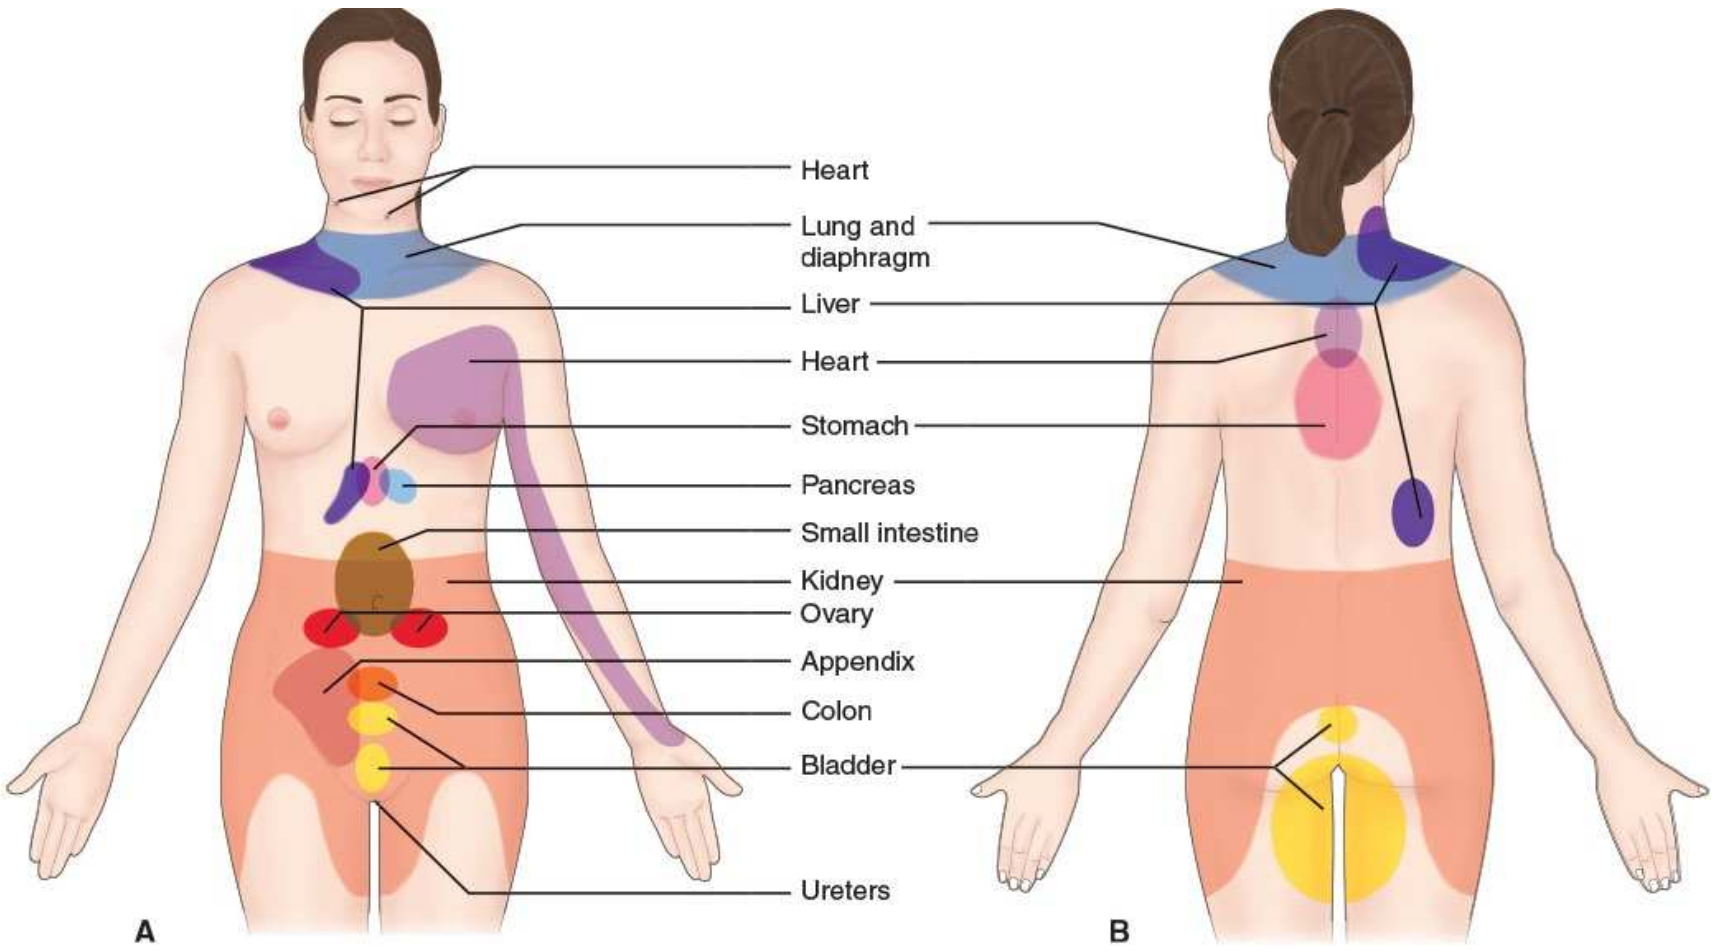

FIGURE 36-3. These drawings representing the anterior (**A)** and posterior (**B)** views of the body illustrate areas to which various organs refer pain.

Table 36-1 Common Pain Syndromes Producing Neuropathic Pain

PAIN SYNDROME	DESCRIPTION
Complex regional pain syndrome (causalgia)	This pain occurs in the area of a partially injured peripheral nerve (the most common lesions are of the brachial plexus or median or sciatic nerve). The pain is described as burning, severe, diffuse, and persistent and is elicited by minimal movement or touch of the affected area. It increases with repeated stimulation and continues even after stimulation ceases.
Postherpetic neuralgia	This pain syndrome follows an acute central nervous system infection, such as herpes zoster (shingles). The herpes syndrome is characterized by a vesicular eruption and neuralgic pain, which is usually unilateral and encircles the body in band-like clusters. The severity of the pain may be mild to severe. Intractable pain may persist for months to years.
Phantom limb pain	This pain may occur in any person who has had a body part amputated either surgically or traumatically. Pain varies and may be a severe, burning, fiery sensation; crushing; cramping; a sense that the limb is edematous; or a sensation that the limb is being twisted and distorted. It may be triggered by the sensation of touching the residual limb, the occurrence of another illness, fatigue, atmospheric changes, and emotional stress.
Trigeminal neuralgia	This manifests as sudden, violent, lightning-like stabs of intense pain in one or more divisions of the trigeminal nerve, the fifth cranial nerve. Pain is usually experienced in the mouth, gums, lips, nose, cheek, chin, and surface of the head and may be triggered by everyday activities such as talking, eating, shaving, or brushing one's teeth.
Diabetic neuropathy	This is a common complication of long-term diabetes. Metabolic and vascular changes result in damage to peripheral and autonomic nerves. Sensory loss can result when peripheral nerves are involved and eventually lead to injury progressing to infection and gangrene. Symptoms include sensations of numbness, prickling, or tingling (paresthesias).

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

When pain is resistant to therapy and persists despite a variety of interventions, it is referred to as **intractable**. Nurses and other health care providers need to determine the appropriate pain treatment for each case of intractable pain so that a person can regain a healthy quality of life.

The pain that often occurs with an amputated leg where receptors and nerves are clearly absent, is a real experience for the patient. This type of pain is called **phantom pain** or phantom limb pain and does not have an identifiable physiologic or pathologic cause. One theory suggests that sensory misrepresentations from the missing limb may remain in the brain, thereby causing phantom pain.

Box 36-1 Common Responses to Pain

Behavioral (Voluntary) Responses

Moving away from painful stimuli
Grimacing, moaning, and crying
Restlessness
Protecting the painful area and refusing to move

Physiologic (Involuntary) Responses

Typical Sympathetic Responses When Pain Is Moderate and Superficial

Increased blood pressure[a]
Increased pulse and respiratory rates[a]
Pupil dilation
Muscle tension and rigidity
Pallor (peripheral vasoconstriction)
Increased adrenaline output
Increased blood glucose

Typical Parasympathetic Responses When Pain Is Severe and Deep

Nausea and vomiting
Fainting or unconsciousness
Decreased blood pressure
Decreased pulse rate
Prostration
Rapid and irregular breathing

Affective (Psychological) Responses

Exaggerated weeping and restlessness
Withdrawal
Stoicism
Anxiety
Depression
Fear
Anger
Anorexia
Fatigue
Hopelessness
Insomnia and other sleep disturbances
Powerlessness

[a]An increase in vital signs may occur briefly in acute pain but may not occur when chronic pain is present.

Responses to Pain

Three types of responses to pain are physiologic, behavioral, and affective. Examples of these responses are listed in Box 36-1. The severity of pain and its duration affect responses to pain. Increases in vital signs may occur briefly in acute pain and may be absent in chronic pain states (Pasero & McCaffery, 2011).

Concept Mastery Alert

Physiologic responses are involuntary body responses; behavioral responses reflect body movements;

affective responses reflect mood and emotions.

Recall **Xavier Malton**, the child with ulcerative colitis experiencing an acute episode of pain. The nurse is initially able to assess that Xavier is in pain by his screams. In addition, the nurse interprets his behavioral and affective responses, such as his body posture, inability to get off the toilet, and later his fetal position in bed. Moreover, the nurse would validate these findings with physiologic responses such as skin color, muscle tension, and possibly vital signs.

Mild pain experienced briefly may produce little or no behavioral response; intense pain experienced briefly usually results in reflex action to escape the cause. The patient is often able to accept pain that continues for a relatively short time, such as for a few days or a week, without it being all-consuming. The patient expects relief and believes the cause is self-limiting, but may experience some level of anxiety. On the other hand, chronic pain tends to consume the entire person. It demands total attention so that the patient has limited resources to take care of other matters of daily living. It is physically and emotionally exhausting and is associated with ongoing irritability, isolation, fatigue, fear, anger, feelings for helplessness, stress/anxiety, and depression (LeFort et al., 2021). Lack of an obvious response to pain does not mean the patient is without pain. Careful assessment is especially important to understand what the patient is experiencing.

FACTORS AFFECTING THE PAIN EXPERIENCE

Pain is a highly personal experience. Many factors influence the comfort status of a person at any given moment. When a person experiences pain, almost anything can influence how the painful stimulus is transmitted to the brain, how it is perceived, and the actual response. A biopsychosocial (BPS) model introduced in the late 1970s by Engel (1977) extended the existing biomedical model to consider the dynamic interaction between: (1) biological factors associated with the condition, including developmental and genetic components; (2) social influences of relationships, as well as cultural, situational, and adaptive factors; and (3) psychological influences of personality, coping skills, mental health, and past experiences. The BPS model was originally designed for psychiatry as a way to reframe research, teaching, and health care (Engel). Despite criticism, the model has been used, adapted, and extended to drive assessment and management of pain and suffering in many populations (Bolton & Gillett, 2019; Matteliano et al., 2014; Miaskowski et al., 2020; Murphy et al., 2020; Pickering et al., 2018).

Table 36-2 Additional Terms Used to Describe Pain

TERM	DESCRIPTION
Quality	
Sharp	Pain is stabbing in nature and intense.
Dull	Pain is not as intense or acute as sharp pain, possibly more annoying than painful. It is usually more diffuse than sharp pain.
Diffuse	Pain covers a large area. Usually, the patient is unable to point to a specific area without moving the hand over a large surface, such as the entire abdomen.
Shifting	Pain moves from one area to another, such as from the lower abdomen to the area over the stomach.
Other terms used to describe the quality of pain include sore, stinging, pinching, cramping, gnawing, cutting, throbbing, shooting, and vise-like pressure.	
Severity	
Severe or excruciating	These terms depend on the patient's interpretation of pain.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

Moderate Slight or mild	Behavioral and physiologic signs help assess the severity of pain. On a scale of 0–10, slight pain could be described as being between 1 and 3; moderate pain, between 4 and 7; and severe pain, between 8 and 10.
Periodicity	
Continuous	Pain does not stop.
Intermittent	Pain stops and starts again.
Brief or transient	Pain is intermittent and passes quickly.

A person learns what causes unpleasantness and what to interpret as pain. Each person's interpretation is influenced by background, such as how they have experienced and dealt with pain in the past, and what culture has taught the person about pain. Through past experiences, each person also learns to differentiate among the various types of pain and to associate pain with certain descriptive words. Table 36-2 lists common definitions for additional terms used by patients to describe pain.

Cultural and Ethnicity Variables

Cultural norms, or social norms, dictate much of our daily behavior, attitudes, and values. Therefore, it is natural that culture influences the person's response to pain. Ethnicity is a broad term that has many facets. Ethnicity generally refers to the social, religious, political, cultural, and/or psychological characteristics of a group of people that are maintained generation to generation. These characteristics provide a sense of identity and are rooted in ancestry, nationality, language, and a shared set of beliefs and values; sociocultural and environmental factors that are influenced by geographic location also need to be considered (Kim et al., 2020). Despite the understanding that the terms *ethnicity* and *race* do not capture all the complex factors that impact on the health or pain experience of people, they provide a means for: (1) beginning to describe the diversity present in the United States, (2) collecting complete data that can be shared across systems, and (3) developing a comprehensive picture of health care quality (Agency for Healthcare Research and Quality [AHRQ], 2018).

Nurses must appreciate that a patient's response to pain is based on a host of experiences and factors, and therefore requires an individualized plan of care. For example, one patient may present with a calm, objective, matter-of-fact approach to pain, while another patient may present with loud vocalizations, an emphasis on their unique experience, physical movements, and demands for relief. Both patients are experiencing pain. It is particularly important to avoid stereotyping responses to pain because the nurse frequently encounters patients who are either in pain or anticipating that it will develop. A form of pain expression that is frowned on in one culture may be desirable in another cultural group. For example, enduring pain stoically is a sign of strength among some groups (Cancio, 2020; Purnell, 2013). Be knowledgeable about cultural variations and develop an understanding of cultural influences on pain tolerance, expressions of pain, and alternative practices used to manage pain. Health care providers demonstrate respect and cultural humility if they acknowledge the potential effects of culture and ethnicity on the pain experience. Intentionally involve your patient in the pain assessment by asking questions and taking care to not make assumptions or generalizations based on ethnicity or race. It is important to note that the mixed ethnic heritage that is common in many patients today makes it more difficult to anticipate individual responses to pain based on their ethnicity. Asking direct questions regarding pain experiences, expectations, and management will serve you well when dealing with patients from any background.

QSEN PATIENT-CENTERED CARE

Intentionally involve your patient in the pain assessment, taking time to appreciate the potential effects of culture and ethnicity, without making assumptions or generalizations about the patient's individual pain experience.

By 2044, it is projected that more than half of all Americans will belong to a minority group, with the non-Hispanic White population comprising only 44% of the population of the United States (Colby & Ortman, 2015). This more diverse population will include people from many different ethnicities, who may express themselves in many different languages. This poses potential challenges for pain assessment and management. When the patient's language differs from that of the nurse, the nurse runs the risk of misinterpreting the patient's level of pain. For example, there are nuanced differences between the term *pain*, which usually describes the most severe discomfort, and *ache*, typically used to describe a dull, less severe type of discomfort. Communication is the cornerstone of a nurse's subjective assessment and associated teaching. Perceived and actual barriers to verbal and written communication should be considered and directly addressed with appropriate tools and resources including information sheets in different languages and the use of medical interpreters. It is important to remember that the greater the language differences or barriers, the poorer a

patient's pain is controlled (Purnell, 2013).

Even though culture and ethnicity affect a patient's behavioral response to pain, consistent pain assessment is possible. Pain assessment tools have been translated into multiple languages and some assessments have empirical support for their "use across race/ethnicity and sex" (Rogers et al., 2020, p. 818). Pain rating scales are discussed later in this chapter.

Social determinants of health greatly impact on pain management outcomes. Recent research has confirmed that those who reside in low-income settings (Newman et al., 2018) and minority populations are less likely to receive the recommended treatments for pain in health care settings (Beletsky et al., 2021; Kim et al., 2020). Although pain is undertreated in the general population, minority patients often experience pain for a lengthy period of time before seeking treatment for it. There tends to be a disconnect between patients' beliefs, values, health behaviors, and individual preferences and what is available to them in the conventional/dominant health care system. Geographic location (whether a remote rural or densely populated urban setting) where physical barriers limit travel or where resources are lacking can also negatively impact on pain assessment and treatment. Language barriers, culturally inappropriate pain assessment tools, and prejudice and misconceptions may contribute to unsatisfactory pain outcomes. There is agreement that health care providers need to be aware of these inequities and make a concerted effort to confront these disparities (Beletsky et al., 2021; Newman et al., 2018; Purnell, 2013). Initiatives to address health care access and treatment disparities begin at the local and community level. Additional information on cultural influences on pain is presented in Chapter 5.

QSEN ENSURING HEALTH EQUITY

Initiatives to address treatment disparities and advance health equity begin at the local or community level, where assessments and interventions have a direct impact on the health-related social, policy, and economic needs of these vulnerable populations (National Academies of Sciences, Engineering, & Medicine, 2017).

Family, Biological Sex, Gender, and Age Variables

Other culturally related variables are family, biological sex, gender, and age. A person's response to pain or symptoms may be affected or influenced by the response of family members. Spouses also may reinforce pain behavior in their partners. Children growing up in different families may learn to *be brave* and ignore pain, or to use the pain experience to secure attention and service from caregivers. Family size and birth order do not appear to be significant in distinguishing those who suffer from chronic pain.

Similarly, children may learn that there are gender differences in pain expression. It may be acceptable for a little girl to run home crying with a scraped knee, but a little boy may be told that he should be brave and not cry. Adult men and women may hold on to gender expectations regarding pain communication and incorrectly interpret the presence or absence of pain expressions in others. Women are more comfortable communicating the discomfort associated with pain, but this ability to verbalize may cause some to view the pain as emotionally or psychologically based. Data suggest that there may be a biologic component to pain responses as well. The American Society of Anesthesiologists (2016) performed a review of the literature to describe the chronic pain experienced by females and discuss options to manage this pain. The triggers, experience of pain, recommended anesthesia, and other coping strategies may vary by biological sex and require more exploration.

In addition, different age groups have different beliefs and norms regarding pain sensation and response. At one time, the infant's inability to communicate pain led health care practitioners to the erroneous assumption that pain sensation was diminished or absent. More recently, it has been demonstrated that infants and small children are sensitive to and experience pain. Conditions normally painful in young adults (e.g., myocardial infarction) may result in minimal pain reports from older adults. An older adult not reporting pain may indicate that the person fears the treatment for the pain, the pain is dulled based on processes inherent in normal aging or chronic disease progression, or the older adult simply refuses to give in to the pain. For many older adults, pain has become accepted as a daily occurrence and is regarded as part of the normal aging process. Because of this false assumption, health care providers have often ignored or undertreated pain in older adults. These variables, which influence pain sensation, perception, and response, make pain assessment a complex task for the nurse.

Religious Beliefs and Spirituality

Religious beliefs can be a powerful influence on the person's experience of pain. In some religions, people view pain and suffering as a *lack of goodness* in themselves. Thus, pain and suffering are viewed as a means of purification or of making up for individual and community sin. This meaning helps the person to cope with pain, thus becoming a source of strength. Patients with this belief may refuse analgesics and other pain relief measures, feeling that this lessens their suffering. On the other hand, illness and pain may also be viewed as punishment from a vengeful God. People may find their faith shaken and question the existence of a loving God. Persistent pain, disability, and suffering can enhance

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

spiritual awareness or may lead to anger and frustration. Spirituality includes a search for meaning in life and underpins many of the treatments identified as effective for managing addiction, such as the 12-step program identified by Alcoholics Anonymous. Recognizing these religious or spiritual manifestations as part of the biopsychosocial model provides patients and nurses space to recognize vulnerabilities and address intrinsic and extrinsic factors of pain and addiction (Matteliano et al., 2014). Patients may find it helpful to confer with a spiritual adviser about their pain experience.

Environment and Support People

A person's environment and the presence or absence of caring support people may also influence the experience of pain. Many people find that the strangeness of the health care environment, especially the lights, noise, lack of sleep, and constant activity of a critical care unit, compounds the experience of pain. The sense of powerlessness that accompanies admission to a health care facility may decrease the person's ability to cope with pain.

Recall **Sheree Lincoln**, the postoperative patient in pain described at the beginning of the chapter. In addition to the pain related to surgery, the nurse would need to assess the effect of the environment on Sheree's pain. For example, she may be frightened by equipment being used postoperatively. In addition, she may feel alone and powerless due to her current condition. Assessment also would need to include information about past experiences with pain, support people available, and teaching she received preoperatively.

Depersonalization or separation from a favorite pillow, pet, or source of music may further decrease the person's sense of comfort. For some, the presence of a loved family member or friend is essential to their sense of well-being. Others prefer to be alone when in pain and may become agitated in the presence of a family member.

Some patients may use their pain to acquire secondary gains, such as special attention and services from their families. If unchecked, this tendency may lead to resentment and anger in family members and their eventual avoidance of the patient. Intervening and attempting an honest discussion of this problem is important.

Anxiety and Other Stressors

Anxiety, which is almost always present when pain is anticipated or being experienced, tends to increase the perceived intensity of pain. The threat of the unknown is ordinarily more devastating and anxiety-producing than a threat for which one has been prepared. Many studies have focused on the relationship between anxiety and pain (Rogers et al., 2020), or depression and pain. In chronic or persistent pain specifically, depressive symptoms are interrelated and often provide the impetus for seeking treatment (Kim et al., 2020; Newman et al., 2018).

Although a cause-and-effect relationship has not clearly been verified, pain may be aggravated with anxiety, muscular tension, and fatigue. The rested and relaxed person can often cope with more discomfort than someone who is suffering from a lack of sleep.

Think back to **Carla Potter**, the woman experiencing complications from her diabetes. She also reports feeling stressed, fearful, and anxious over her constant pain and likely progression of her disease. In order to individualize her care plan, the nurse needs to gather additional data and investigate the possibility of specific measures that may effectively empower Carla Potter to reduce some of the anxiety and fear she reports.

A person who is greatly fatigued and who has no competing demands requiring their attention may experience pain more acutely. For example, many people have discovered that the pain of a foot ache or an ingrown toenail that was only mildly annoying during the day's work becomes unbearable at night when there is nothing else to distract the mind from the pain.

Past Pain Experience

A person's experience of pain in the past and the qualities of that experience profoundly affect new pain experiences:

- Some patients have never known severe pain and have no fear of pain, not realizing how intense the sensation can be.
- Some patients have experienced severe acute or chronic pain in the past but received immediate and adequate pain relief. These patients are generally unafraid of pain and initiate appropriate requests for assistance.
- Some patients have known severe pain in the past and were unable to secure relief. Even the suggestion of new pain can lead to acute feelings of fear, despair, and hopelessness.
- A person whose past pain experience led to correction of unhealthy behavior and produced a greater sense of health and well-being, may respect and value pain and consider the meaning and significance of new pain carefully.
- In general, people who have experienced more pain than usual in their lifetimes tend to anticipate more pain and exhibit increased sensitivity to pain.
- Some pain memories are virtually unforgettable. New contact with conditions similar to those that caused the earlier pain can provoke a violent response.

NURSING PROCESS FOR COMFORT AND PAIN MANAGEMENT

Assessing

Because the pain experience is unique to each person, the nurse who wants to help the patient achieve comfort and pain control needs sophisticated pain assessment skills. Assessing all factors that affect the pain experience—psychological, sociocultural, spiritual, and physiologic—is essential. Pain is complex and difficult to interpret and requires a reliable assessment tool.

Routine Pain Assessment

In an effort to improve patients' quality of life and make pain management a priority, the American Pain Society (1995) encouraged caregivers to include assessment for pain as the fifth vital sign. Routine measurement of vital signs accompanied by a pain assessment was thought to raise awareness of the existence of pain, place additional emphasis on optimizing pain relief, and move patients more quickly toward comfort and recovery. However, this framing led to the problematic interpretation that pain needed to be assessed *every* time vital signs were taken on *every* patient. This phrasing was removed from the Joint Commission Accreditation Standards in 2004 (Baker, 2017). Current emphasis is on pain assessment and management of acute and chronic pain that is individualized and includes recognition, management, and referral of patients with addiction (Baker, 2017). Effective pain management should be implemented and evaluated by the interprofessional team and the patient, not measured solely with patient satisfaction surveys or a numeric score on a pain scale. Realistic pain management goals need to be set with each patient.

Common Misconceptions

Many patient misconceptions interfere with the patient's ability to communicate pain. Some of these instances can lead to undertreatment of pain. It is important to assess for the following common patient beliefs related to pain and communicating it:

- The doctor has prescribed pain-relieving medication for me, which I will be given routinely.
- If I ask for something for my pain, I will immediately become addicted to the medication.
- Sometimes it is better to put up with the pain than to deal with the side effects of the pain medication.
- I should somehow be able to control my pain. It is immature to talk about pain.
- It is better to wait until the pain gets really bad before asking for help. If I take the medication now for moderate pain, it won't relieve severe pain later on.
- I don't want to bother anyone—I know how busy everyone is.
- It's natural for me to have excruciating pain after surgery. After a few days, I should notice it lessening.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

Recall **Sheree Lincoln**, the woman who has undergone abdominal surgery. It would be important for the nurse to investigate Sheree's understanding of her postoperative pain and what her expectations are. Doing so would provide clues for the nurse indicating possible patient misconceptions about pain and pain relief, thereby providing a basis for teaching and correcting these misconceptions.

Components of a Pain Assessment

The nurse will generally assess the following characteristics of pain:

- Patient's initial verbalization and description of the pain
- Onset of the pain: etiology or mechanism of injury (if known)
- Duration of the pain
- Location of the pain: localized, generalized, radiation
- Quality and character of the pain
- Intensity: severity of the pain
- Aggravating or causal factors: what triggers or makes it worse
- Alleviating/relieving factors: what makes it better
- Other contributing or related factors: anxiety, fear, depression, insomnia
- Effect on function: activities of daily living, recreation, work, quality of life
- Pain management goal

When assessing a person's pain, Pasero and McCaffery (2011) discuss these basic methods that are still relevant today:

1. Obtain the patient's self-report of pain.
2. Identify pathologic conditions or procedures that may be causing pain; consider physiologic measures (increased blood pressure and pulse). However, most research verifies that reliance on vital signs to indicate the presence of pain should be minimized. The absence of an increase in vital signs does not mean that pain is not present.
3. Consider patient behaviors that may indicate pain such as nonverbal behaviors (restlessness, grimacing, crying, clenching fists, protecting the painful area).
4. Take into account the report of a family member, another person close to the patient, or a caregiver who is familiar with the patient.
5. Attempt an analgesic trial and monitor the results.

Focused Assessment Guide 36-1 (on pages 1350–1351) suggests questions and approaches helpful in assessing pain factors.

Focused Assessment Guide 36-1

THE PAIN EXPERIENCE

THE PAIN EXPERIENCE

Factors to Assess	Questions and Approaches
Characteristics of the pain	
Location	*Where is your pain? Is it external or internal?* Asking the patient with acute pain to point to the painful area with one finger may help to localize the pain. Patients with chronic pain may have difficulty trying to localize their pain.
Severity	Ask the patient to indicate the degree (amount) of pain currently experienced on the following scale: 0 1 2 3 4 5 6 7 8 9 10 No pain — Mild pain — Moderate pain — Severe pain — Pain as bad as it can be Note that it is important to give patients *zero/no pain* as an option. It is also helpful to ask how much pain the patient has (on the same scale) when the pain is at its least and at its worst: Least _____ Worst _____
Quality	*What words would you use to describe your pain?*
Duration	*How long have you been experiencing pain? How long does a pain episode last? How often does a pain episode occur?*
Aggravating or causal factors	*How does the pain develop and progress? Has the pain changed since it first began? If so, how? What makes the pain occur or increase in intensity?* If pattern can be identified, interventions early in a pain sequence will often be far more effective than those used after the pain is well established.
Alleviating factors	*What makes the pain go away or lessen? What methods of relief have you tried in the past? How long were they used? How effective were they?* Pharmacologic and nonpharmacologic methods of relief currently in effect for hospitalized patients should be apparent from the chart. It is important to verify the use of current prescriptions and their effectiveness with the patient. Outpatients may need to be asked to record a medication profile, a thorough and accurate account of all medications they are taking.
Contributing or related factors	*Are there any other factors that seem to relate consistently to your pain? Any other symptoms that occur just before, during, or after your pain?*
Physiologic responses	
Vital signs (blood pressure, pulse, respirations) Skin color Perspiration Pupil size Nausea	Signs of sympathetic stimulation may occur with acute pain but need not be present to verify the presence of pain. Signs of parasympathetic stimulation (decreased blood pressure and pulse, rapid and irregular respirations, pupil constriction, nausea and vomiting, and warm, dry skin) may occur, especially in prolonged, severe, visceral, or deep pain.
Muscle tension	Observe. Is the patient aware of any tight, tense muscles?
Anxiety	Are signs of anxiety evident? May include decreased attention span or ability to follow directions, frequent asking of questions, shifting of topics of conversation, avoidance of discussion of feelings, acting out, or somatization (physical symptoms arise from emotional or psychological distress).
Behavioral responses	
Posture, gross motor activities	Does patient rub or support a particular area? Make frequent position changes? Walk, pace, kneel, or assume a rolled-up position? Does patient rest a particular body part? Protect an area from stimulation? Lie quietly? In acute pain, postural and gross motor activities are often altered; in chronic pain, the only signs of change may be postures characteristic of withdrawal.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

Facial features	Does the patient have a pinched look? Are there facial grimaces? Knotted brow? Overall taut, anxious appearance? A look of fatigue is more characteristic of chronic pain.
Verbal expressions	Does the patient sigh, moan, scream, cry, or repetitively use the same words?
Affective responses	
Anxiety	*Do you feel anxious? Are you afraid? If so, how bad are these feelings?*
Depression	*Do you feel depressed, down, or low? If so, how bad are these feelings? Are your feelings about yourself mostly good or bad? Do you have feelings of failure? Do you see yourself or your illness as a burden to those you care about?*
Interactions with others	How does the patient act when in pain in the presence of others? How does the patient respond to others when not in pain? How do significant others and caregivers respond to the patient when the patient is in pain? When the patient is not in pain?
Degree to which pain interferes with patient's life (use past performance as baseline)	*Does the pain interfere with sleep? If so, to what extent? Is fatigue a major factor in the pain experience? Is the conduct of intimate or peer relationships affected by the pain? Is work function affected? Participation in recreational–diversional activities?* An activity diary is often helpful—sometimes crucial. One to several weeks of hourly activity recorded by the patient may be necessary. Levels of pain, intake of food, and sleep–rest periods are noted along with activities performed. Separate diaries for inpatient and outpatient episodes may be necessary because hospitalization markedly affects the nature and type of activities performed.
Perception of pain and meaning to patient	*Are you worried about your illness? Do you see any connection between your pain and the nature or course of illness? If so, how do you see them as related? Do you find any meaning in your pain? If so, is this beneficial or detrimental to you? Are you struggling to find some meaning for your pain?*
Adaptive mechanisms used to cope with pain	*What do you usually do to relieve stress? How well do these things work? What techniques do you use at home to help cope with the pain? How well have they worked? Do you use these in the hospital? If not, why not?*
Outcomes	*What would you like to be doing right now, this week, this month, if the pain were better controlled? How much would the pain have to decrease (on the 0–10 scale) for you to begin to accomplish these goals? What is your pain goal (on the 0–10 scale)?* Keep in mind that NO pain may not be an option for some patients. Helping them to identify a realistic goal promotes effective pain management.

Concept Mastery Alert

Assessment of pain requires information from a variety of sources. However, patients are the experts on their pain, and their ratings and descriptions of the pain are very important.

Various forms used to help guide the assessment of pain have been described in the nursing literature. The primary purposes of using a guide to assess pain are to: (1) eliminate guesswork and biases when dealing with the patient's pain; (2) appreciate what the person is experiencing; (3) analyze findings that will help prepare an appropriate nursing response to the patient's pain; and (4) facilitate improved outcomes, such as fewer complications, shorter hospital stays, and improved quality of life.

For continued assessment of pain and evaluation of pain control measures, a pain scale allows the patient to rate pain experienced on a continual basis. A numerical pain scale that is currently the national standard is displayed in the Focused Assessment Guide 36-1. This scale is best for use with verbally communicative patients.

Do not overlook pain in patients who have difficulty with communication. Their pain requires adequate treatment. Examples of pain rating scales that can be used with patients who are nonverbal or have difficulty communicating verbally include the Behavioral Pain Scale (BPS) for use with critically ill patients who are intubated, and the Face Legs Activity Cry and Consolability (FLACC) pain scale for use with infants and young children (from ages 2 months to 7 years) and in children with cognitive impairment. Information about these pain-rating scales is included in Table 36-3 (on page 1352). The range of available scales and instruments allows the nurse or other interprofessional team member to choose a tool that is developmentally appropriate for each individual. Whichever tool is used, it is best to use the same tool to rate a patient's pain throughout a hospital stay.

A comprehensive pain assessment must also include discussion of the patient's expectations for pain relief. The patient and health care team need to set a realistic goal or a number on the pain scale that is acceptable and facilitates recovery. For example, it may not be possible to have a pain rating of zero after a surgical procedure when the movement required to prevent complications naturally causes some pain or discomfort. Having this conversation and setting a realistic, mutually agreed upon goal facilitates the patient's recognition and report of pain that is unacceptable. Setting pain management goals also provides the nurse the opportunity to establish rapport, discuss individualized pain management interventions, and evaluate the plan with the patient and caregivers.

Assessment of Special Populations

Pain rating scales attempt to confirm and, if possible, quantify the presence of pain in a variety of populations and situations. Alternative approaches to pain assessment for special populations ensure that unacceptable levels of pain are addressed and treated. For example, a nurse caring for a patient in an intensive care unit would use a valid and reliable pain assessment tool that considers the unresponsive and/or noncommunicative status of the patient. Recommended tools for critically ill patients unable to self-report pain include the Behavioral Pain Scale (BPS) and Critical-Care Pain Observation Tool (CPOT; see Table 36-3). Pain is common in critically ill patients when they are at rest, during routine care related to activities of daily living, and with the performance of specific procedures. Untreated severe pain negatively affects critically ill patients; consistent, routine assessment and intervention should guide pain management. Pain should be treated in patients in the intensive care unit before a sedative agent is considered (Devlin et al., 2018).

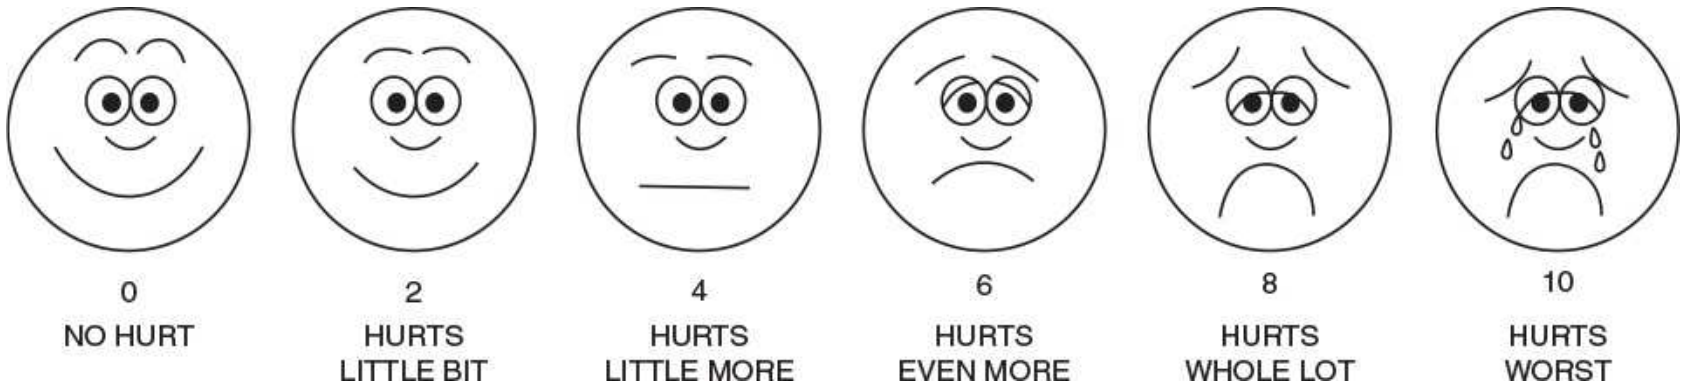

FIGURE 36-4. Wong–Baker FACES pain rating scale. Instructions: Explain to the person that each face is for a person who feels happy because he has no pain (hurt) or sad because he has some or a lot of pain. *Face 0* doesn't hurt at all. *Face 2* hurts just a little bit. *Face 4* hurts a little more. *Face 6* hurts even more. *Face 8* hurts a whole lot. *Face 10* hurts as much as you can imagine, although you don't have to be crying to have this worst pain. Ask the person to choose the face that best describes how much pain they have. Rating scale is recommended for people ages 3 years and older. (*Source:* ©1983 Wong-Baker FACES Foundation. ww.WongBakerFACES.org. Used with permission.)

CHILDREN

In recent years, health care personnel have become much more concerned about addressing pain and pain relief in infants and children. At one time, it was believed that young children lacked the neurologic development to sense pain the way adults do. Thus, pain relief was not a priority when children were hospitalized. Young children frequently received no treatment for pain for medical or surgical procedures during their entire hospital stay. Yet, infants, particularly premature infants, are as sensitive to painful stimuli as older children and adults.

Chronic pain in children represents a significant public health problem nationally and globally; there is the potential for significant impact on the child's social, emotional, and physical development and functional abilities. Family members and caregivers are also deeply affected. Chronic pain management in children requires an individualized, **multimodal approach** (using two or more different methods or medications to manage pain) that is collaborative, represents best practice, and is integrated (World Health Organization [WHO], 2021).

Current methods of assessing and measuring children's pain frequently involve use of more than one technique for assessment. A pain history provides information about the language the child uses to indicate pain, how and to whom this pain is usually reported, and indications of previous pain experiences and coping strategies. Self-report by the child is usually the most reliable account of pain. Communication with parents, guardians, or other people important to the patient is also vital for accurate pediatric pain assessment and management. In addition, the following observations may provide an indication of the presence and severity of pain in a child:

- Irritability and restlessness
- Crying, screaming, or other verbal expression of pain
- Grimacing, grinding of teeth, or clenching fists
- Touching or grabbing of painful body part
- Kicking, thrashing, or attempting to move away from a painful stimulus

Numerous scales and tools can be used to assess a child's pain. One commonly used pain assessment scale, the Wong–Baker FACES Pain Rating Scale (Fig. 36-4), asks children to compare their pain to a series of faces ranging from a broad smile to a tearful grimace. The Oucher Pain Scale, developed by Beyer et al. (1992) for use in young patients, combines a 0-to-100 scale with six photographic images of children in pain. This scale is helpful for use with older children. Adaptations of the Oucher pain scale are also available for various ethnic groups.

The CRIES Pain Scale is a tool intended for use with neonates and infants from ages 0 to 6 months. The COMFORT Scale, used to assess pain and distress in critically ill pediatric patients, relies on six behavioral and two physiologic factors that determine the level of analgesia needed to adequately relieve pain in these children. The FLACC Scale (F—Faces, L—Legs, A—Activity, C—Cry, C—Consolability), designed for infants and children from ages 2 months to 7 years who are unable to validate the presence or severity of pain, rates each of the five categories on a 0-to-2 scale. In addition, children may be asked to record their pain experiences in a daily diary. Detecting and accurately assessing pediatric pain have resulted in new and innovative approaches toward pain control in children.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

Think back to **Xavier Malton**, the 5-year-old with acute pain. Incorporating the use of an age-appropriate pain assessment tool would be crucial in assessing Xavier's pain. Because Xavier is 5 years old, he may have difficulty describing his pain and its severity. For example, according to Xavier, "Something was hurting very much." Using the FACES Scale or the Oucher Scale would help the nurse to quantify the severity of Xavier's pain, providing objective evidence from which to intervene appropriately. The tool also would be extremely useful in determining the effectiveness of pain relief interventions, providing objective evidence denoting any changes in the pain's severity. This evaluation would serve as a basis for continuing pain management.

PATIENTS WITH COGNITIVE IMPAIRMENT

Assessment of pain in people with cognitive impairment presents special challenges to nurses. It is generally recognized that people with cognitive impairment are frequently undertreated, which raises concerns regarding the treatment of vulnerable populations. In order to manage their pain effectively, an accurate assessment of their pain is imperative. Work must continue to be done to improve pain management for patients with cognitive impairment and residents of long-term care facilities (Fain et al., 2017). Nurses must also consider the potential negative impact of pain on cognitive function, specifically the impact of high levels of chronic pain on the development of memory impairment in older adults (van der Leeuw et al., 2018).

To manage pain effectively, nurses must rely on their own careful assessments, their empathic qualities, and the expectation that a patient with cognitive impairment will experience pain if a verbal patient usually reports this event as painful. Some common behaviors that can be assessed for indicators of pain in this population include (Pasero & McCaffery, 2011):

- Facial expressions
- Verbalizations and vocalizations
- Body movements
- Changes in interpersonal interactions
- Changes in activity patterns or routines
- Changes in mental status, such as agitation and aggression

The combination of a history of pain, observations of a patient's pain by families and caregivers, and the presence of medical diagnoses associated with pain also facilitates pain assessment in this population. Moreover, special efforts are needed to identify accurate methods for assessing pain in this population. The Pain Assessment in Advanced Dementia (PAINAD) Scale has been developed to assess pain in this population. It relies on observation of five specific items: breathing, vocalization, facial expression, body language, and consolability (Warden et al., 2003). Refer to Table 36-3 for additional information regarding the PAINAD scale.

OLDER ADULTS

Assessing pain in the older adult population can be challenging. Adults older than age 65 years experience pain more frequently than do younger adults. Up to 50% of older adults who live in the community and at least half of those who live in long-term care facilities report pain on a daily basis (Galicia-Castillo & Weiner, 2021). Pain negatively impacts the emotional well-being, functional ability, sleep, coping, and resources of older adults. Physiologic changes in older adults affect their sensation of pain and the pharmacokinetics and pharmacodynamics considerations of pain medications. Polypharmacy, especially with comorbidities, cognitive function, and misconceptions regarding pain and older adults influence decisions regarding multimodal pain management regimens (Rajan & Behrends, 2019). Although pain is not a normal part of aging, it is one of the most common health conditions in older adults and is associated with significant disability, primarily related to changes in mobility (Schwan et al., 2019).

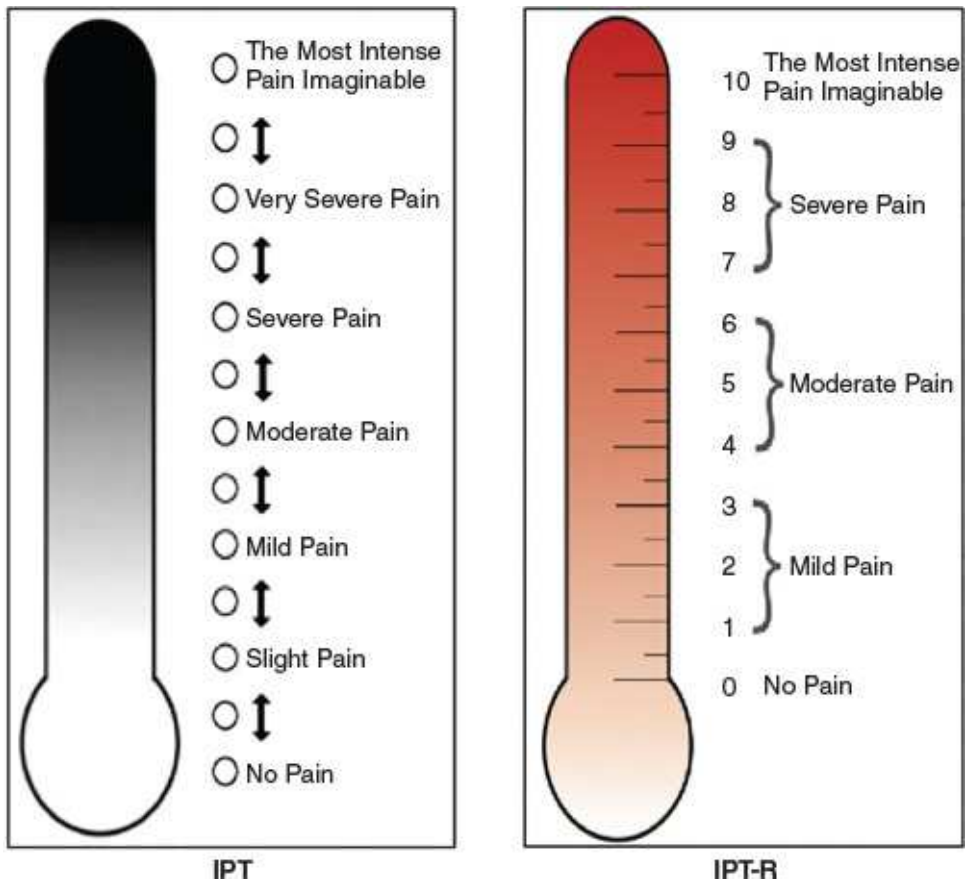

FIGURE 36-5. Iowa pain thermometer (IPT) and IPT-R (revised). (*Source:* Reprinted from Ware, L. J., Herr, K. A., Booker, S. S., Dotson, K., Key, J., Poindexter, N., Pyles, G., Siler, B., & Packard, A. [2015]. Psychometric evaluation of the Revised Iowa Pain Thermometer [IPT-R] in a sample of diverse cognitively intact and impaired older adults: A pilot study. *Pain Management Nursing*, *16*[4], 475–482. http://dx.doi.org/10.1016/j.pmn.2014.09.004, Copyright [2015], with permission from Elsevier.)

Assessment of pain in the older adult can be problematic. Vision or hearing impairments may influence the assessment format. Multiple-drug regimens that are common in older people can also affect reliable reporting of pain. Many older adults view pain as a forecast of serious illness or death and thus are reluctant to admit its occurrence or report it. Boredom, loneliness, and depression may affect an older adult's perception and report of pain.

Experts agree that pain is best assessed using a comprehensive pain assessment that includes using a standardized tool, determining the impact of chronic pain on functional status (mood, mobility, ADLs, sleep, weight changes, and cognitive status), identifying attitudes and beliefs, including family members and caregivers in the data-gathering phase, identifying resources, and reviewing comorbidities and medications (Rajan & Behrends, 2019; Schwan et al., 2019). Although the Numeric Rating Scale is the most commonly used standardized tool, the Wong–Baker FACES Pain Rating Scale (see Fig. 36-4) or Faces Pain Scale–Revised (FPS-R) may also be effective for this age group. Some research has indicated that older adults prefer a vertical pain scale such as the Iowa Pain Thermometer (IPT) or Revised Iowa Pain Thermometer (IPT-R) shown in Figure 36-5, rather than the horizontal numeric pain scales (Herr et al., 2007; Ware et al., 2015). Special attention and consideration of an older adult's pain can positively affect the nurse's ability to assess pain accurately.

Diagnosing Actual or Potential Health Problems and Needs

Pain is such a complex phenomenon that its analysis often requires interprofessional collaboration. Although nursing has much to offer people experiencing both acute and chronic pain, the data collected by the nurse during the comprehensive pain assessment benefit the patient most when shared with physicians and other members of the health care team.

Attempting to intervene before an accurate assessment has been completed may mask the underlying cause of the patient's pain. False assumptions may result in progression of symptoms and the disease process. For example, the nurse who notes a pattern of headaches in a patient and relates this to the patient's description of recent stress (divorce, relocation, new job), may erroneously determine that the headaches are merely stress-related and implement a plan of relaxation exercises. A more careful analysis of patient data, however, may indicate that the headaches are of vascular origin or migraine in nature, and warrant further medical intervention. The headaches may also be symptomatic of intracranial disease such as a brain tumor, in which case delay in diagnosis could decrease the possibility of treatment and cure.

When diagnosing an actual or potential health problem or need related to acute or chronic pain, the coordinated care plan should identify the following:

- Type of pain
- Etiologic factors, to the extent that they are known and understood
- Patient's behavioral, physiologic, and affective responses
- Other factors affecting pain stimulus, transmission, perception, and response

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

Pain or Chronic Pain as the Problem

Problems related to pain require a nuanced approach. The importance of identifying these problems and including them as priorities in the care plan cannot be overstated. See the accompanying box, Examples of Actual or Potential Health Problems or Needs: Patients Experiencing Pain or Discomfort.

Pain or Chronic Pain as the Etiology

Because the experience of pain affects so many other aspects of human functioning, pain may be the etiology of numerous other problem statements (Wolters Kluwer, 2020), including but not limited to:

- Ineffective airway clearance related to unwillingness to ambulate secondary to postoperative incisional pain
- Acute anxiety related to pain anticipation and inadequate pain management in the past
- Constipation related to chronic use of narcotic analgesics
- Altered health maintenance related to loss of will to live secondary to prolonged chronic pain
- Grief related to belief that present pain means imminent death
- Injury risk related to decreased pain sensation
- Fatigue related to lack of relief from chronic pain
- Fear related to possible significance of pain
- Sleep deprivation from inability to fall asleep related to pain worsening at night

Examples of Actual or Potential Health Problems and Needs

PATIENT EXPERIENCING PAIN

Actual or Potential Health Problem or Need	Possible Etiologic Factors	Potential Signs and Symptoms
Acute Pain	• Nociceptive pain: Postoperative recovery, sports or other injury, sickle cell crisis	• Patient's report and description of pain using a standardized instrument, scale, or methodology • Nonverbal expressions of pain: grimacing, wincing, guarding or bracing, rubbing • Physiologic changes in heart rate, respirations, and blood pressure
Chronic Pain	• Unresolved acute injury, neuropathic pain (involving the nervous system), or nociplastic pain (fibromyalgia, low back pain, headache)	• Patient's report and description of pain using a standardized instrument, scale, or methodology • Clinical course of pain • Functional changes: mood, mobility, ADLs, sleep, weight changes, and cognitive status • Associated symptoms: depression, anxiety, social isolation
Difficulty Coping With Pain	• Inadequate pharmacologic and nonpharmacologic therapy based on evidence-based practice • Fear of medication/drug dependence • Mental state, fatigue, social stigma, • Lack of support from family, caregiver(s), partner, friends, or interprofessional team	• Verbal expressions of coping difficulty, stress, or pressure • Refusal of or apprehension with engagement with pharmacologic and nonpharmacologic interventions • Other sequelae: lack of problem-solving skills, change in life situation, or physiologic decline

Source: International Council of Nurses (ICN). (2019). *Nursing diagnosis and outcome statements*. https://www.icn.ch/sites/default/files/inline-files/ICNP2019-DC.pdf; Wolters Kluwer. (2022). Problem-based

care plans. In Lippincott Advisor. Wolters Kluwer. https://advisor.lww.com/lna/home.do

- Psychosocial/spiritual needs related to belief that God is unfairly causing this pain as some sort of undeserved punishment
- Self-harm risk related to loss of will to live with unrelieved chronic pain

Outcome Identification and Planning

After the identification of a pain problem is made, developing and implementing a plan of care that demonstrates nursing's commitment to assist the patient in developing effective pain management strategies is crucial.

Nursing measures are directed toward the achievement of the following patient outcomes for people whose pain is acute in nature (i.e., it is expected that with healing the pain will subside and eventually disappear). The patient will:

- Describe a gradual reduction of pain, using a scale ranging from 0 (no pain) to 10 (pain as bad as it can be), clearly identifying numeric pain goals
- Demonstrate competent execution of successful pain management program (specify)

When pain or chronic pain is the etiology in a diagnosis or problem statement, outcomes will be specific to the underlying causes(s) and any functional changes associated with the pain.

For patients whose pain is chronic, an expected outcome may be contacting a center with expertise in pain management to explore options and develop a plan of care. Numerous practitioners and outpatient centers are available to support patients with chronic pain and to improve their pain management through a multimodal approach. Hospice care (also mentioned in Chapters 11 and 44) addresses the physical, spiritual, social, and economic needs of terminally ill patients and their families or caregivers in either the home or a hospice center. Pain relief is a priority in this setting. The provider, nurse, and other members of the health care team collaborate to develop the optimal pain management plan for each patient with chronic pain.

Implementing

After the care plan is developed, the nurse implements the nursing strategies that are most likely to assist the patient in achieving pain relief outcomes, whether at home or in a health care facility. Nursing interventions described in this chapter include establishing a trusting nurse–patient relationship, manipulating factors that affect the pain experience, initiating nonpharmacologic pain relief measures, managing pharmacologic interventions, reviewing additional pain control measures, ensuring ethical and legal responsibility to relieve pain, and teaching the patient about pain.

Through the Eyes of a Patient

I've always thought of myself as a "take charge" kind of person. It's important for me in my business to be calm and always in control of my emotions. The *big C* changed everything for me. A recent hospitalization made me take time to think about what's happening to me.

Even in the hospital, I had a steady stream of visitors—some friends and some business associates. Even the mayor stopped by to see me. For all of them, I was my usual self—smiling, joking, and acting as if everything was normal. I made sure I took my pain medicine before they came. I kept all my fears about cancer and dying hidden behind my smiling face. I never broke down—not even in front of my wife. Men aren't supposed to cry, you know.

One nurse's simple gesture changed all that. One evening after all my visitors, my wife, and my son had left, she must have sensed something. She came over, stood next to me, put her arm around my shoulders and quietly said, "You know, Bob, it's all right to cry." It was like the dam opened up. I looked at her, my face cracked, and suddenly I couldn't stop sobbing. She must have known that I needed to talk about what was happening to me. I needed to say those words out loud to someone—"I'm afraid the pain will get too bad. I'm afraid of dying. I can't let my family see me this way!" She just let me cry, kept holding my hands, and just by being there and listening, helped me at that moment in ways that you will never know.

Establishing a Trusting Nurse–Patient Relationship

Most patients with pain feel better, suffer less, and experience less anxiety when they believe that a competent nurse cares about their experience of pain and is available for help and support. Without the confidence developed in a good nurse–patient relationship, fear and apprehension can make the patient feel like nothing seems to work. A good working relationship can increase the efficacy of basic nursing interventions. Measures that help strengthen the nurse–patient relationship and promote pain relief include discussing pain with the patient, setting pain goals together, listening to the patient about their preferred method of pain relief, and being intentionally present with the patient in pain. Being with them physically, psychologically, and spiritually, while focusing on their vulnerability and individual feelings, is one way we can provide holistic care that acknowledges their pain experience and improves their well-being. A provider's empathy, coupled with a patient's optimism, can positively impact on the chronic pain experience

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

and associated outcomes (Cánovas et al., 2018). These measures promote a collaborative relationship in which the patient's pain is treated with respect (see the accompanying box, Through the Eyes of a Patient).

Manipulating Factors Affecting the Pain Experience

There are many ways to manage pain (Chou et al., 2021; Chou et al, 2022). In addition to a holistic approach that includes pharmacologic and nonpharmacologic measures, simple nursing interventions can positively alter patients' pain experience and speed their recovery.

REMOVING OR ALTERING THE CAUSE OF PAIN

Removing or altering the cause of the pain is ideal and sometimes possible. Possible measures that promote comfort and help in pain relief include removing or loosening a tight binder, if permissible; assisting the patient in emptying a full bladder; taking steps to relieve constipation and flatus; changing body positions and ensuring correct body alignment; and changing soiled linens and dressings that may be irritating the skin. Providing a needed snack or drink may help the patient feel more comfortable.

Certain medications are useful for removing or altering the intensity of painful stimuli. For example, drugs that decrease smooth-muscle spasms in the GI tract and those that decrease contractions of skeletal muscles reduce discomfort.

ALTERING FACTORS AFFECTING PAIN TOLERANCE

Pain tolerance level is the maximum intensity of a stimulus that produces pain a person is willing to accept in a given situation (IASP, 2021). By performing an accurate pain assessment and establishing a trusting relationship, the nurse is better-able to identify factors that contribute to the patient's pain experience. Alleviate the identified contributing factors whenever possible. For example, patients who have never had their pain acknowledged or who have repeatedly been told that their pain is all *in their head* may experience a greater ability to deal with their pain when someone finally takes the pain seriously. Nursing measures include communicating to the patient that their individual response to pain is acceptable and providing education to the patient's family and caregivers. A discussion of goals and expectations regarding pain also increases the amount of control the person feels and can impact their ability to tolerate a certain level of pain at a given moment in time.

Fatigue tends to increase pain, so promoting rest is helpful. The patient in pain usually feels more comfortable when the environment is quiet and restful. Although sensory restrictions—such as eliminating unnecessary noise and bright lights—are usually indicated, it is rarely helpful to leave the patient alone in an environment with little sensory input. The patient is then more likely to focus on themself and the discomfort.

Lack of knowledge, finding no meaning in the pain, being pessimistic about its relief, and fear may also interfere with the patient's ability to deal with pain. Common fears include a loss of control and embarrassment by being unable to deal with the pain maturely. Another fear may be a fear of taking pain relief medication. Patients, especially older adults, may view the need for medication as a sign of weakness, may fear addiction, or may be concerned about the medication losing its effectiveness, which could impact on future pain management needs.

Initiating Complementary Health Approaches and Integrative Health Care

Although analgesics are usually the primary treatment measure for pain, a growing trend is seen involving integration of complementary health approaches (CHA) and integrative health care (IH) concepts. These nonpharmacologic interventions are varied—they can be practiced in all health care settings as part of a holistic pain management strategy. Refer to Chapter 29 for additional discussion of complementary and alternative relief measures.

USING DISTRACTION

Focused attention on pain may increase the perception of pain, whereas preoccupation with other things has been observed to decrease the experience of pain. Distraction requires the patient to focus attention on something other than the pain. It is not entirely clear whether distraction raises the threshold of pain or increases pain tolerance. Many patients whose pain is relieved by distraction report being able to place pain in the periphery of awareness. This is compatible with the theory that if the reticular formation in the brainstem receives sufficient sensory input, it can ignore or block out select sensations such as pain. The Lamaze method of childbirth is one common example involving the use of distraction.

Distraction alone may relieve mild pain. However, it is most effective when used before pain begins or soon thereafter. It has also been proven effective when used with analgesics for treatment of a brief episode of severe pain (e.g., pain that accompanies a diagnostic procedure). Distraction may also be used successfully with children.

Recall **Xavier Malton**, the child with ulcerative colitis who was in severe pain. The nurse could incorporate the use of nonpharmacologic measures for pain relief, such as distraction, to enhance the effectiveness of analgesics.

Techniques that distract attention include the following:

- Visual distractions: counting objects, reading, or watching TV
- Auditory distractions: listening to music
- Tactile kinesthetic distractions: holding or stroking a loved person, pet, or toy; rocking; slow rhythmic breathing
- Interactive video games
- Project distractions: playing a challenging game, performing meaningful play or work

EMPLOYING HUMOR

Humor can be an effective distraction, can help a person cope with pain, and may even have a positive effect on the immune system. It has been proven beneficial in relieving acute painful procedural pain in children. Many pain, cancer, and ambulatory care centers encourage patients to view humorous videos before a painful, tedious procedure (IOM, 2011). Laughter may indeed be the best medicine. The potential physiologic and psychological benefits of laughter are highlighted in Box 36-2 (on page 1358).

Remember to use humor only with patients who are responsive to its use and wish to use it. Humor should not be used with patients in moderate to severe pain, nor should it be a replacement for pharmacologic analgesia. In addition, humor must be patient specific. The nurse will need to determine what makes a patient laugh, how the patient has used humor or play in the past, and how it helped. Let the patient select the humorous materials, and when possible, incorporate strategies that include the patient's family and friends.

Box 36-2 **Therapeutic Effects of Laughter**

Laughter causes the following physiologic and psychological effects:

- Increases the pain threshold
- Reduces arterial wall stiffness and improves endothelial function
- Reduces the risk of myocardial infarction (MI); reduces recurrence after MI in diabetes
- Improves lung function in patients with chronic obstructive pulmonary disease (COPD)
- Improves glycemic control; impacts on obesity
- Improves the success rate of in vitro fertilization
- Associated with satisfaction and an increased quality of life

Source: Adapted from Femer, R. E., & Aronson, J. K. (2013). Laughter and MIRTH (methodical investigation of risibility, therapeutic and harmful): Narrative synthesis. *The BMJ*, *347*, f7274. https://doi.org/10.1136/bmj.f7274; Noureldein, M. H., & Eid, A. A. (2018). Homeostatic effect of laughter on diabetic cardiovascular complications: The myth turned to fact. *Diabetes Research and Clinical Practice*, *135*, 111–119. https://doi.org/10.1016/j.diabres.2017.11.014

LISTENING TO MUSIC

Listening to music can relax, soothe, decrease pain, and provide distraction. Music affects various neurotransmitters (such as epinephrine and norepinephrine), hormones (particularly cortisol), components of the immune system (especially with the cytokine interleukin-6), the autonomic nervous system (sympathetic and parasympathetic components), and psychological responses (Howland, 2016). Recent studies have confirmed that perioperative music therapy resulted in a decrease in postoperative pain, anxiety, and use of analgesics, with an increase in patient satisfaction (Hole et al., 2015; Kühlmann et al., 2018; Schneider, 2018). When used with patients experiencing self-reported chronic pain, there was also a decrease in depressive symptoms and other comorbidities associated with untreated pain (Garza-Villarreal et al., 2017). Acute pain guidelines recommend music and relaxation as interventions that, in combination with opioids, help to relieve moderate postoperative pain. Music therapy is a readily accessible

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

therapy that is not associated with significant adverse effects. It should be considered a viable, potential treatment for many patients, including those in pain. Specific best practice recommendations include: (1) using music before, during, and after surgical procedures; (2) identifying calming music (60 to 80 BPM); (3) playing music continuously during the procedure or surgical intervention; and (4) playing music for 15 to 30 minutes at least twice a day during the pre- and postoperative periods (Poulsen & Coto, 2018).

USING IMAGERY

Patients who use imagery (an example of mind–body interaction) to decrease pain sensation imagine something that involves one or all of the senses, concentrate on that image, and gradually become less aware of the pain. Imagery may be as simple as a child thinking of happy things (a beloved pet, lollipops, Christmas morning, Grandma's lap) or as involved as an adult recreating a favorite place and then experiencing the healing presence or touch of a loved person, or the healing energies of nature in that setting. The imagery technique has also been used to create an image in which the cause of the pain is visualized and then overcome or counteracted by some more powerful image.

Imagery has been found to be more effective for patients with chronic pain than for patients with acute, severe pain. General techniques for successfully guiding a patient to use imagery include the following:

- Help the patient to identify the problem or goal.
- Suggest that the patient begin the imagery with several minutes of focused breathing, relaxation, or meditation.
- Help the patient to develop images of the problem, as well as personal internal resources (e.g., coping strategies) and external healing therapies (e.g., medications, treatments).
- Encourage images of the desired state of well-being at the end of the session.

If the patient becomes restless or upset, the imagery experience is terminated and attempted later when the patient seems better disposed. Guided imagery is also discussed in Chapter 43. Technology provides the opportunity to augment imagery or guided imagery techniques using virtual reality (VR), a computer-generated environment that may involve a screen or head-mounted display (HMD). Although more research needs to be done to determine the effectiveness of VR in varied situations with different populations, there is the potential for incorporating this specific modality into the holistic approach to acute and chronic pain management (Chuan et al., 2021).

MINDFULNESS PRACTICE

Mindfulness practice requires intentional presence in a nonjudgmental, accepting way using techniques such as centering, relaxation, meditation, and breath work. Mindfulness-Based Stress Reduction (MBSR), an evidence-based practice, was formalized by Dr. Kabat-Zinn (1982) in the late 1970s as a strategy to manage chronic pain. Since then, mindfulness practices have evolved to include health care professionals, patients, and the general public in myriad situations, including those related to chronic illnesses, the opioid crisis, and the stress of COVID-19. MBSR is often compared to or considered in relation to cognitive behavioral therapy (CBT), a psychotherapeutic treatment focused on challenging unhelpful thought or behavioral patterns through education; cognitive restructuring of thoughts and beliefs; problem resolution; relaxation; and, ultimately, a behavioral change that involves engagement in meaningful activities (Hawk et al., 2020; Pardos-Gascón et al., 2021). Although the results are mixed, with some studies showing a reduction in depression, disability, and chronic pain after an MBSR intervention (Marske et al., 2020) and others highlighting little support for the efficacy in managing acute or chronic pain (Pei et al., 2021; Shires et al., 2020), mindfulness and related interventions have made their way into mainstream wellness discussions and are likely to continue to be used.

Research in Nursing

Bridging the Gap to Evidence-Based Practice

Examination of the Effects of Implementing a Nurse-Led Pain Program for Patients With Nonmalignant Chronic Pain

Pain regimens require interprofessional collaboration to support implementation of a multimodal approach to pain management. Although nurses require prescriptions or orders for medication administration, there are a number of educational and nonpharmacologic interventions that are nurse-driven and support a holistic approach to pain management.

Related Research

Morales-Fernández, Á., Jimenez-Martín, J. M., Morales-Asencio, J. M., Vergara-Romero, M., Mora-Bandera, A. M., Aranda-Gallardo, M., & Canca-Sanchez, J. C. (2021). Impact of a nurse-led intervention on quality of life in patients with chronic non-malignant pain: An open randomized controlled trial. *Journal of Advanced Nursing*, *77*(1), 255–265. https://doi.org/10.1111/jan.14608

This IRB-approved study used an experimental design, with the 279 participants randomly assigned to the usual care (n = 105) or intervention group (n = 174). The intervention consisted of an introductory one-on-one session, followed by six 90-minute weekly group sessions in which the 8 to 12 participants engaged in therapeutic dialogue and

educational sessions with an advanced practice registered nurse (APRN) who specializes in chronic pain. The education deliverables were rooted in the principles of cognitive behavioral therapy (CBT) and focused on myriad topics including self-esteem, perceptions of pain, communication strategies, and relaxation techniques. The APRNs who ran the intervention all received a 2-month training course at a local university that collaborated on the study. Results were measured, using valid and reliable instruments, at baseline, then again at 3, 6, and 9 months after enrolling in the study. The nurse-led program led to improvements in several aspects of the patients' health-related quality of life and a (likely-related) decrease in the patient's self-reported levels of pain, anxiety, and depression. Patients reported satisfaction with the intervention, and the results were sustained over time.

Relevance to Nursing Practice

This article out of Spain reinforces that holistic pain management is not a U.S.-centric principle. Quality of life, pain level and description, and associated anxiety and depression are universal considerations because of their impact on patient well-being and satisfaction. Nurses make a difference in the patient chronic pain experience by providing patients the tools and confidence needed to take control and drive their own pain management program.

Relaxation practices are similar to mindfulness practices in that both decrease stress, tension, anxiety, depression, and pain. Both practices require intentionality and focus, augment the multimodal pain management plan, and can be used in tandem with each other. However, they differ in intention—mindfulness practices focus on acceptance in the moment, and relaxation practices are focused on strategies to change internal processes (Luberto et al., 2020). See Research in Nursing box. Relaxation techniques are also discussed in Chapters 29 and 43.

Consider **Carla Potter**, the older adult experiencing new-onset persistent pain in her lower extremities. Mindfulness practices may help her cope with the anxiety she is experiencing with this new pain. The first step is to assess her familiarity with mindfulness techniques and discuss which of these measures suit her current lifestyle and can be incorporated into her daily routine.

USING CUTANEOUS STIMULATION

The success of cutaneous stimulation (techniques that stimulate the skin's surface) in relieving pain is often explained using the gate control theory. The gate control theory of pain involves cutaneous nerve fibers, which are large-diameter fibers carrying impulses to the CNS. When the skin is stimulated, pain is believed to be controlled by closing the gating mechanism in the spinal cord. This decreases the number of pain impulses that reach the brain for perception. These techniques can be used in all health care settings to supplement a pain control regimen. Some forms of cutaneous stimulation include the following:

- Massage (with or without analgesic ointments or liniments containing menthol); see Skill 36-1 (on pp. 1377–1380)
- Application of heat or cold, or both intermittently (see detailed discussion in Chapter 33)
- Acupressure or trigger point release
- Transcutaneous electrical nerve stimulation (TENS) or electrical muscle stimulation (EMS, ESTIM, E-Stim)

Acupressure, a modern-day Western descendant of acupuncture, involves the use of the fingertips to apply gentle but firm pressure to usual acupuncture sites. This technique of holding and releasing various pressure points is rooted in traditional Chinese medicine (TCM) and focused on energy or *chi*. The calming effect of acupressure is most likely related to the body's release of endorphins and enkephalins. Members of the interprofessional team, particularly physical therapists, focus on trigger point release primarily to address referred pain. Trigger point release does not occur at the same points as acupressure. Because patients, with training, can perform acupressure and trigger point release on themselves, it gives them a feeling of control in their care. See the accompanying PICOT in Practice box.

PICOT in Practice

ASKING CLINICAL QUESTIONS: ACUPUNCTURE/ACUPRESSURE

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

Scenario: You are a nurse working with a large maxillofacial surgery group who attended a conference on integrative nursing. One presenter that stood out discussed the benefits of acupuncture/acupressure in managing the gag reflex in patients undergoing dental procedures. Gagging is a common problem encountered during dental treatment, making therapeutic procedures distressing and often difficult or even impossible to perform. One of the surgeons asks if you learned something new at the conference and you discuss the results of the presentation.

The office currently only uses sedatives to facilitate sedation in patient undergoing procedures. You wonder if acupuncture/acupressure compared to sedatives has any benefit in the care of patients "specifically pediatric patients" undergoing procedures.

- **Population:** Children receiving sedation
- **Intervention:** Use of acupuncture/acupressure
- **Comparison:** Use of sedatives
- **Outcome:** Decreased gag reflex
- **Time:** During dental procedures

PICOT Question: Does the use of acupuncture/acupressure by a nonanesthesiologist compared to administration of sedatives result in depression of gag reflex in children undergoing dental treatment and improved experience?

Findings:

1. Ashley, P. F., Chaudhary, M., LourençoMatharu, L. (2018). Sedation of children undergoing dental treatment. *Cochrane Database of Systematic Reviews*, *(*12*),* CD003877. https://doi.org/10.1002/14651858.CD003877.pub5

Included 50 studies with a total of 3,704 children up to age 16 years. Thirty-four different sedatives were used, often with inhalational nitrous oxide. There is moderatecertainty evidence that oral midazolam is an effective sedative agent for children undergoing dental treatment. There is a need for further welldesigned and wellreported clinical trials to evaluate other potential sedation agents.

2. Eachempati, P., Kumbargere Nagraj, S., Kiran Kumar Krishanappa, S., George, R. P., Soe, H. H. K., Karanth, L. (2019). Management of gag reflex for patients undergoing dental treatment. *Cochrane Database of Systematic Reviews, (*11*),* CD011116. https://doi.org/10.1002/14651858.CD011116.pub3

The interventions used to manage gagging include antinausea medicines, sedatives, local and general anesthetics, herbal remedies, behavior therapy and cognitive behavior therapy, acupressure, acupuncture, laser, and prosthetic devices. This systematic review included four trials with 328 people (263 adults and 65 children who were ages 4 years and older). Of the trials reviewed, one compared acupuncture and acupressure (with thumb, device, and sea band) at P6 (point located three finger breadths below the wrist on the inner forearm in between the two tendons) to sham acupuncture and acupressure with and without sedation. One trial compared acupuncture at the P6 point to sham acupuncture. These trials reported both completion of dental procedure and reduction in gagging as their outcomes.

Level of Evidence I: systematic review.

Recommendations: Conscious sedation or moderate sedation is the ability of the patient to independently maintain an open mouth and respond sensibly to verbal commands. In addition, the patient will retain adequate function of protective reflexes such as the gag reflex. There is a fine line between a sedated patient and an anesthetized patient. The ideal sedative agent would reduce anxiety and improve behavior. Oral midazolam probably improves the behavior of children during dental treatment. Acupuncture at the P6 point when compared to acupressure to reduce gagging when undergoing dental procedures is appropriate. The same intervention with sedation did not show a difference.

TENS is a noninvasive alternative technique that involves electrical stimulation of large-diameter fibers to inhibit transmission of painful impulses carried over small-diameter fibers. The TENS unit consists of a battery-powered portable unit, lead wires, and cutaneous electrode pads that are applied to the painful area (Fig. 36-6). The use of TENS requires a health care provider's prescription. TENS therapy has reportedly been effective in reducing postoperative pain and improving mobility after surgery. It is used for temporary relief of acute pain and for symptomatic chronic pain. Positive results have also been noted when it is used as an adjunct to physical therapy and for patients with low back pain. The TENS unit may be applied intermittently throughout the day or worn for extended periods of time, depending on the provider's order.

Although similar to a TENS unit, EMS tends to cause greater muscle contraction than a TENS unit. EMS is often used in conjunction with strength training to improve muscle strength and decrease pain in patients and athletes. It is associated with rehabilitation of neurologic or musculoskeletal issues and may be specifically referred to as functional (FES) or neuromuscular electrical stimulation (NMES; Johnston et al., 2021; Novak et al., 2020).

Use of cutaneous stimulation is limited because the pain must be localized. Otherwise, it is most likely too diffuse to be effective. In addition, most people cannot tolerate stimulation of the painful area; however, they may be helped by stimulation of the surrounding or contralateral area.

USING ACUPUNCTURE AND DRY NEEDLING

Traditional Chinese medicine (TCM) originated in ancient China and has evolved over the years. Chinese herbal

medicine, acupuncture, and tai chi have integrated into Western CHA (National Center for Complementary and Integrative Health [NCCIH], 2019). Acupuncture is a technique that uses thin needles of various lengths inserted through the skin at specific locations to produce insensitivity to pain by affecting meridians, *chi*, and energy flow. It has gained acceptance in the Western world as a CHA to help control discomfort from disorders such as headaches, low back pain, neck pain, osteoarthritis or knee pain, and cancer (NCCIH, 2019). The relief of pain by acupuncture is generally explained on the basis of the gate control theory; however, more research is needed on the efficacy of acupuncture. Licensed acupuncturists, usually chiropractors or those who hold a Doctor of Science in Oriental Medicine (DSOM)/Oriental Medical Doctorate (OMD), most often administer acupuncture. This therapy is considered safe when a licensed, experienced practitioner who uses sterile acupuncture needles performs it. Repeated treatments are often needed.

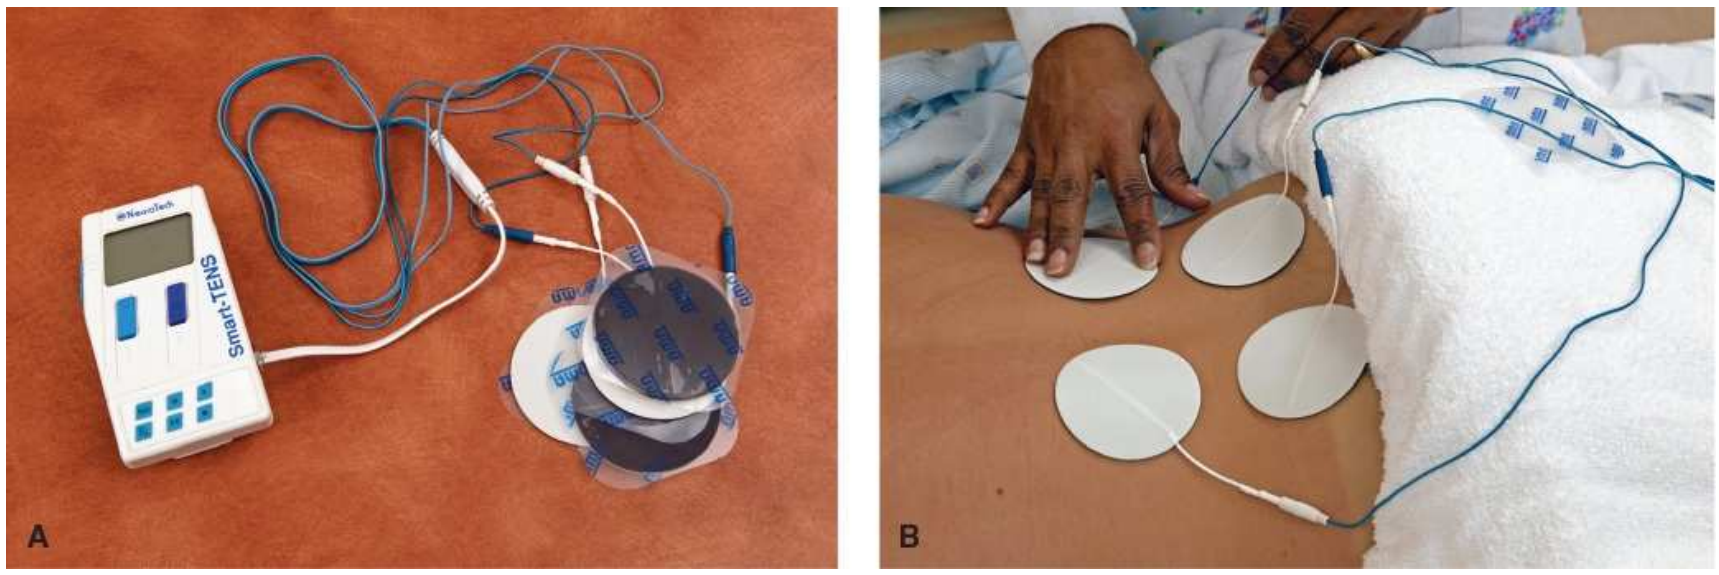

FIGURE 36-6. **A.** TENS unit. **B.** Applying TENS electrodes.

Trigger point dry needling (TDN) is a technique used by trained practitioners, including physical and occupational therapists. Although it uses sterile, filiform (solid, not hollow) needles such as acupuncture, TDN is based on Western medicine and began in the 1950s. The needles are inserted into key trigger points identified through a medical examination, the patient's report of pain and symptoms, and the practitioner's knowledge of anatomy. Dry needling involves penetration of the skin, followed by stimulation of myofascial trigger points, muscles, and connective tissues. This therapy focuses on the management of neuromusculoskeletal pain and impairments in movement (range of motion, strength, spasticity) that impact on the functional ability of the patient (Bynum et al., 2021; Institute of Advanced Musculoskeletal Treatments [IAMT], 2021; Sánchez-Infante et al., 2021).

USING HYPNOSIS

Hypnosis, a technique that produces a subconscious state accomplished by suggestions made by a hypnotist, has been used successfully in many instances to control pain. The person's state of consciousness is altered by suggestions so that pain is not perceived as it normally would be. According to many hypnotists, it also alters the physical signs of pain. Many people can be taught autohypnosis, that is, self-induced hypnosis, for the control of pain. It is generally believed that a successful response to hypnosis is related to the person's openness to suggestion, belief that hypnosis will work, and emotional readiness.

EMPLOYING BIOFEEDBACK

Biofeedback is a technique that uses a machine to monitor physiologic responses through electrode sensors on the patient's skin. The feedback signal or unit transforms the autonomic and neuromuscular physiologic data into visual, acoustic, and verbal feedback for the patient (Wagner et al., 2021). Upon seeing pain-related responses, such as increased muscle tension or elevated blood pressure, the patient is taught to regulate this physiologic response and control pain by practicing techniques such as deep-breathing exercises, progressive relaxation exercises, or visual imagery. Biofeedback decreases the person's pain by reducing the anxiety associated with lack of control over bodily functions, directing the person's attention away from the pain to the person's inner state and the feedback signal, and addressing the underlying, physiologic cause of the pain. Eventually, the person learns to recognize the sensations and employ measures to reduce pain without the use of the biofeedback machinery. The goal is to improve quality of life and increase physiologic function. Although biofeedback is safe and has not been shown to have adverse effects, limitations of this additive method include cost factors and limited availability of specialists (Wagner et al., 2021).

PROVIDING HEALING/THERAPEUTIC TOUCH

Healing Touch (HT) is an energy therapy that may be valuable as an adjunct to Western medicine. Some studies have indicated that it has been effective in reducing pain and anxiety in hospitalized patients and is recognized as an alternative therapy in end-of-life care for both adults and children (Weaver, 2017). It requires no equipment, uses light touch, and is appropriate for every level of care. Acceptance has been an obstacle for HT therapy, primarily because

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

there is little evidence to support its use.

Although the terms are often used interchangeably, Therapeutic Touch (TT) historically is focused more on the universal field and directing life energy to patients. Patients who have received TT state that it helps with feelings of comfort, calmness, and well-being. It is derived from the ancient practice of laying on of hands, but nurses skilled in TT never actually touch their patients when using this technique. Nurses caring for patients with terminal diseases relate that TT complements their efforts to alleviate suffering and can be used to promote comfort during the final stages of life (Tabatabaee et al., 2016).

Both HT and TT were developed by nurses, do not require a provider's prescription, and can be used in any setting.

PROVIDING ANIMAL-ASSISTED INTERVENTION

Either a patient's own pet or an animal with an experienced handler can be used as complementary therapy to help relieve pain and provide a degree of comfort to people in various health care settings. Pet Partners (n.d.) is an organization that has been involved in therapy animal programs since 1977. These visits are either casual (*animal-assisted activities*—AAA) or more focused with a stated goal and documented results (*animal-assisted intervention*—AAI). Animals that visit patients include dogs, rabbits, guinea pigs, birds, cats, and even llamas. AAI has been used to relieve pain in children in acute care settings. Although evidence supports the use of AAI, acute and long-term care settings may have rules that preclude admitting animals. The introduction of pet-robot interventions (PRI), led to reductions in depression, anxiety, and loneliness in older adults with dementia. This innovation may represent a viable way to replicate the effects of AAI while eliminating barriers (Park et al., 2020).

Managing Pharmacologic Relief Measures

Pharmacologic pain management is a complex process that requires adequate assessment, consideration of guidelines and regulations, knowledge of medications, sufficient tracking and follow-up, patient teaching, and an interprofessional, multimodal approach. To make informed decisions and individualize care, nurses need updated information and ongoing education about drug therapy, the cornerstone of many pain-treatment regimens.

ADMINISTERING ANALGESICS

An **analgesic** is a pharmaceutical agent that relieves pain. Analgesics function to reduce the person's perception of pain and to alter the person's responses to discomfort. There are three general classes of drugs used for pain relief:

- **Opioid** analgesics (all controlled substances, e.g., morphine, codeine, oxycodone, meperidine, hydromorphone, methadone)
- Nonopioid analgesics (acetaminophen and nonsteroidal antiinflammatory drugs [NSAIDs])
- **Adjuvant** analgesics (anticonvulsants, antidepressants, multipurpose drugs)

The nurse administering analgesics needs to combine a healthy respect for the drug being administered with a thorough knowledge of its mechanism of action, side effects, and administration guidelines. This combination of knowledge of and respect for the drug should result in analgesics being used wisely to produce their desired effect.

Knowledge of common analgesics enables the nurse to tailor the patient's regimen and communicate professionally with prescribing health care providers about a patient who is being undermedicated, needs a different drug, or requires a different route of administration. Nurses should not independently decide to refrain from using an analgesic or reduce a prescribed dose because of a patient's unrealistic fear of a medication's potency or side effects. Pain medication choice and dosing requires a collaborative approach that includes the patient, nurse, pharmacist, and prescriber.

Repeated studies have confirmed improvement in pain assessment and documentation, but not in pain relief. Health care providers are questioning prescribing practices for opioids and admit a lack of confidence regarding how to prescribe opioids safely, how to detect abuse or emerging addiction, and how to broach these topics with their patients (Centers for Disease Control and Prevention [CDC], 2021b; Volkow & McLellan, 2016). This can lead to pain that is not appropriately managed. Nurses, who typically spend the most time with the patient and are trained in pain assessment and management, often compound this problem by further reducing an insufficient analgesic dose or by not administering the medication at all. Nurse variables include the low priority given to pain management, arbitrary pain assessments, erroneous judgments about a patient's pain and need for analgesia, and fear of being the person who administers the drug that causes respiratory depression or another serious side effect. Health care providers work to achieve optimum pain relief for all people (Karch, 2020). The inability of many patients to discuss their pain and to request pain assistance perpetuates this problem. However, consideration needs to be given as to whether reported pain is acute or chronic in nature. Nurses must employ best practices that consider evidence-based guidelines, position statements from associations, and consensus reports from expert panels to prevent the transition of acute pain to chronic pain (Jungquist et al., 2017). The interprofessional team must maintain responsibility for balancing reasonable, adequate pain relief with the actual and potential risks of pain medication prescription and use. Clear guidelines regarding the management of chronic pain exist and should guide practice (CDC, 2021b; National Institute on Drug Abuse, 2020).

Opioid Analgesics

Opioids, formerly called narcotic analgesics, are generally considered the major class of analgesics used in the management of moderate to severe nociceptive, neuropathic, and cancer-related pain. Although the term *opiates* refers to natural opioids such as heroin or morphine, and *opioids* refers to all natural, synthetic, and semisynthetic opioids, we use the broader term opioids in our discussion (CDC, 2021a). In sufficient dosage, opioids are considered effective in relieving pain that is peripheral/nociceptive in nature, such as acute pain due to injury, pain associated with rheumatoid arthritis, or cancer pain (National Institute on Drug Abuse, 2020). Opioids produce analgesia by attaching to opioid receptors in the brain, similar to how a key fits a lock. Ongoing research on opioid analgesics also indicates that opioid receptors are present on cells of the immune system and may suppress immune function (Brejchova et al., 2021). Opioid receptor sites are further classified as mu-receptors that primarily block pain but are also involved in respiratory changes, euphoric feelings, pupil and GI changes, and physical dependence; delta-receptors that are thought to be involved with peripheral terminals; and kappa-receptors that block some pain but are also associated with pupil changes, dysphoria (profound unease that result in restlessness, anxiety, and depression), and sedation (Brejchova et al., 2021; Karch, 2020). The difference in opioid effects is related to their interaction with these three opioid types of receptors. Opioids that produce analgesia (agonists) can compete for binding sites on the receptors with opioids that do not produce analgesia (antagonists). An opioid agonist such as morphine binds to the mu-receptor site and produces analgesia (Norris, 2020). An opioid antagonist such as naloxone also competes for binding on the mu site, but it blocks the analgesic effect of morphine as well as its side effects. Most of the opioid analgesics commonly used in a clinical setting bind primarily to mu-receptor sites. Patients differ in their sensitivity to morphine because of genetic variability of the mu-receptor site.

There are many opioid analgesics that range from weak (codeine or tramadol) to strong (morphine, oxycodone, or hydromorphone). Health care providers individualize the choice of medication based on the disease process, level/type of pain, and other assessment factors. Current recommendations advise using evidence-based practice pain management that is multimodal and incorporates opioid-sparing therapies (Jungquist et al., 2020). Morphine, the prototype opioid, is often the opioid of choice because providers are familiar with it, it is readily available in multiple forms, and it is relatively inexpensive. Fentanyl, a synthetic opioid that is 50 to 100 times stronger than morphine, is available in a variety of forms that range from rapid-acting to long-acting (PDQ® Supportive and Palliative Care Editorial Board, 2021). Methadone is most commonly used to treat cancer pain (PDQ® Supportive and Palliative Care Editorial Board, 2021) and to manage detoxification in people with opioid dependence/addiction. If patients have continued uncontrolled pain, unmanageable side/adverse effects, a change in status that requires a change in route of administration, or develop toxicity, an opioid rotation (switch to another medication) may be initiated (PDQ® Supportive and Palliative Care Editorial Board, 2021).

QSEN DRUG SAFETY

Methadone is a mu-receptor agonist and an *N*-methyl-D-aspartate (NMDA) receptor antagonist that must be used cautiously because it has a rapid onset of action and a long half-life.

Nurses who are involved in the administration of opioids to manage acute and chronic pain must become familiar with equianalgesic opioid dosing, which involves using opioid conversion calculations that consider the dose, route, and potency of a medication. For example, although a patient may receive 4 mg of morphine IV, 4 mg of fentanyl IV would be lethal. This skill requires clinical judgment and is essential to determine safe and therapeutic dosage ranges of specific opioids (Curtis et al., 2021).

The most common side effects associated with opioid use are sedation, nausea, and constipation. Most side effects disappear with prolonged use, but if constipation persists, it usually responds to treatment with increased fluids and fiber and use of a mild laxative or stool softener. An opioid-naive person who has not developed tolerance may experience all of the side effects. This contrasts with an opioid-tolerant person who has taken opioids long enough and at sufficient levels to develop tolerance to the analgesic effect of the opioid and most of the side effects, except constipation.

Respiratory depression is a commonly feared adverse effect of opioid use. Opioid-induced respiratory depression can result in an increased length of stay and cost expenditures, readmission, and even death, especially with concurrent use of other respiratory depressant drugs such as alcohol or benzodiazepines (Khanna et al., 2020; National Institute on Drug Abuse, 2018). Current recommendations include integrating a comprehensive assessment of patient-specific, treatment-related, and environment-related risk factors before initiating opioid therapy, and for the duration of clinical care. Specific recommendations include electronic monitoring for patients deemed high-risk (Jungquist et al., 2020). A new predictive tool (PRODIGY), developed through international collaboration at 16 different sites with 1,266 patients, used continuous oximetry and capnography data to identify age ≥60 years (greatest risk for those ≥80 years old), male sex, opioid naivety, sleep disorders (such as sleep apnea), and chronic heart failure as predictive for an opioid-induced respiratory depression episode (Khanna et al., 2020). Another tool, the Pasero Opioid-Induced Sedation Scale, requires only nursing assessment and can be used to assess respiratory depression in adult and pediatric populations (Pasero & McCaffery, 2011; Hall & Stanley, 2019):

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

- S = sleep, easy to arouse: no action necessary
- 1 = awake and alert; no action necessary
- 2 = occasionally drowsy but easy to arouse; requires no action
- 3 = frequently drowsy and drifts off to sleep during conversation; decrease the opioid dose
- 4 = somnolent with minimal or no response to stimuli; discontinue the opioid and consider use of naloxone

If respiratory depression is suspected and the opioid dose is withheld, the patient may be physically stimulated by shaking or using a loud sound, along with reminders every few minutes to breathe deeply. If this is ineffective, naloxone, an opioid antagonist that reverses the respiratory-depressant effect of an opioid, can be used. Naloxone is administered intravenously in the hospital setting. Within 1 to 2 minutes, the patient usually opens their eyes and is able to respond to the nurse. When the patient is alert again and the respiratory rate is back to baseline, the opioid may be resumed. However, the half-life (time required for the concentration to decrease by half; duration of action) of naloxone is very short, so re-sedation may occur, and subsequent doses of naloxone may be required (every 5 minutes). Keep in mind that the naloxone works by blocking the action of the opioid, so if naloxone is required and/or the opioid cannot be resumed in a reasonable amount of time, the nurse must ensure another method of pain relief is administered.

There is a difference between opioid use short term (<3 weeks) for acute pain and long-term (>3 months) management of chronic pain with opioids. Patient education often needs to include a review of these key terms in order to allay fears and collaboratively develop a plan for pain management. Physical dependence and tolerance are frequently confused with addiction. **Physical dependence** is a phenomenon in which the body physiologically becomes accustomed to opioid therapy and suffers withdrawal symptoms if the opioid is suddenly removed, or the dose is rapidly decreased. **Tolerance** occurs when the body becomes accustomed to the opioid and needs a larger dose (up to 10 times the original dose) for pain relief. Tolerance can be avoided by administering smaller doses of a drug or using a multimodal approach. Physical dependence and tolerance are different from addiction primarily because physical dependence and tolerance are expected responses; addiction is not a typical or predictable result of opioid use (Karch, 2020; PDQ® Supportive and Palliative Care Editorial Board, 2021; Volkow & McLellan, 2016). **Addiction** is a "chronic, relapsing brain disease characterized by compulsive drug seeking and use despite adverse consequences" (National Institute on Drug Abuse, 2020, p. 4). If people are not misusing the prescribed drug(s), addiction occurs over time and in a small percentage of patients exposed to opioids, even if they have preexisting vulnerabilities such as long-term opioid use, a history of depression, or an existing substance use disorder. Key indicators of addiction include a profound craving for the drug, erosion of the inhibitory mechanisms that control efforts to refrain from drug use, and compulsive drug taking. The hallmark of addiction is this impairment to exert self-control. Addiction is associated with long-term opioid use, but surveillance with short-term use is also beneficial. Primary clinical efforts to prevent drug use, misuse, and addiction include performing an assessment of risk factors and protective factors before prescribing opioids, regular monitoring, referral to addiction treatment as needed, and prescription of amounts that minimize the risk of diversion (National Institute of Drug Abuse, 2020; Volkow & McLellan, 2016).

Opioid use disorder (OUD) and the opioid crisis have been at the center of public discourse for more than 15 years. Although prevention of OUD remains the primary goal, emergent intervention for opioid overdose and long-term pharmacologic treatment of OUD may be required. The U.S. Food and Drug Administration (FDA) has approved three forms of naloxone for community use: injectable, auto-injector, and nasal spray. Naloxone kits and the associated training are currently available to trained first responders and laypeople in the community either through prescriptions or state-based standing orders (FDA, 2019). The FDA (2021) actively seeks to increase the availability of naloxone by encouraging drug manufacturers to pursue approval for over-the-counter naloxone products, requiring manufacturers to include recommendations regarding naloxone with opioid-prescribing information, and extending the shelf life of naloxone from 24 to 36 months. Methadone, an opioid agonist; buprenorphine, a partial opioid agonist; and naltrexone, an opioid antagonist, are approved to support recovery from OUD and heroin use. Another common agent used to treat OUD, Suboxone® , contains both naloxone and buprenorphine. These medications all reduce opioid use and OUD-related symptoms, but they also increase adherence to a treatment plan, reduce the risk of HIV and HCV transmission, reduce legal issues and incarceration, and lead to a greater likelihood of maintaining employment (National Institute on Drug Abuse, 2018). See the Vulnerable Populations Alert on patients with an OUD.

National guidelines include a checklist for prescribing opioids for chronic pain. This guideline stems from the need to ensure safe, effective pain management for chronic pain while reducing the risk of OUD, overdose, and potential death (CDC, 2021b; Dowell et al., 2016). The checklist for prescribing opioids for chronic pain (that does not involve cancer-related, palliative, or end-of-life care) includes these three main patient-centered foci (CDC, 2021b):

- Determining when opioids should be started and continued to manage chronic pain; this includes using nonopioid and nonpharmacologic methods in conjunction with opioids, setting realistic treatment goals, and discussing the risk and benefits with patients
- Selecting the appropriate opioid (immediate-release, extended-release, long-acting), dose, duration of treatment, follow-up plan, and discontinuation parameters
- Assessing risk and mitigating harms of opioid use; this includes a review of the Prescription Drug Monitoring Program (PDMP) database, urine drug testing, co-prescribing benzodiazepines, and treating OUD as needed

The American Society of Pain Management Nurses and the American Pain Society (Drew et al., 2018) released a consensus statement on the nurse's role in interpreting and implementing as needed/PRN or titrated pain medications. The role of nurses in this process includes:

- Basing decisions on a complete pain assessment including (at least) pain intensity, temporal characteristics, and patient's previous response to this or other analgesics
- Using valid and reliable tools that are consistent and individualized to the patient
- Considering the pharmacokinetics of the opioid
- Avoiding administration issues such as giving partial doses more frequently or making a patient wait the full time interval after a partial dose; waiting until the peak effect of the first partial dose is reached before giving a subsequent dose

Vulnerable Population Alert

COVID-19 gave the world time to reflect on social injustice and racial disparities. There is a clarion call for a reckoning rising from bioethicists, legal experts, drug experts, sociologists, psychologists, researchers from many disciplines, physicians, and allied health professionals to end the war on drugs and begin to establish a system of racial justice. In addition to legalizing cannabis, which is well underway in many states, this group is in "favor of the ultimate legalization and careful regulation of MDMA (ecstasy), psychedelic drugs such as LSD and psilocybin, heroin, and other opioids, methamphetamine, and powder and crack cocaine—that is, all drugs used for nonmedical purposes that are currently deemed illicit" (Earp et al., 2021). But this group is not alone in their endeavors. MDMA, which is known to increase dopamine, norepinephrine, and serotonin, is being used in conjunction with manualized therapy (MDMA-assisted therapy) in a phase 3 clinical trial to address posttraumatic stress disorder (PTSD) with significantly positive results (Mitchell et al., 2021). This trial, part of the Multidisciplinary Association for Psychedelic Studies (MAPS) founded by Doblin in 1986, is moving MDMA toward U.S. Food and Drug Administration approval (Carpenter, 2020). Dr. Nate L. Hart, a professor of psychology of Columbia University, wrote a new book, *Drug Use for Grown-Ups: Chasing Liberty in the Land of Fear* that details his 5-year regular use of heroin for recreational purposes and combats the notion that drugs are inherently bad. Although the book provides much more nuance, it mentions that opioid overdoses are the product of mixing agents, not the opioids themselves, and that addiction does not happen with every person who ingests drugs, even drugs previously deemed highly addictive. The larger issue posited by Hart (Schwartz, 2021) and Earp et al. (2021) is that the war against drugs disproportionately affects poor and Black people. Criminal convictions trace back to slavery and Jim Crow–era tenets and are better handled by health care programs and social support, not the criminal justice system.

For your consideration:

- How does this framing change your attitudes toward what are currently consider illegal/illicit drugs?
- How does this affect your interactions with patients with opioid or substance abuse disorder?
- What are your perspectives regarding advocacy as a nurse regarding the U.S. criminal justice system? What can you use from our Code of Ethics to guide you?
- Pretend your patient presents you with these studies they read about on Twitter. How do you incorporate or counter this information?

Schwartz, C. (2021, January 12). When getting high is a hobby, not a habit. *The New York Times*. https://www.nytimes.com/2021/01/12/books/review/drug-use-for-grown-ups-carl-l-hart.html

- Teaching the patient the name of the drug, the dose administered, the monitoring process, and potential side effects to report
- Evaluating the patient's response to dose and dosing interval
- Ensuring complete documentation and communication during transitions of care
- Assisting with the development of policies that ensure patient comfort and safety

Prescribers should provide a fixed time interval (every 3 hours) but may provide a dosage range for a PRN opioid (e.g., 20 to 30 mg). Prescribing dosages based solely on a 0 to 10 numeric value reported by the patient does not consider other factors that the nurse considers when determining the appropriate dose for an individual patient. A

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

registered nurse who is competent in pain assessment and medication administration can manage the pain management regimen using a correctly written prescription/order set (Drew et al., 2018).

Nonopioid Analgesics

Nonopioid analgesics, such as acetaminophen and NSAIDs, are usually the drugs of choice for both acute and persistent moderate chronic pain. The simplest dosage schedules and least invasive pain management modalities should be used first. Many times, these drugs alone can provide adequate pain relief. Many of these medications are OTC products, whereas some are available by prescription only. Some can cause gastric side effects, but these symptoms may be preventable if the drug is taken with food or antacids.

Acetaminophen has long been viewed as one of the safest and best-tolerated analgesics. It has proven to be an effective drug for acute pain treatment and is the most commonly used analgesic for children in the United States (Karch, 2020). It has a low incidence of adverse effects, but the risk of hepatotoxicity must be considered when acetaminophen is used for a lengthy period or at larger than the recommended dose (maximum of 4 grams/day). If pain is not controlled using the recommended dose of acetaminophen, NSAIDs or an opioid analgesic may be required to achieve pain relief.

NSAIDs have an antiinflammatory effect. Individual responses to NSAIDs vary, but these agents are contraindicated in patients with bleeding disorders (their action may interfere with platelet function), probable infections (NSAIDs can mask the signs of an infection), and in pregnancy at 20 weeks or later (potential fetal renal dysfunction; FDA, 2020b). The FDA (2020b) requires that NSAID labels contain information about the potential for GI bleeding and skin reactions associated with all NSAIDs, and a warning that all NSAIDs, except for aspirin, increase the risk of myocardial infarction (heart attack) or stroke. The combination of nonopioid analgesics and opioids provides more analgesia than either drug taken alone. Multimodal analgesic therapy is a relatively recent approach to pain management (Fig. 36-7). It combines two or more classes of analgesics that target different sites in the peripheral and central nervous systems to maximize pain relief with fewer adverse effects. The most common multimodal approach is a combination of nonopioid, opioid, and adjuvant analgesics (PDQ® Supportive and Palliative Care Editorial Board, 2021). The patient and caregivers will require an explanation regarding why multiple medications have been prescribed and how they work to relieve pain. Although often considered in relation to chronic pain, multimodal analgesia is also a valid approach to the management of acute pain. The pain associated with the postoperative period and trauma are positively impacted by the synergistic effect of multimodal analgesia, which maximizes pain relief at lower doses, thus reducing the risk of adverse effects of specific drugs (Polomano et al., 2017).

The COX-2 inhibitors, a class of NSAIDs, have a lower risk of GI bleeding but are thought to significantly increase cardiovascular risks. Celecoxib is available in the United States and used for treatment of osteoarthritis and rheumatoid arthritis (FDA, 2020b).

Adjuvant Analgesics

Adjuvant drugs are typically used for other purposes but are also integral to an optional pain management program. They may also reduce side effects from prescribed opioids or lessen anxiety about the pain experience. Adjuvant analgesics include antidepressants (venlafaxine, duloxetine, and tricyclics), anticonvulsants/gabapentinoids (gabapentin and pregabalin), alpha-2-agonists (clonidine and dexmedetomidine), local anesthetics (lidocaine), corticosteroids (dexamethasone, methylprednisolone, and prednisone), bisphosphonates (specifically for bone metastases), and NMDA agonists (ketamine and magnesium). They may be used to treat acute pain resulting from surgery, burns, or trauma; neuropathic pain syndromes such as diabetic neuropathy and postherpetic neuralgia; nociplastic pain such as fibromyalgia; and cancer-related pain (PDQ® Supportive and Palliative Care Editorial Board, 2021; Schwenk & Mariano, 2019).

APPLYING GENERAL PRINCIPLES FOR ANALGESIC ADMINISTRATION

When using medications for pain relief, the nurse must first assess the patient's pain and understand the patient's goals for pain relief. In the home as well as in acute care settings, nurses provide quality nursing care when they empower patients to take charge of their own pain relief measures. The following guidelines are recommended for effective, individualized pain management in any setting:

- Choose a pain scale or instrument that most accurately assists with assessment of pain.
- Try various pain control measures.
- Use pain control measures before pain increases in severity.
- Ask the patient what has been effective for pain relief in the past.
- Select and modify pain control measures based on the patient's response.
- Encourage the patient to try the pain treatment several times before labeling it ineffective.
- Be open minded about alternative, nonpharmacologic pain relief strategies.
- Be persistent.
- Be a safe practitioner.

Accurate documentation is imperative to determine effectiveness of the current regimen or the need to change pain control measures if relief is not obtained. Pain diaries or flow sheets provide a method for people to document their particular pain experience, list medication or alternative therapies that were used to treat the pain, and record the effectiveness of the interventions used. Attempts to recall particular aspects of a painful experience are not always accurate. Pain diaries can be used in a variety of settings and help improve the overall management of pain. Since more patients with acute and chronic pain are cared for in their home environment, effective patient and caregiver teaching is the cornerstone of pain relief therapy.

Ongoing Assessment

Just as the pain experience of each patient is unique, so too is the response of each patient to a prescribed analgesic. The nurse needs to continuously evaluate whether a medication is producing the desired analgesic effect; identify changes in the patient's condition (correction or worsening of pathology, increased drug tolerance) that necessitate changes in the analgesic agent, dose, or route of administration; and identify the development of side effects of the analgesic that may warrant its discontinuance. Assessment must include consideration of all agents integrated into the multimodal analgesia plan as well as any nonpharmacologic interventions. As long as the patient's pain exists, ongoing assessment and documentation of pain control is imperative. Fundamental to this assessment is the knowledge of the basic action, doses, and routes of administration; side effects; and administration guidelines of the analgesic(s) being administered.

Timing is an important consideration when administering analgesics. To time analgesics appropriately, know the average duration of action for the drug and time administration so that the peak analgesic effect occurs when the pain is expected to be most intense. For example, an analgesic would be offered before ambulating a patient postoperatively.

A PRN (as needed) drug regimen has not been proven effective for people experiencing acute pain. In the early postoperative period, when pain is expected, this protocol may result in an intense pain experience for the patient. Later, however, in the postoperative course, a PRN schedule may be acceptable to relieve occasional pain episodes. Continuous intravenous infusion has proved effective for the relief of acute postoperative pain. PCA and epidural analgesia are discussed later in the chapter.

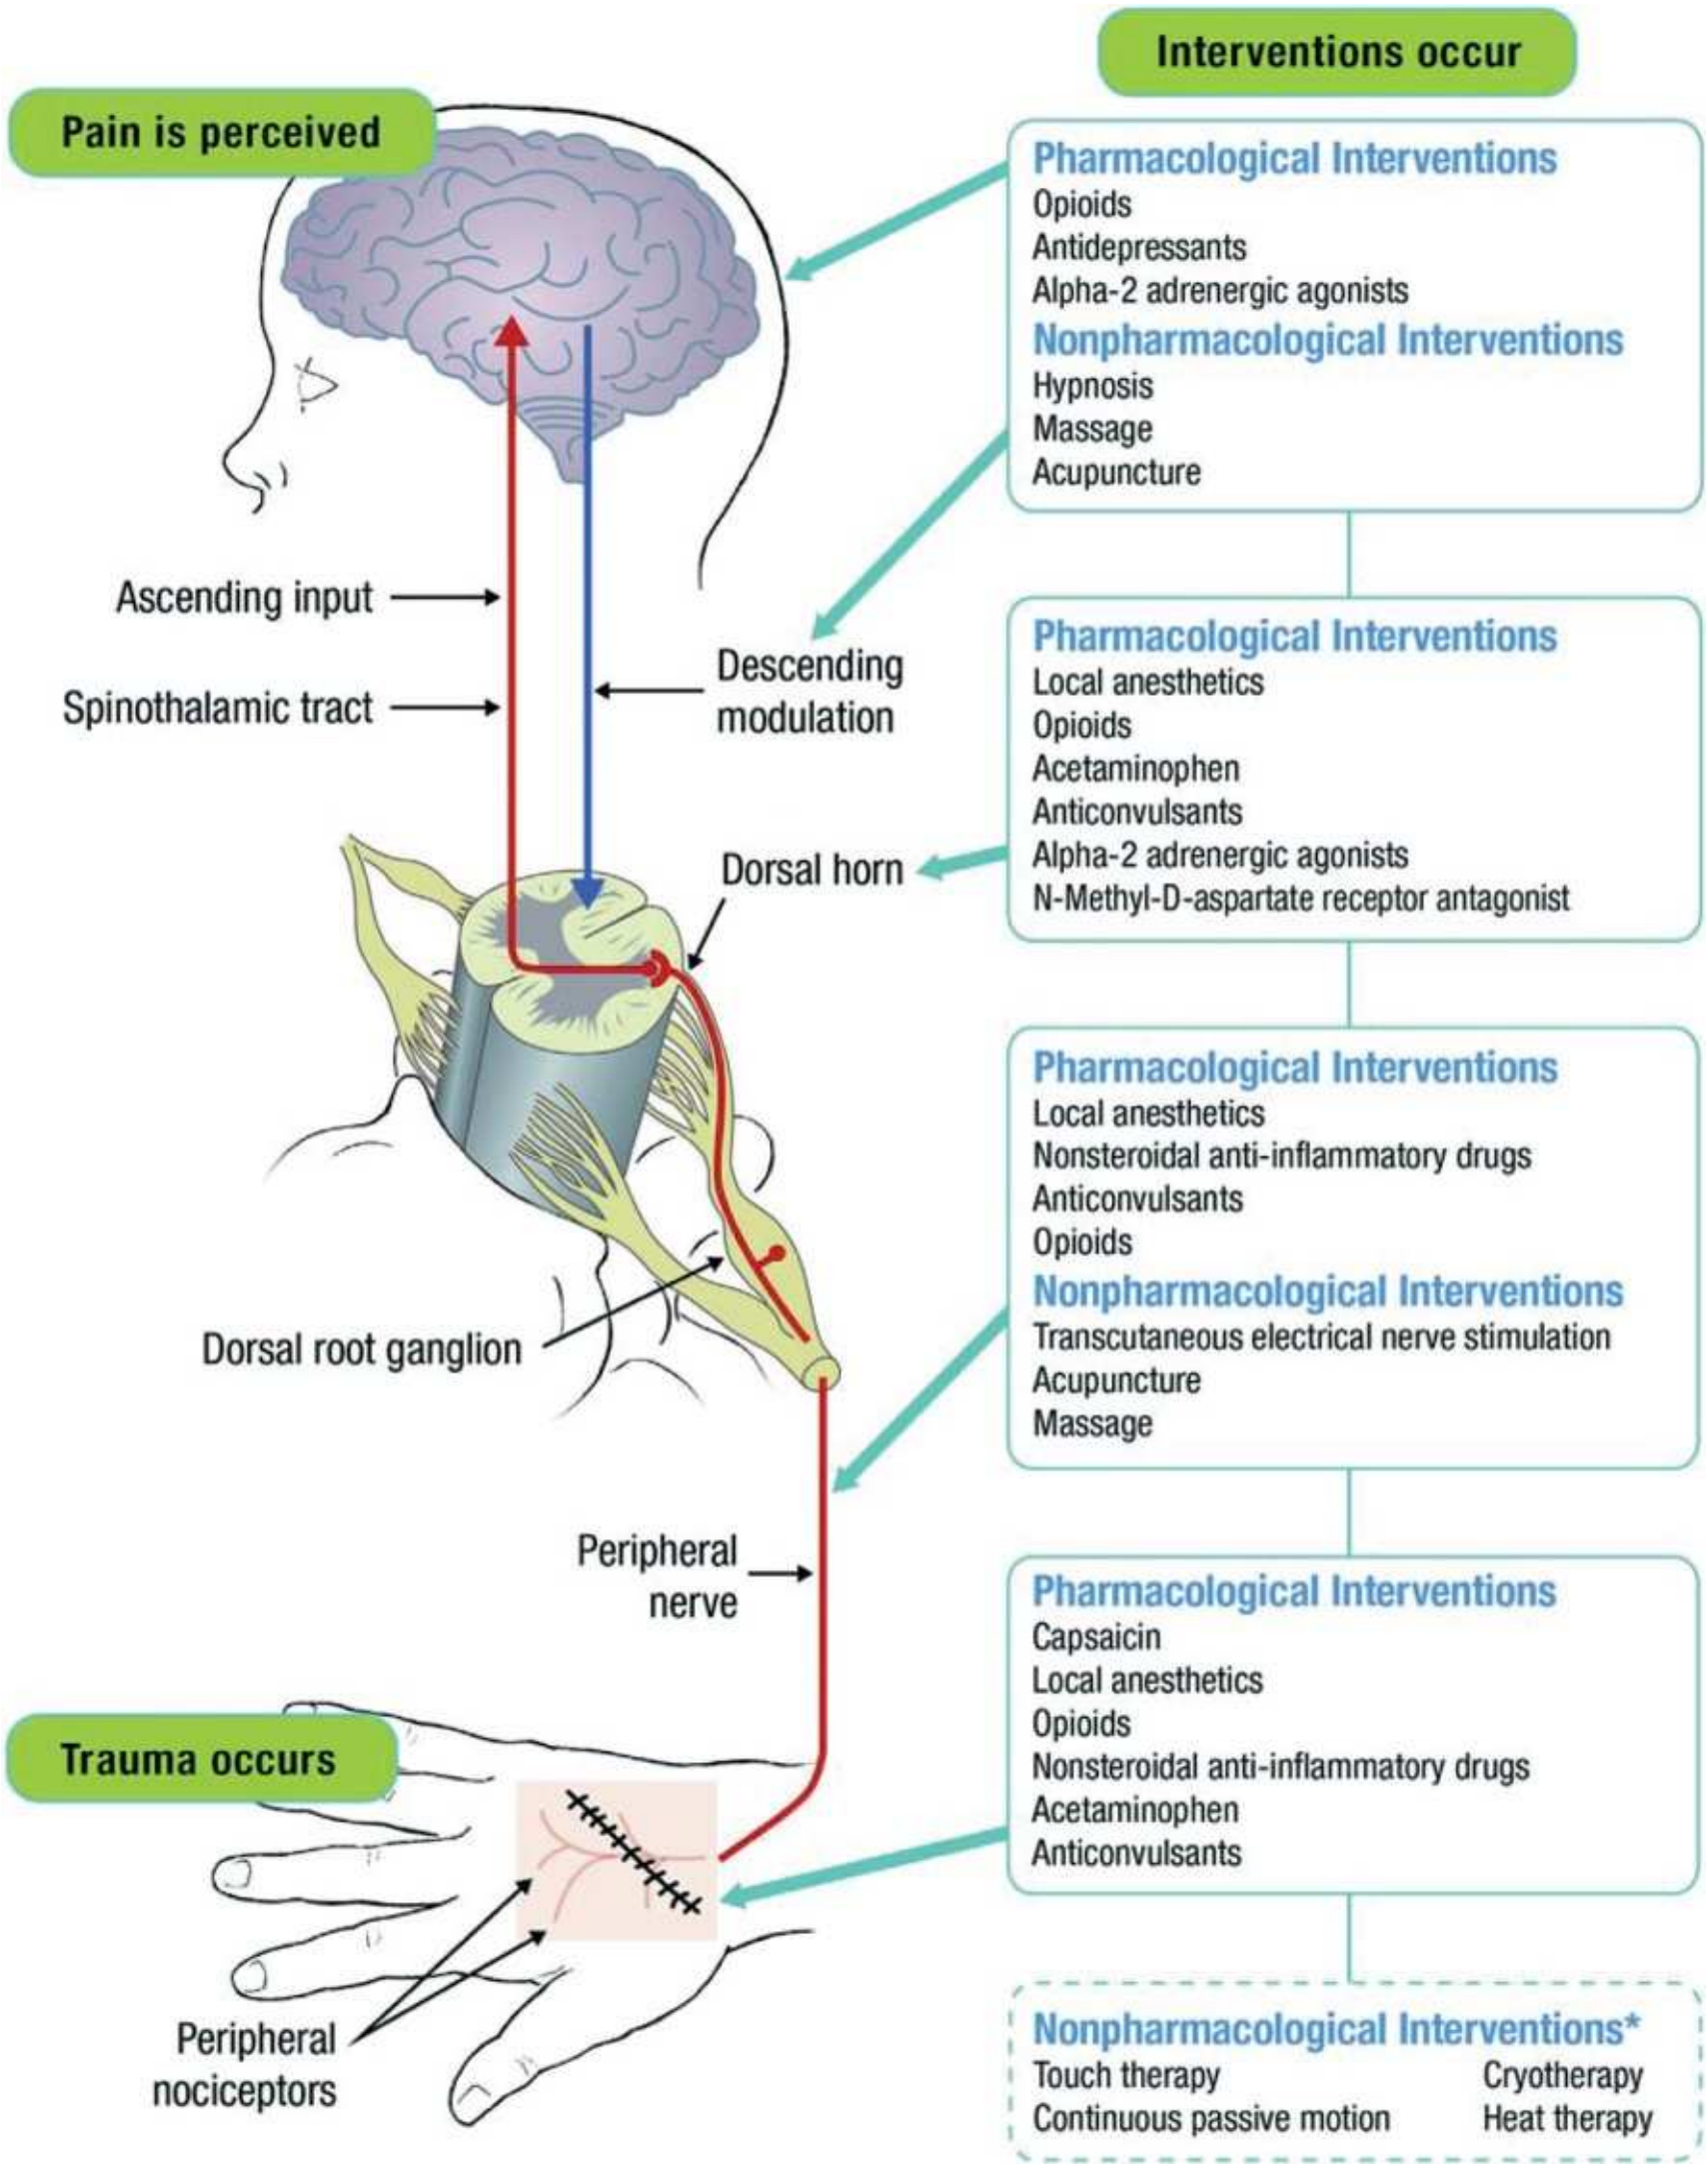

FIGURE 36-7. Multimodal pain management. (*Source:* Reprinted from Manworren, R. C. B. [2015]. Multimodal pain management and the future of a personalized medicine approach to pain. *AORN Journal*, *101*[3], 307–318.)

Nonpharmacologic and nonopioid pharmacologic therapies are the preferred choices for chronic pain that is not related to active cancer, palliative care, or end-of-life care. If progression to opioids becomes necessary, the lowest effective dose of an immediate-release opioid should be initiated first. Ongoing assessment and careful monitoring should guide the prescription of opioids for the management of chronic pain (CDC, 2021b; Dowell et al., 2016). Long-acting, controlled-release oral morphine or oxycodone or use of a fentanyl patch may be used in pain associated with cancer. Patients need instruction to apply the patch according to the time interval prescribed, avoid the application of heat in areas where the patch is in place, and dispose of used patches appropriately. Used and unneeded patches should be disposed of by folding together the adhesive side of the patch and flushing the patch down the toilet.

Management of Breakthrough Pain

Breakthrough pain, or breakthrough cancer pain, is a temporary flare-up of moderate to severe pain that occurs even

when the patient is taking around-the-clock (ATC) medication for persistent pain and has had well-controlled background pain. As many as 75% of patients with cancer experience breakthrough pain, with the frequency higher in late- and end-stage cancer (PDQ® Supportive and Palliative Care Editorial Board, 2021). This pain is often not diagnosed correctly and is frequently undertreated. Breakthrough pain can be classified as incidental pain (e.g., pain caused by movement) or idiopathic (spontaneous pain due to an unknown cause) and should be differentiated from end-of-dose pain, which is when the pain occurs before the next dose of analgesic is due. Incident and idiopathic breakthrough pain is treated more effectively with supplemental doses of a short-acting opioid taken on a PRN basis, rather than with an increase in the dose of the ATC medication or shortening of the interval between doses, which typically is more effective with end-of-dose pain. Effective management of BTcP requires use of rapid-onset opioids administered via the oral, transmucosal, intranasal, or sublingual route (PDQ® Supportive and Palliative Care Editorial Board, 2021; FDA, 2020a).

Concern about Prescription Analgesic Abuse

More than 11.5 million people in the United States, ages 12 years and older, reported misusing opioids in 2016 (CDC, 2021b). A 2021 report from the U.S. Drug Enforcement Administration (DEA) noted that over 70% of the almost 71,000 drug overdose deaths in 2019 involved an opioid, with 72.9% of those deaths involving synthetic opioids other than methadone, typically fentanyl (CDC, 2021c). They identified controlled prescription drugs, heroin, illicit/synthetic fentanyl, cocaine, and methamphetamine as the most significant drug-related threats to the United States (DEA's Strategic Intelligence Section, 2021). Practitioners had responded to the need for improved pain relief by prescribing more opioids for patients. In some cases, the **diversion** (any act that results in a drug not reaching the person who was originally prescribed the controlled drug) and substance abuse that subsequently occurred was an unintended consequence. People who abuse opioids often capitalize on the well-intentioned desire of health care providers to sufficiently address pain. They visit multiple providers and request opioid prescriptions for high daily doses. This group is at high risk for a drug overdose, and some may even distribute drugs to others who are using them without a prescription (diversion). National guidelines and recommendations guide providers in the prescribing and dispensing of these high-risk medications. However, a multifaceted approach that involves collaboration between public health officials, law enforcement, educators, and community advocates is required to address this issue (DEA's Strategic Intelligence Section, 2021). One initiative is the creation of the Prescription Drug Monitoring Program (PDMP) database that allows prescribers to access prescription and dispensing data on prescription drugs for individual patients from multiple institutions within a geographic area. Although not mandatory, many states require the use of PDMPs prior to prescribing an opioid (The Joint Commission, 2017).

Concept Mastery Alert

A multifaceted approach to pain management and opioid abuse issues should involve the individual patient, public health officials, law enforcement, educators, and community advocates.

USING ACUTE PAIN MANAGEMENT TREATMENT REGIMENS

As a patient's advocate, ensure that a strong emphasis is placed on the need for aggressive, individualized strategies that can minimize or eliminate acute pain and promote positive patient outcomes. Preventing pain is easier than treating it once it has occurred. Discuss pain control options with patients before surgery and address the patient's responsibility regarding reporting pain. Additional nursing interventions that can eliminate acute postoperative pain include maintaining a steady serum level of the analgesic (PCA or epidural analgesia can help here), treating side effects quickly and aggressively, encouraging use of nonpharmacologic complementary therapies as adjuncts to the multimodal pharmacologic regimen, and identifying supports and resources for managing the biopsychosocial components of the pain experience.

Undertreatment of pain that accompanies procedures, whether performed in a hospital, home, or outpatient clinic, is a common occurrence. If there is any possibility of the patient experiencing more than mild pain or discomfort from a procedure, consider providing analgesia. In situations in which the patient is unable to report the presence of pain (e.g., an unconscious patient), it is important to consider pain relief if a procedure is planned that normally elicits a pain. This could include turning a patient or a dressing change. In some instances, if the patient is unable to communicate verbally but is capable of some response, it may be necessary to provide a method for the patient to indicate that pain is occurring during a procedure. The simple raising of a finger or hand or squeeze of a squeak toy can alert the caregiver that analgesia is needed.

EMPLOYING CANCER OR CHRONIC PAIN MANAGEMENT TREATMENT REGIMENS

People with cancer sometimes suffer needlessly from pain. The major principles that guide treatment for cancer or chronic pain include:

- Giving medications orally, if possible, for ease and convenience of administration
- Administering medication ATC rather than on a PRN basis

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

- Adjusting the dose to achieve maximum benefits with minimal side effects
- Allowing patients as much control as possible over their medication regimen

In an effort to alleviate unnecessary pain and suffering, the World Health Organization (WHO, 2019) supports a three-step analgesic ladder that outlines the appropriate progression of drugs and dosages that should be used to manage cancer-related pain effectively. Emphasis is on individualizing treatment and using the analgesic ladder to provide attentive, aggressive pain relief. The effectiveness of the WHO analgesic ladder is widely acknowledged; this regimen provides relief to 70% to 90% of patients with cancer pain. Movement through the analgesic ladder may not always progress through all steps in an orderly manner, depending on the intensity of the patient's pain. Some clinicians have suggested that the WHO three-step analgesic ladder may require some adjustment based on the clinical experience that has occurred in the 20 years since the ladder was proposed. A revised version (Fig. 36-8) superimposes management of acute pain (indicated by arrows) on the original WHO stair-step model, which provides a good visual representation of the basic differences between acute and chronic cancer pain management (Gai et al., 2020). The 10% to 30% of patients with severe pain who do not obtain satisfactory pain relief using this guideline may require alternative routes of drug administration, nerve blocks, or other invasive procedures to relieve their pain. The WHO ladder approach to pain management has also proved effective in treatment of patients with phantom limb pain and end-stage renal disease (Pasero & McCaffery, 2011).

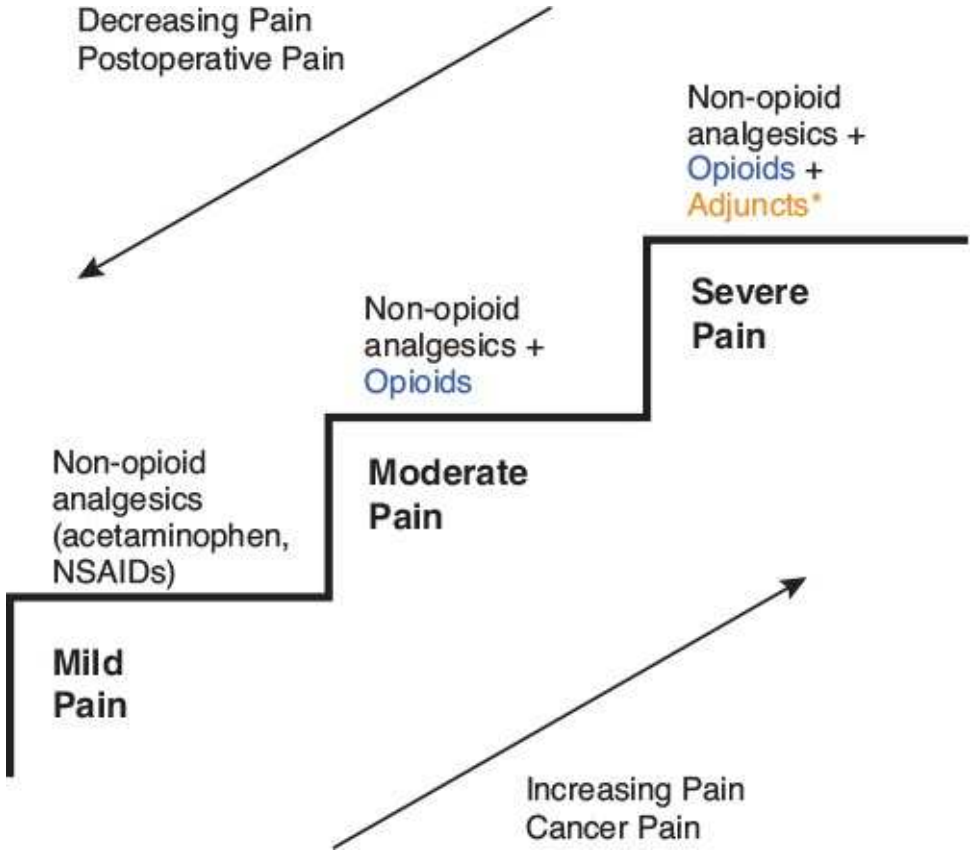

FIGURE 36-8. Various opioid (narcotic) and nonopioid medications may be combined with other medications. This adaptation of the WHO analgesic ladder for relieving cancer pain superimposes management of acute pain (indicated by arrows) on the original WHO stair-step model, which provides a visual representation of the basic differences between acute and chronic pain management. (*Source:* From Gai, N., Naser, B., Hanley, J., Peliowski, A., Hayes, J., & Aoyama, K. [2020]. A practical guide to acute pain management in children. *Journal of Anesthesia*, *34*[3], 421–433. https://doi.org/10.1007/s00540-020-02767-x.)

PROVIDING PAIN TREATMENT IN SPECIAL POPULATIONS

Children and older adults need accurate assessment and treatment of pain. Their behavioral indicators of pain are unique, which necessitates special approaches to determine the presence and level of pain as well as individualized techniques to relieve the pain.

Children

Effective pain management in children requires careful assessment; good communication among patient, family, and caregivers; and a thorough understanding of the actions and side effects of drugs used to relieve pain. The child is still the best source of information about the pain; various assessment tools mentioned previously help to measure the intensity of the pain.

Think back to **Xavier Malton**, the child with ulcerative colitis in acute pain. The nurse needs to assess Xavier continually for effectiveness of the prescribed analgesic and request changes in any orders if the analgesic is not effective. Considering Xavier's current state, suggesting that the health care provider change the analgesic administration from PRN dosing to around-the-clock dosing may be appropriate for a short period of time.

In postoperative situations, children need analgesics ATC or by continuous infusion. Opioids are the drug of choice for moderate to severe pain, but intentional dispensing, identified disposal procedures, and proactive prescriptions for naloxone are essential, especially with adolescents who are particularly vulnerable to diversion and OUD (Yaster et al., 2020; WHO, 2021). Pain management for cancer pain or chronic pain in children follows the guidance outlined in the WHO analgesic ladder and requires a biopsychosocial, interprofessional, multimodal approach (WHO, 2021). Withholding opioid drugs from children with cancer because of fear of addiction is unjustified because current knowledge does not indicate that they are vulnerable to this problem.

Children also require pain management to minimize or alleviate the pain and distress associated with some procedures. The misconception persists that children experience pain differently. It is important to understand that if a procedure is painful for an adult, it is also painful for a child. Adequate education before the procedure and using drug and nondrug therapies to complement each other can take the pain and fear out of the experience. This is especially important for children with a chronic disease who must undergo multiple procedures as part of the treatment regimen.

Older Adults

Research on pain management in older adults has focused on pain associated with chronic illness and acute postoperative pain. Up to 50% of older adults who live in the community report that pain impacts on their normal daily function, and at least half of older adults who reside in a long-term care facility report having pain on a daily basis (Galicia-Castillo & Weiner, 2021). Pain management in this population needs to involve strategies used for all adults, including biopsychosocial considerations, multimodal pharmacologic interventions, and nonpharmacologic strategies but must also consider polypharmacy, pharmacokinetics, and pharmacodynamics. Physical therapy, exercise, and rehabilitation often provide strength, stability, and stamina training that can mitigate pain and improve function (Pickering et al., 2018; Schwan et al., 2019). Recommendations for analgesic administration for older adults include the following (Ali et al., 2018; Galicia-Castillo & Weiner, 2021):

Focus on the Older Adult

NURSING STRATEGIES TO ADDRESS AGE-RELATED CHANGES AFFECTING COMFORT

Age-Related Changes	Nursing Strategies
Communication Difficulties	• Observe carefully for any behavioral manifestations or indications of pain (e.g., change in activity level or grimacing with movement). • Use open-ended questions to solicit information about pain. • Include family or caregiver to assist with information-gathering process. • Monitor for any behavior changes or confusion after medication has been taken.
Denial of Pain	• Clarify terms used to describe pain or discomfort. • Emphasize importance of reporting pain to caregivers. • Express concern about pain and a willingness to help. Explain that pain is not a normal consequence of aging.
Altered Physiologic Response to Analgesics	• Be aware of dosage and frequency to avoid oversedation and toxicity. • Monitor carefully for oversedation and respiratory depression. • Explain side effects of analgesics to patient. • Use memory aid if necessary to avoid overdosing. • Discourage self-medication of OTC medications. • Caution about use of alcohol with analgesics. • Caution about driving or operating machinery when taking analgesics.

- Use acetaminophen for older adults with mild to moderate pain.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

- Use NSAIDs (oral or topical) when other treatments have failed; use for the shortest period of time possible.
- Progress to opioids for severe pain when other treatments have been unsuccessful and the pain is impacting on quality of life and functional issues; consider risk versus benefits.
- Consider adjuvants that address depression and neuropathic pain.
- Consider the use of legal cannabis and cannabinoids while considering the potential dysphoric effects.

Opioid drugs can be used safely for older adult patients as long as appropriate precautions are taken, pain is conscientiously assessed, and potential side effects are monitored. A general rule when administering pain medications to older adults is *start low and go slow*. Adjust dosage and dosing intervals for the older adult based on therapeutic response to the drug and the presence of adverse effects. The accompanying Focus on the Older Adult box describes additional strategies pertinent to this age group.

ADMINISTERING ANALGESICS BY OTHER METHODS

In addition to the variety of drugs used to treat pain, multiple options exist for drug delivery systems. PCA, epidural analgesia, and other advanced interventions have improved pain management and the quality of life for many people.

Patient-Controlled Analgesia

PCA provides effective individualized analgesia and comfort (Fig. 36-9). This method of analgesia therapy may be used to manage acute and chronic pain in a health care facility or the home. It is used less frequently with cancer pain, for which oral medication is the preferred route. This device is most commonly used to deliver analgesics intravenously, subcutaneously, or via the epidural route. The most frequently prescribed drugs for PCA administration are morphine, fentanyl, and hydromorphone.

The PCA system consists of a computerized, portable infusion pump containing a chamber for a syringe that is prefilled with the prescribed opioid analgesic. Both The Joint Commission and the Institute for Safe Medication Practices (ISMP) recommend standard doses and concentrations prepared in prefilled syringes. Initially, a loading dose is administered to raise blood levels to a therapeutic level and control the pain. Although a PCA pump can be set to deliver at a set rate (automatic dose or basal rate), these pumps are more typically used to deliver a dose when initiated by the patient, especially in patients who are opioid-naïve (Gai et al., 2020; Polomano et al., 2017). When the sensation of pain reoccurs, the patient pushes a button that activates the PCA device to deliver a small preset bolus dose of the analgesic. A dose interval that is programmed into the PCA unit (usually 6 to 8 minutes) prevents reactivation of the pump and administration of another dose during that period of time. The pump mechanism can also be programmed to deliver only a specified amount of analgesic within a given time interval (the lock-out interval). These safeguards limit the possibility of possible overmedication. In addition, the preprogrammed intervals provide time for the patient to evaluate the effect of the previous dose. PCA pumps also have a locked safety system that prohibits any tampering with the device (Karch, 2020; Pasero & McCaffery, 2011). The goal with hospitalized patients who are using a PCA for acute pain management is to transition to an oral regimen prior to discharge. Adults and children weaning off a PCA to an oral opioid regimen may benefit from a hybrid PCA-oral administration model (Gai et al., 2020).

FIGURE 36-9. A patient-controlled analgesia unit allows the patient to regulate the intravenous infusion of small amounts of analgesic as needed.

The proper selection of patients for PCA is vital for a positive experience. Suitable candidates for this type of delivery system include people who are alert and capable of controlling the unit. The Joint Commission and ISMP both identify people who are not recommended for this type of pain relief. These include confused older adults, infants and very young children, cognitively impaired patients, patients with conditions for which oversedation poses a significant health risk (e.g., asthma and sleep apnea), and patients who are taking other medications that potentiate opioids. PCA has proven safe for use in children as young as 4 years of age who do not have developmental delays (Pasero & McCaffery,

2011).

PCA has many advantages:

- Consistent analgesic blood level is maintained rather than the inconsistent analgesia obtained with periodic injections, which prevents in sharp rises and falls of serum opioid levels.
- The analgesic is delivered intravenously or epidurally so that absorption is faster and more predictable than with the intramuscular route.
- The patient is in charge of the pain management program.
- The patient is able to ambulate earlier, which causes fewer pulmonary complications.
- The patient is more satisfied and has improved pain relief.

PCA by proxy, which means that someone other than the patient activates the pump, continues to be a controversial issue. Unauthorized family members or caregivers (instead of the patient) who administer PCA by pushing the dosage button can cause serious analgesic overdoses resulting in oversedation, respiratory depression, and death. Some clinicians argue that in a pediatric or critical care setting (Benjenk et al., 2020), nurse-controlled analgesia or caregiver-controlled analgesia is appropriate. For this to be safe, rigid facility protocols need to be in place. The Joint Commission issued a sentinel event alert on PCA and does not recommend PCA by proxy; the ISMP (2016) recently reiterated a similar position based on their original recommendations from 1996. Institutions must verify that they have protocols in place to protect against unauthorized PCA delivery. It is also recommended that clear warning labels stating, "WARNING: BUTTON TO BE PRESSED ONLY BY THE PATIENT" be attached to PCA pumps (ISMP). Refer to Chapter 28 for a discussion of sentinel event alerts. The Joint Commission and ISMP also advise that health care providers need to carefully monitor patients for respiratory depression using pulse oximetry and capnography (measurement of carbon dioxide concentrations) as appropriate. The carbon dioxide level in a patient's expirations can be measured by a sensor contained in a mask or nasal cannula that the patient is wearing. This provides a more reliable measure of impending respiratory depression.

Setting up the PCA system and ensuring that it is functioning properly are nursing responsibilities. Improper programming of the pump is the most common human error associated with this therapy. Both The Joint Commission and the ISMP recommend that a second nurse checks the patient ID, drug dose and concentration, PCA pump settings, the infusion tubing, and site prior to the initiation of PCA. The ISMP (2020) identified targeted medication safety best practices that include ensuring appropriate antidotes, reversal agents, and rescue agents are readily available, and verifying that associated protocols and directions for use/administration permit emergency administration of these agents.

Recall **Sheree Lincoln**, the postoperative patient who is to use the PCA system for pain control. Two hours after surgery, the patient reports pain but has not used the PCA system. The nurse would need to determine the underlying reasons for not using the device. This assessment would include investigation of Sheree's knowledge base and what, if any, teaching she received preoperatively. For example, Sheree may have received teaching on how to use PCA but may not have understood when or why to use it. Possibly she may want to avoid use of any medication. The nurse would use this opportunity to reinforce instructions for using PCA, and also for other nonpharmacologic measures for pain relief such as distraction, relaxation, massage, or imagery.

There are now several manufacturers of oral PCA devices that allow hospitalized patients to self-administer oral doses of opioid analgesics. These systems utilize a wireless device that grants single-patient access to a prescribed medication. Use of these devices results in a significant reduction in administration time and significantly lower reported pain scores (Collins et al., 2020; Pizzi et al., 2020; Wirz et al., 2021).

Opioid analgesia via a continuous subcutaneous infusion is a safe, effective alternative when IV access is not available and oral analgesia is no longer possible. Candidates for subcutaneous infusion are often patients requiring hospice and palliative care. Equipment consists of a small-gauge needle inserted subcutaneously, an infusion pump, and an administration set that is clearly labeled *subcutaneous infusion*. This setup delivers the opioid in a small amount of fluid (typically 2 to 3 mL/hr). Nurses can initiate subcutaneous infusion therapy once competence has been validated. Assessment includes monitoring of vital signs, pain level, and the insertion site for leakage, bleeding, or other complications (Gorski et al., 2021).

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

Epidural Analgesia and Peripheral Nerve Blocks

Epidural analgesia can be used to provide pain relief during the immediate postoperative phase (particularly after thoracic, abdominal, orthopedic, and vascular surgery) and for chronic pain situations. Epidural pain management is also being used for children with terminal cancer and for children undergoing hip, abdominal, spinal, or lower extremity surgery (Gai et al., 2020). Absolute contraindications include an allergic response to analgesics being used, coagulation disorders, anticoagulants, and localized infection or sepsis; relative contraindications include hypotension or compromised cardiovascular system, increased intracranial pressure, spinal abnormalities, and certain neurologic conditions. The patient must agree to the analgesia and the intraprofessional team must be competent in the administration and management of epidural analgesia (Galligan, 2020). The anesthesiologist usually inserts the catheter in the midlumbar region into the epidural space between the walls of the vertebral canal and the dura mater or outermost connective tissue membrane surrounding the spinal cord. For temporary therapy, the catheter exits directly over the spine, and the tubing is positioned over the patient's shoulder, with the end of the catheter taped to the person's chest. For long-term therapy, the catheter is usually tunneled subcutaneously and exits on the side of the body or on the abdomen (Fig. 36-10).

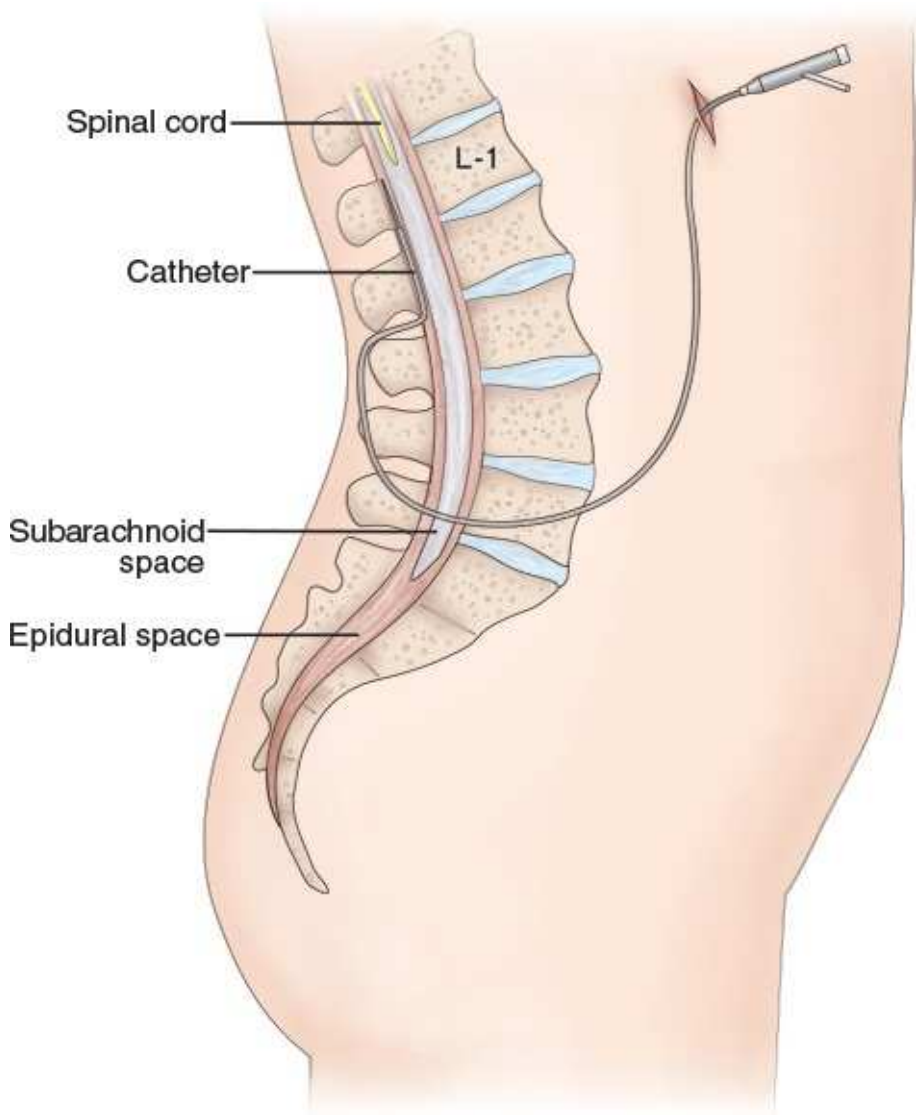

FIGURE 36-10. Placement of an epidural catheter for long-term use.

Typically, the opioid is combined with a local anesthetic (bupivacaine, levobupivicain, or ropivacaine). This combination improves pain management, and pain relief is achieved with smaller doses and less severe side effects (Galligan, 2020). The epidural analgesia can be administered as a bolus dose (either one time or intermittent) via a continuous infusion pump or by means of a patient-controlled epidural analgesia (PCEA) pump (Polomano et al., 2017; Wong & Lim, 2018). Because the epidural space contains blood vessels, nerves, and fat, lipid-soluble fentanyl is readily dissolved and has a rapid onset of action (5 minutes) but a short duration of action (approximately 2 hours). Hydromorphone has a 15- to 30-minute onset and a duration of action of up to 12 hours. Morphine has a slower onset of action (20 minutes) but may exert its analgesic effect for as long as 24 hours because it remains longer in the cerebrospinal fluid (CSF) and spinal tissue (Burchum & Rosenthal, 2019). Epidural catheters used for the management of acute pain are typically removed within 5 days of surgery, when oral medication can be substituted for relief of pain (Gai et al., 2020; Galligan, 2020).

Nursing responsibilities vary among institutions but must include careful monitoring and documentation of vital signs, laboratory values, pain intensity, motor and sensory block/function, the insert site and dressing, the delivery system, urinary output, and side effects related to surgery and opioid use (Gai et al., 2020; Galligan, 2020). See Guidelines for Nursing Care 36-1.

Peripheral nerve blocks produce a temporary loss of sensation and motor and autonomic function in a localized area. The local anesthetics work by chemically blocking the nerve pathways involved in pain sensation and response and are sometimes called *nerve blocks*. Many people have experienced nerve blocks during dental work, when having a wound sutured, during delivery of a newborn, or for some minor surgical procedures. Nursing measures include noting any

allergic responses the patient has had in the past to anesthetic agents, alerting the patient to the pain associated with the initial injection of the anesthetic or numbing agent, offering emotional support to the patient during the procedure, observing for any untoward effects, and protecting the patient from injury until sensory and motor functions return.

Topical Anesthesia

Anesthetic agents may be applied topically to the skin or mucous membranes. Two topical anesthetic creams (EMLA, which contains 2.5% lidocaine and 2.5% prilocaine, and LMX-4, formerly ELA-Max, a 4% lidocaine cream) provide safe, effective analgesia for children before painful procedures such as phlebotomy, lumbar puncture, or bone marrow aspiration. EMLA cream is prescribed by the health care provider and must be covered by an occlusive dressing for at least 1 hour before the procedure to provide local pain relief. After the time period, the cream is removed. LMX-4 is an OTC preparation that takes effect in 30 minutes or less (Hsu et al., 2020).

Guidelines for Nursing Care 36-1

Caring for Patients Receiving Epidural Opioids

Nursing Action	*Rationale*
Verify the health care provider's prescription for analgesia, drug preparation, and rate of infusion with another RN.	Verification provides for safe administration of the correct dose at the correct rate.
Keep an ampule of 0.4 mg of naloxone available on the unit.	Naloxone reverses the respiratory depressant effect of opioids.
Use epidural tubing. Label solution, tubing, and pump apparatus "For Epidural Infusion Only."	Labeling prevents inadvertent administration of other intravenous medications through this setup.
Assess and record sedation level (using a sedation scale) and respiratory status, including pulse oximetry continually for the first 20 minutes, at least q1h for the first 12 hours, every 2 hours up to 24 hours followed by q4h intervals until the epidural infusion is discontinued (or according to facility policy). Notify provider for the following: sedation rating of 3, ↓ in depth and respiratory rate below 8 breaths/min.	Opioids can depress respiratory center in the medulla. Change in level of consciousness is usually the first sign of altered respiratory function.
Keep head of bed elevated 30 degrees unless this is contraindicated.	Elevation of the patient's head minimizes upward migration of opioid in the spinal cord, thus decreasing risk for respiratory depression.
Record level of pain and effectiveness of pain relief.	Referencing helps in determining need for subsequent *breakthrough* pain medication.
Monitor urinary output and assess for bladder distention.	Opioids can cause urinary retention.
Assess movement and motor strength of lower extremities q4h.	Catheter may migrate into the intrathecal space and allow opioids to block transmission of nerve impulses completely through the spinal cord to the brain.
Monitor for side effects (pruritus, nausea, vomiting).	Opioids may spread into the trigeminal nerve, causing itching or resulting in nausea and vomiting due to slowed gastrointestinal function or stimulation of a chemoreceptor trigger zone in the brain. Medications are available to treat these side effects.
Assess for signs of infection, hematoma, or abscess at the insertion site.	Inflammation or local infection may develop at the catheter insertion site. Strict aseptic technique and sterile dressing and tubing changes according to facility policy can prevent infection. Monitor the site for

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

	bleeding.
Do not administer any other narcotics or adjuvant drugs without approval of clinician responsible for epidural management.	Additional medication may potentiate the action of the opioid, increasing the risk for respiratory depression.

Technology Alert

One system, ON-Q Pain Relief System, involves administration of local anesthetic medication directly at the affected surgical site. The benefit of this temporary system is earlier mobility and effective pain relief, with fewer side effects because of decreased opioid use postoperatively (Cinar et al., 2021; Porter et al., 2021).

Teaching the Patient and Family/Caregivers About Pain

Often, a well-informed person can cope better with the distress of pain and tends to experience less anxiety about pain. See the Promoting Health Literacy box (on page 1374) for suggestions regarding communicating with your health care provider to facilitate effective pain management.

Teaching about pain should include family members or caregivers so that they understand the concept of pain and are able to help the person in pain. The patient and anyone the patient identifies need information about the nature and causes of pain, explanation about a pain scale that can be used easily, practice with this assessment tool, and assistance to set goals for comfort and either optimal function or recovery. Encourage caregivers to be creative and specifically attuned to children's varied responses to pain. Play may be used effectively to discover a child's experience of pain and to teach the child how to cope with pain. Children are usually receptive to using dolls to act out pain experiences. Teaching Tips 36-1 includes specific suggestions related to safety concerns about pain control in the home setting. In addition, provide the patient and caregivers with information about available resources, including reputable online sources for pain control and treatment, and encourage them to use them.

Promoting Health Literacy

In Patients With Pain

Patient Scenario

Jennifer Tyler, 44, has had several visits to her primary provider about her pain. She told the office nurse that she "doesn't know how much more of this I can take." Her history reveals that she has had an "aching pain, literally all over my body" for the last 3 months. Jennifer states, "It's taking over my life now. Everything I do hurts, and to make matters worse, I don't sleep well at night, and I can't even think straight." Specific symptoms she reported include fatigue, occasional muscle spasms and pain in her legs, aching in her right shoulder, constant lower back pain, headaches that are occurring on a more frequent basis, and general anxiety about her health. Jennifer reports that initially she tried "Advil® off and on" with some mild relief and even admits taking some "old muscle relaxants" that her husband had from a back injury. Despite the antidepressants and sleeping pills that were prescribed for her, she has not been able to get much in the way of pain relief. After their initial examination, her provider has ordered a variety of laboratory studies to try and determine exactly what is causing Ms. Tyler's pain. At this visit, they told Ms. Tyler that they suspect fibromyalgia may be the cause of her pain and other symptoms. They prescribe pregabalin (Lyrica®) and want to see her again in 3 weeks to see how this medication is working for her. As she is making the next appointment, Jennifer tells the nurse, "I sure hope this new medicine works. I'm running out of hope here. What kind of a life is this?"

Nursing Considerations: *Tips for Improving Health Literacy*

Provide Ms. Tyler with printed literature about fibromyalgia. Explain that this disease is difficult to diagnose and that pregabalin (Lyrica®) was the first drug approved by the FDA to treat fibromyalgia. Tell Ms. Tyler that the provider may adjust her dose depending on how she tolerates the medicine and what kind of results she is getting from the drug. Caution her that dizziness and blurred vision may occur as side effects. Tell her if she has any signs of an allergic reaction, she should immediately stop taking the medication and report this to the health care provider. Inform her that she should avoid alcohol consumption while taking pregabalin and not drive if she experiences any dizziness or blurred vision. Explain to her that the provider may prescribe physical or occupational therapy for rehabilitation as she begins to rebuild her strength and stamina. Provide Ms. Tyler online resources, links, or apps to track her symptoms, locate a support group, and review other resources to increase the likelihood that Ms. Tyler is

accessing appropriate, verified information on the internet. Encourage Ms. Tyler when she returns for her next visit to be prepared to ask her health care provider the following questions:

- What is my main problem?
- What do I need to do?
- Why is it important for me to do this?
- What can you do if this new medication is not working?
- What else can you or I do to treat my pain?

What additional measures can you take to help maintain health literacy in this patient? What other measures would be helpful if Ms. Tyler did not speak English, could not read, did not have access to electronic resources, or had a learning disability?

Teaching Tips 36-1

COMFORT

Health Topic	Teaching Tip	Why Is This Important?
Safety	Do not drive vehicle or operate heavy machinery after taking opioids or other medications that cause drowsiness.	Reflexes may be slowed and cognitive thinking decreased due to opioids and other medications.
	Avoid alcohol and other CNS depressants while taking pain medication.	Alcohol may interact with the pain medication and further depress the CNS, leading to respiratory failure.
	Do not smoke without someone else present while taking pain medication.	The patient may become tired due to the medication, fall asleep while smoking, and start a house fire.
	Get assistance with walking and other ADLs as needed	Some pain medications can cause drowsiness, dizziness, and blurred vision.
	Keep a record or pain diary of level of pain, medication taken, and effect of medication.	Provides more accurate documentation of pain experience, allows for appropriate prescribing, and prevents overdoses.
Diet	Do not take pain medication on an empty stomach.	Many patients become nauseated if pain medication is taken on an empty stomach.
Miscellaneous	Do not breastfeed without checking with your health care provider while taking pain medication.	Many pain medications can be found in breast milk and may harm the baby.

Ensuring the Ethical and Legal Responsibility to Relieve Pain

Quality pain management results when patients have access to safe, effective, evidenced-based, multimodal pain relief measures. Health care providers, in addition to monitoring, delivering, and documenting administration of analgesics, have a responsibility to inform patients that effective pain management is vital to their treatment. Patients also have the right to expect that their statements of pain will be heeded. Institutions must assign and educate clinicians to address these issues in a timely, knowledgeable manner. The rights of patients with pain recognize the multidimensional aspects of the pain experience and a person's right to have pain management strategies implemented in conjunction with the health care team. Keep in mind that our treatment of pain is evolving, especially our use of opioids and management of OUD. See Box 36-3 for information on the HEAL initiative. The interprofessional team provides ongoing clinical consultation, support, and education, while engaging the patient in discussions regarding pain management goals, interventions, and reasonable outcomes.

Legal Alert

Patients have the right to be treated with dignity and to be involved in developing their pain management plan of care.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

Consider **Xavier Malton**, the child with acute pain. The nurses in the scenario advocated for Xavier, reinforcing his rights to have pain controlled as soon as possible.

Pain assessment and management is complex and prevention, mitigating, and treatment strategies are ever-evolving. To meet the specific needs of patients and the populations nurses serve, health care facilities have committed to a focus on best practices and improved patient outcomes by supporting the use of clinical experts. The Pain Resource Nurse (PRN) has an expressed interest in pain management, is an effective interprofessional/intraprofessional communicator, and acts as a coach or mentor for colleagues. The PRN role, which has been around since the 1990s, requires specific training and is often filled by a staff nurse involved with direct patient care. Goals of these PRN programs include: (1) demonstrating pain management as an institutional priority; (2) increasing staff knowledge of pain and serving as a peer resource; (3) driving evidence-based pain management education that is reflected in protocols, policies, and procedures; (4) translating best practices into daily clinical practice, supported by sustainable program improvement processes; and (5) delivering safe, quality patient care (Allen et al., 2018; Crawford et al., 2016).

Box 36-3 **National Institutes of Health (NIH) Helping to End Addiction Long-Term (HEAL) Initiative℠**

The NIH HEAL Initiative℠ is an aggressive, transagency effort to fund and support projects nationwide to address the opioid epidemic. It focuses on:

1. Enhancing pain management strategies rooted in preclinical, clinical, and translational research—designed to foster better understanding, treatment, and management of pain
2. Improving treatments for opioid use disorder (OUD) and addiction through research that will help prevent OUD and provide evidence-based, holistic, treatment of OUD (and overdose) that can be replicated in myriad settings

Source: U.S. Department of Health and Human Services-National Institutes of Health. *NIH HEAL Initiative℠*. Retrieved February 18, 2022, from https://heal.nih.gov/

Understanding the Placebo Controversy

The term placebo comes from the Latin word meaning "I shall please." A **placebo** is any sham medication or procedure that is designed and known to not be of any therapeutic clinical value. The person receiving the placebo treatment, unaware of the placebo's properties, may find it to be effective for the relief of pain because of the perception that it will provide comfort and because of belief in the person administering it. This is referred to as the *placebo effect*. Many of the nonpharmacologic and multimodal pharmacologic strategies described in this chapter relied upon a sham intervention or placebo to test their efficacy. Various researchers have reported that a positive placebo effect may be related to a physiologic response (release of endorphins) or the patient's cultural expectations, attitudes, health beliefs, or anticipation of a positive response. Use of a placebo also has the potential to cause a harmful or undesirable response referred to as a *nocebo*. This negative outcome may involve mild discomforts such as nausea and pruritus or life-threatening complications.

The use of placebos outside of IRB-approved clinical trials, raises serious ethical questions. Is lying to a patient ever justifiable? A nurse who administers a hidden placebo must be willing to risk the possible consequence of the patient becoming aware of the duplicity and then refusing to trust the nurse or any other health care professional again. Patients who feel themselves to be in pain are vulnerable. If such patients discover a seeming plot to trick them into feeling better, it is unlikely that those patients will respect or appreciate the intentions of the physicians and nurses involved. The long-term negative effects of this practice far outweigh any of its benefits. Multiple facilities and professional organizations directly oppose placebo use outside of clinical trials, including the Oncology Nursing Society, the American Nurses Association, the American Society of Pain Management Nurses, and the American Pain Society (Arnstein et al., 2011). The nurse has firm legal and ethical grounds for refusing to administer a placebo to a patient who is not aware that receiving a placebo is possible.

Evaluating

As soon as a pain problem is identified and a treatment plan developed and implemented, evaluation becomes ongoing. Evaluation is directed toward the changing nature of the pain experience, the treatment modalities (pain management program), and the patient's and family's or caregiver's response(s) to the care plan, all of which overlap.

Experience of Evolving Pain

The pain the patient is experiencing may change in many ways, thus the nurse must be careful not to make a judgment about this too quickly. For example, if the pain lessens in intensity or disappears, it may mean that the underlying cause of the pain is diminished or absent and that treatment should be stopped, or it may mean that the pain management program is effective and should be continued. When pain intensity increases, it may simply indicate the need for more aggressive therapy, or it may be a warning that the underlying pathology has changed or worsened, and that new medical intervention is required. Often, a new problem amenable to treatment is masked by old or underlying pain, and its detection may be delayed to the point that treatment is useless.

Management Regimens

The use of both multimodal pharmacologic and nonpharmacologic therapies must be continually evaluated to determine whether they are the best possible means the patient could use to obtain pain relief, and whether they are effective with only minimal risk to the patient. Too often, a patient stays with the first analgesic prescribed without questioning whether it is the most effective drug for the particular pain, whether the dosage and timing guidelines are correct for the patient, and whether the analgesic is producing annoying or even harmful side effects that another drug would not produce. Patient and public safety are the priority when establishing and maintaining a pain management regimen.

Similarly, one patient may take to progressive relaxation exercises and find them helpful, whereas another patient may obtain similar benefits from a daily walking program. Nursing time spent evaluating the effectiveness of each pain relief therapy is well spent and results in a pain management program that is truly individualized for the patient.

Patient and Family Response

Ultimately, the plan of care is unsuccessful unless the patient and family (as defined by the patient) are satisfied with the results. But keep in mind that the elimination of pain is not always a reasonable goal. The interprofessional health care team needs to work directly with the patient and family to set and then evaluate reasonable, individualized goals for pain management. A successful plan of care results in the achievement of specified patient outcomes valued by the patient.

REFLECTIVE PRACTICE LEADING TO PERSONAL LEARNING

Remember that the object of reflective practice is to look at an experience, understand it, and learn from it. As you begin to develop your expertise in evaluating the care plan, reflect on your experiences—successes and failures—in order to improve your practice. How can you do it better next time? What did you learn today that can help you tomorrow? Begin your reflection by paying close attention to the following:

- How consistently do you personally incorporate pain assessment into your daily care? How have you worked to develop skills related to this assessment? How do you integrate your objective assessment with the subjective pain report from the patient?
- What value do you attach to involving the patient in establishing a pain management regimen? Which multimodal pharmacologic and nonpharmacologic interventions do you feel comfortable explaining and integrating into a recommended regimen? How do you individualize the care for patients when so many guidelines, policies, and procedures dictate your care?
- How does the public health issue of opioid abuse impact on your practice? How do you engage in pain management interventions while ensuring safety for your patient and the public?

Keeping up with the latest evidence-based practice guidelines can be challenging. Complex, multimodal pharmacologic regimens, a measured emphasis on nonpharmacologic interventions, the nature of pain as an individual experience, and national concerns and guidelines all impact on the nurse's ability to assist the patient in pain management. Balancing the needs of your individual patient with these responsibilities requires mindfulness and intentionality.

Perhaps the most important questions to reflect on are: Are your patients and their families/caregivers better for having had *you* share in the critical responsibility of partnering with them to ensure appropriate pain management practices? Are your patients now receiving thoughtful, person-centered, prioritized, holistic, evidence-based treatment and care because of your efforts?

Skill 36-1 Giving a Back Massage

DELEGATION CONSIDERATIONS

Providing a back massage may be delegated to assistive personnel (AP) as well as to licensed practical/vocational nurses (LPN/LVNs). The decision to delegate must be based on careful analysis of the patient's needs and circumstances as well as the qualifications of the person to whom the task is being delegated. Refer to the Delegation Guidelines in Appendix A.

EQUIPMENT

- Pain assessment tool and pain scale
- Lotion or oil, to which the patient has no allergy or aversion (Westman & Blaisdell, 2016)
- Bath blanket
- Towel
- Nonsterile gloves, if indicated
- Additional PPE, as indicated

IMPLEMENTATION

ACTION	RATIONALE
 1. Perform hand hygiene and put on PPE, if indicated.	Hand hygiene and PPE prevent the spread of microorganisms. PPE is required based on transmission precautions.
 2. Identify the patient.	Identifying the patient ensures the right patient receives the intervention and helps prevent errors.
3. Offer a back massage to the patient and explain the procedure.	Explanation encourages patient understanding and engagement and reduces apprehension.
4. Put on gloves, if indicated.	Gloves are not usually necessary. Gloves prevent contact with blood and body fluid.
5. Close the room door and/or the curtain around the bed. Turn down the lights, if possible, and adjust the room temperature for patient comfort (Westman & Blaisdell, 2016).	Closing the door or curtain provides privacy, promotes relaxation, and reduces noise and stimuli that may aggravate pain and reduce comfort (Aparício & Panin, 2020; Goeren et al., 2018). Lowering the lights, reducing noise, and adjusting the temperature of the room create a calming environment (Westman & Blaisdell, 2016).
6. Assess the patient's pain using an appropriate assessment tool and measurement scale. Ask the patient if they have any aversion to touch (Westman & Blaisdell, 2016).	Accurate assessment is necessary to guide treatment and pain relief interventions and to evaluate the effectiveness of pain control measures. Patients with posttraumatic stress disorder or previous negative experience with massage may not want to receive massage (Westman & Blaisdell, 2016).
7. Raise the bed to a comfortable working position (VHA Center for Engineering & Occupational Safety and Health [CEOSH], 2016), and lower the side rail.	Having the bed at the proper height prevents back and muscle strain.
8. Assist the patient to a comfortable position, preferably the prone or side-lying position. Remove the covers and move the patient's gown just enough to expose the patient's back from the shoulders to sacral area. Drape the patient, as needed, with the	This position exposes an adequate area for massage. Draping the patient provides privacy and warmth.

	bath blanket.	
9.	Warm the lubricant or lotion in the palm of your hand, or place the container in small basin of warm water. During the massage, observe the patient's skin for reddened areas or injury. **Avoid areas of injury, such as wounds, burns, and pressure ulcers and areas with rashes, tubes, and IV access/lines** (Westman & Blaisdell, 2016). See Chapter 33 for detailed information regarding skin assessment.	Cold lotion causes chilling and discomfort. Massage of these areas could result in further injury and is contraindicated (Westman & Blaisdell, 2016).
10.	Using light, gliding strokes (*effleurage*), apply lotion to patient's shoulders, back, and sacral area (Figure 1).	Effleurage relaxes the patient and lessens tension.
11.	Place your hands beside each other at the base of the patient's spine and stroke upward to the shoulders and back downward to the buttocks in slow, continuous strokes (Figure 2). Continue for several minutes.	Continuous contact is soothing and stimulates circulation and muscle relaxation.
12.	Massage the patient's shoulders, entire back, areas over iliac crests, and sacrum with circular, stroking motions, keeping hands in contact with the patient's skin. Continue for several minutes, applying additional lotion, as necessary.	A firm stroke with continuous contact promotes relaxation.
13.	Knead the patient's back by gently alternating grasping and compression motions (*pétrissage*) (Figure 3).	Kneading increases blood circulation.
14.	Complete the massage with additional long, stroking movements that eventually become lighter in pressure (Figure 4).	Long, stroking motions are soothing and promote relaxation; continued stroking with gradual lightening of pressure helps extend the feeling of relaxation.

FIGURE 1. Using light, gliding strokes to apply lotion.

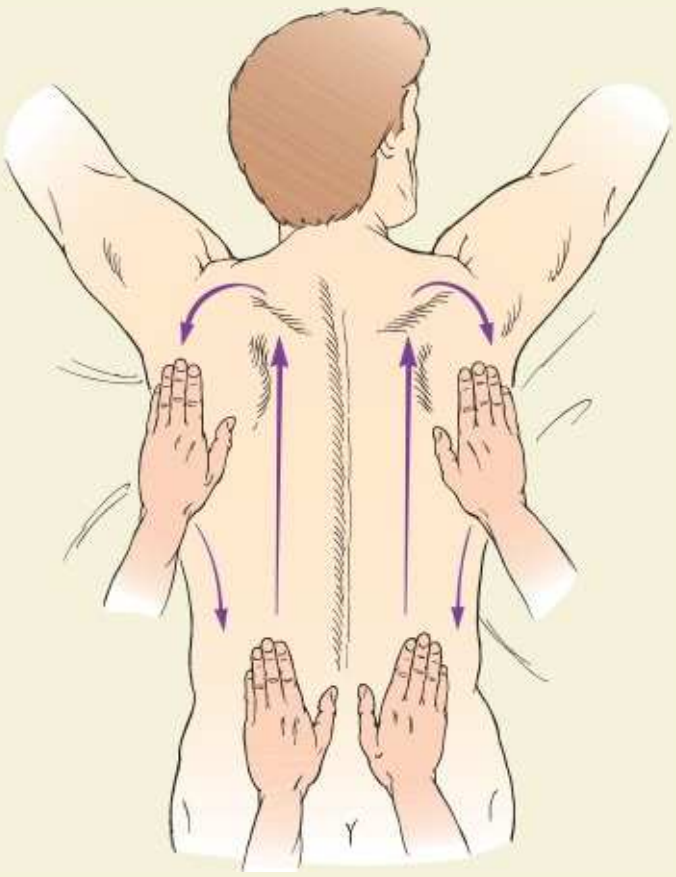

FIGURE 2. Stroking upward to shoulders and back downward to the buttocks.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

FIGURE 3. Kneading the patient's back.

FIGURE 4. Using long strokes with lessening pressure.

15. If excess lotion remains, use the towel to pat the patient dry.	Drying provides comfort and reduces the feeling of moisture on the back.
16. Remove gloves, if worn, and perform hand hygiene. Reposition patient's gown and covers. Raise side rail and lower bed. Assist patient to a position of comfort.	Removal of gloves and hand hygiene prevent transmission of microorganisms. Repositioning bedclothes, linens, and the patient helps to promote patient comfort and safety.
17. Remove additional PPE, if used. Perform hand hygiene.	Proper removal of PPE reduces the risk for infection transmission and contamination of other items. Hand hygiene prevents transmission of microorganisms.
18. Evaluate the patient's response to this intervention. Reassess level of discomfort or pain using original assessment tools. Reassess and alter care plan, as appropriate.	Reassessment allows for individualization of the patient's plan of care and promotes optimal patient comfort.

DOCUMENTATION

Guidelines

Document pain assessment and other significant assessments. Document massage use, length of time of massage, and patient response.

Sample Documentation

12/6/25 2330 Patient reports inability to sleep and increased pain at surgical site, rated 3/10. Medicated with acetaminophen 650 mg, as prescribed. Back massage administered ×10 minutes. Skin intact without redness. Patient reports increased comfort and relaxation; "I feel like I can sleep now."

—B. Black, RN

12/6/25 2400 Patient reports pain level 0/10.

—B. Black, RN

DEVELOPING CLINICAL REASONING AND CLINICAL JUDGMENT

UNEXPECTED SITUATIONS AND ASSOCIATED INTERVENTIONS

- *Patient cannot lie prone, so you are giving them a back massage while they are lying on their side. However, as you begin to massage the back, the patient cannot maintain the side-lying position:* If possible, have the patient hold on to the side rail on the side to which they are facing. If this is not possible or the patient cannot assist, use pillows and bath blankets to prevent the patient from rolling. If necessary, enlist the help of another person to maintain the

patient's position. If possible, experiment with other positions based on the patient's condition and comfort, such as leaning forward against a pillow on the bedside table while sitting in a chair.

- *While massaging the patient's back, you notice a 5-cm reddened area on the patient's sacrum:* Note this observation in the patient's health record and communicate it to the health care team. Do not massage the area. When the back massage is completed, position the patient off the sacral area, using supports to maintain the patient's position, and institute a turning schedule.

SPECIAL CONSIDERATIONS

General Considerations

- Before giving a back massage, assess the patient's body structure and skin condition, and tailor the duration and intensity of the massage accordingly. If you are giving a back massage at bedtime, have the patient ready for bed beforehand so the massage can help them fall asleep.
- Massage only the hands, feet, or scalp of patients with sepsis, fever over 100°F, sickle cell or HIV crisis, thrombocytopenia, or meningitis (Westman & Blaisdell, 2016).
- Check in frequently with the patient during the massage, asking how the massage feels and adjust the pressure and technique based on the patient's preferences (Westman & Blaisdell, 2016).

Infant and Child Considerations

- Hold infants and small children in a comfortable, well-supported position, such as against the chest or across the lap.
- Oil or lotion should be odorless and edible in case the infant or child gets some in their mouth (MFMER, 2020).

Older Adult Considerations

- Be gentle with massage. The skin on older adults is often fragile and dry.
- Reduce pressure, provide short massage sessions, and consider alternative positions, such as supine or seated positions for massage with older adults (Durand, 2020).

DEVELOPING CLINICAL REASONING AND CLINICAL JUDGMENT

. Work through the Evolving Case Study 36-1 to help develop your clinical reasoning and clinical judgment skills.
. Interview a nurse who specializes in pain management. Ask the nurse to describe the various physiologic, psychological, and social responses to pain that the nurse has observed in patients with acute and chronic pain. Question the nurse about the different nursing interventions most likely to be effective for patients experiencing either acute or chronic pain. Inquire about specific pain management information and guidelines that the nurse usually includes in discharge planning and teaching.
. Consider what you personally believe about pain: what it is, what causes it, what is most likely to relieve it. Determine how pain is currently being managed within the tradition of Western medicine and what role nursing plays in keeping patients pain-free. Visit nontraditional health centers where practitioners use a variety of noninvasive pain relief modalities, such as acupressure, mindfulness techniques, imagery, and dry needling. In what ways, if any, has this new learning experience modified your beliefs about pain? Will it change your ability to design effective pain management regimens for your patients?

EVOLVING CASE STUDY 36-1

Scenario: Carla is a 72-year-old woman who has a history of type 2 diabetes and associated diabetic neuropathy. Her wife is present at Carla's outpatient visit with the nurse practitioner, and Carla asks that she be included in all conversations. Carla is a retired schoolteacher with two grown daughters. She and her wife have been looking forward to traveling, but they are afraid that the complications from Carla's diabetes may impact on these plans. Carla has been followed by an endocrinologist for the past 8 years. The endocrinologist has documented that despite an A1c close to the goal range, Carla has complications from her diabetes, one of which is the direct cause of the persistent pain in Carla's legs.

QUESTION r/t CUES: Based on the patient's history, what initial question is the most important for the nurse to ask?

A. "Can you tell me about your pain?"
B. "So, what's new with you and your wife?"
C. "Have you been following the diet plan we outlined for you?"
D. "Tell me about your daily routine: what do you do on a daily basis?"

Scenario: Carla tells you that she has increased generalized discomfort—fatigue, anxiety, irritability—that she

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

attributes to the stress of this new-onset, persistent pain. Carla tells you the pain is in both legs and began as occasional, sharp pain, but has evolved into a constant ache. Carla appears tense and her brow furrows as she reaches down to touch her legs.

QUESTION r/t ANALYZING CUES: Based on this opening description of pain, what other information would be helpful in determining the plan of care? Select all that apply.

A. Assessment of the quality of care provided by the endocrinologist
B. Carla's wife's objective view of the patient's pain progression
C. Identification of anything that seems to trigger the pain
D. Interventions that have been tried—what worked and what did not work
E. Other symptoms that may be related or associated with the pain experience

Scenario: Carla shakes her head and tells you she is just trying to make it through the day; she is unable to describe any appropriate pain, stress, or anxiety management techniques. She admits she has occasionally taken some of her wife's "old tranquilizers" to ease her through a bad day, but she prefers not to take pain medication. Carla adheres to the general diet and medication regimen mandated by her type 2 diabetes but admits that the stress of these complications is impacting on her desire and ability to maintain control over her blood glucose.

QUESTION r/t PRIORITIZING HYPOTHESIS: Based on the objective and subjective assessment of this patient, where should the nurse focus the initial efforts of the interprofessional team?

A. Collaborating with the endocrinologist to manage the patient's blood glucose and A1c
B. Consulting psychiatry to set up a medication regimen to treat the patient's anxiety and depression
C. Working with the provider, the patient, and the patient's wife to address functional pain goals
D. Providing detailed information on the microvascular and macrovascular complications of type 2 diabetes

Scenario: The nurse works with Carla and her wife to determine the mutually agreed upon pain goal is 1/10 at rest and 3/10 with activity. Carla's functional goal is to have the stability and stamina to plan a walking tour of a new city without the pain impacting on her enjoyment of the trip.

QUESTION r/t GENERATING SOLUTIONS: Based on this information, the provider decides to add pharmacologic strategies to the plan of care. Which interventions are the ***priority*** for Carla? Select all that apply.

A. Provide information about a multimodal pain regimen
B. Focus on the side effects of high-dose immediate-release opioids
C. Discuss the significant risk for addiction with Carla and her wife
D. Teach adjuvant medications such as gabapentin for treatment of neuropathic pain
E. Integrate elements from the biopsychosocial model when designing interventions

Scenario: Carla's wife has been listening intently but has not yet said anything. You ask Carla's wife if she has any questions and she says, "I appreciate that, at this point, medications are probably necessary, but I was hoping for some other ideas about what we could do to help Carla."

QUESTION r/t TAKING ACTION: What other intervention(s) can be implemented for Carla?

A. Nothing quite yet—we need to see how the medications work before implementing other interventions.
B. The nurse could collaborate with Carla's wife to substitute the medications for placebos to see if the idea of medication helps the pain.
C. Carla could take any number of over-the-counter (OTC) and herbal supplements to augment the medications.
D. The nurse could ask Carla if she is willing to incorporate imagery, mindfulness, or other nonpharmacologic interventions.

Scenario: Carla is back in the office for an outpatient visit with the provider. As soon as you see Carla, she pulls out her phone to show you pictures of Helen, Georgia where she and her wife just vacationed.

QUESTION r/t EVALUATING OUTCOMES: How will the nurse and Carla know that the treatment plan has been effective?

A. Carla is completely pain free but is taking large doses of OTC acetaminophen.
B. Carla reports some pain but states she was able to engage in the full walking tour with occasional rest periods.
C. Carla admits that she is not taking the medication because she has just learned to live with the pain.
D. Carla tried a few nonpharmacologic recommendations but has opted to simply double the prescribed dose.

PRACTICING FOR NCLEX

. During postconference, nursing students are exploring definitions of pain and its nature. Which statements should be included in this discussion? Select all that apply.

a. "It is whatever the health care provider treating the pain says it is."

b. “Pain exists whenever the person experiencing it says it is present.”
c. “It is an emotional and sensory reaction to tissue damage.”
d. “Pain is a simple, universal, and easy-to-describe phenomenon.”
e. “When a cause cannot be identified, pain is psychological in nature.”
f. “It is classified by duration, location, source, transmission, and etiology.”

. A nurse in a rehabilitation facility is evaluating patients with chronic pain to develop an interprofessional plan of care. Which patients would the nurse identify who could benefit from a multimodal approach to pain management? Select all that apply.
a. Patient receiving chemotherapy for bladder cancer
b. Adolescent who had an appendectomy
c. Patient who is experiencing a ruptured aneurysm
d. Patient with fibromyalgia requesting pain medication
e. Patient having back pain related to an accident that occurred last year
f. Patient experiencing pain from second-degree burns

. A patient reports diffuse abdominal pain that is difficult to localize. The nurse documents this as which type of pain?
a. Cutaneous
b. Visceral
c. Superficial
d. Somatic

. Which question by the nurse will be most helpful in determining whether a patient who is experiencing a myocardial infarction has referred pain?
a. “Did your chest pain last 2 minutes or less?
b. “Was the pain on the surface of your chest?”
c. “Is this pain in your residual limb shooting or burning?”
d. “Are you having any arm or shoulder pain?”

. A nurse is caring for patients who are nonverbal. What are examples of behavioral responses to pain? Select all that apply.
a. Cradling a wrist that was injured in a car accident
b. Moaning and crying from abdominal pain
c. Increasing pulse following a myocardial infarction
d. Striking out at a nurse who attempts to provide a bath
e. Acting depressed and withdrawn while experiencing chronic cancer pain
f. Pulling away from a nurse trying to give an injection

. A nurse is caring for patients in a hospital setting. Which patient would the nurse place at risk for pain related to the mechanical activation of pain receptors?
a. Older adult on bedrest following cervical spine surgery
b. Patient with a severe sunburn being treated for dehydration
c. Industrial worker who has burns caused by a caustic acid
d. Patient experiencing cardiac disturbances from an electrical shock

. A nurse plans to promote a patient’s natural pain mediators by using a whirlpool following intensive physical therapy to the legs. What is a potent pain-blocking neuromodulator, released through relaxation techniques?
a. Prostaglandins
b. Substance P
c. Endorphins
d. Serotonin

. A postoperative patient asks the nurse about pain management following surgery. What teaching will the nurse provide?
a. “Avoid asking for pain medication often, as it can be addictive.”
b. “It is better to wait until the pain is severe before asking for pain medication.”
c. “It’s natural to have pain after surgery; it will lessen in intensity in a few days.”
d. “You will be more comfortable if you take the medication at regular intervals.”

. The nurse applies the gate control theory of pain to provide pain relief to a patient with chronic lower back pain. What nursing intervention will help relieve pain by “closing the gate”?

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

a. Encouraging regular use of analgesics
b. Applying moist heat to the area at intervals
c. Reviewing the pain experience with the patient
d. Ambulating the patient after administering medication

. The nurse is assessing the pain of a neonate who is admitted to the NICU with a heart defect. Which pain assessment scale would be the best tool to use with this patient?

a. CRIES
b. COMFORT
c. FLACC
d. FACES

. When the nurse assists a patient recovering from abdominal surgery to walk, the nurse observes that the patient grimaces, moves stiffly, and becomes pale. The nurse received in shift report that the patient has consistently refused pain medication. To help promote comfort, which additional data will the nurse gather? Select all that apply.

a. Patient's understanding of or fear of taking prescribed analgesics
b. Assessment of any current pain
c. Presence of anxiety or additional stressors
d. Assessment of the surgical incision for infection
e. What the patient has eaten to this point
f. Whether the patient is using the incentive spirometer

. When developing the care plan for a patient with chronic pain, the nurse plans interventions based on the knowledge that chronic pain not related to cancer or palliative/end-of-life care is most effectively relieved through which method?

a. Providing the highest effective dose of an opioid on a PRN (as needed) basis
b. Using nonopioid drugs conservatively
c. Applying multimodal nonpharmacologic and nonopioid pharmacologic therapies
d. Administering a continuous intravenous infusion on a regular basis

. When assessing pain in a child, the nurse needs to be aware of what considerations?

a. Immature neurologic development results in reduced pain sensation
b. Inadequate or inconsistent relief of pain is widespread
c. Reliable assessment tools are currently unavailable
d. Narcotic analgesic use should be avoided

. A pregnant woman has received an epidural analgesic prior to delivery. Assessment for which outcome to the medication will the nurse prioritize?

a. Pruritus
b. Urinary retention
c. Vomiting
d. Respiratory depression

. A nurse is assessing a patient receiving a continuous opioid infusion. For which outcome of treatment would the nurse immediately notify the primary care provider?

a. A respiratory rate of 11/min with normal depth
b. A sedation level of 4
c. Mild forgetfulness
d. Reported constipation

. A patient is receiving a multimodal medication regimen as part of the treatment plan for neuropathic phantom limb pain. When the patient reports a bloody bowel movement, which medication prescription requires notification of the provider?

a. Acetaminophen
b. Nonsteroidal antiinflammatory
c. Opioid medication
d. Antianxiety medication

. A nurse on an adult surgical floor enters a patient room and observes a family member pressing the button to administer a dose of PCA via the infusion pump. What response by the nurse is most appropriate?

a. "That dose will sure be helpful after their type of surgery."
b. "Having only the patient use the pump prevents respiratory complications."

c. “If the patient asked you to press the button, then it’s OK.”
d. “Since the pump has built in safeguards, you can help with pain management.”

. Students in a leadership class are discussing how social determinants of health affect pain management. Which statement is correct and should be included in the discussion?

a. “Outcomes of pain management are generally satisfactory regardless of income.”
b. “Minority patients often receive excess medication.”
c. “Patients from minority groups often wait a long time before seeking treatment for pain.”
d. “Social determinants of health are unrelated to pain management.”

ANSWERS WITH RATIONALES

. **b, c, f.** Nurses must respect patients’ reports of pain and consider the patient an expert on their pain experience. An accepted definition of pain is that pain is whatever the patient says it is, existing whenever the person says it does, even if the cause is not clearly established.” Pain is a complex, unpleasant sensory and emotional experience associated with actual or potential tissue damage. Pain may be classified according to its duration, its location or source, its mode of transmission, or its etiology.

. **a, d, e.** Chronic pain is pain that may be limited, intermittent, or persistent but that lasts beyond the normal healing period. Examples are cancer pain, fibromyalgia pain, and back pain. Acute pain is generally rapid in onset and varies in intensity from mild to severe, as occurs with an emergency appendectomy, a ruptured aneurysm, and pain from burns.

. **b.** Visceral pain, which is poorly localized and can originate in body organs in the abdomen. Cutaneous pain (superficial pain) usually involves the skin or subcutaneous tissue. A paper cut that produces sharp pain with a burning sensation is an example of cutaneous pain. Deep somatic pain is diffuse or scattered and originates in tendons, ligaments, bones, blood vessels, and nerves. Strong pressure on a bone or damage to tissue that occurs with a sprain causes deep somatic pain.

. **d.** Referred pain is perceived in an area distant from its point of origin, whereas transient pain is brief and passes quickly. One example is the pain of MI (heart attack) that can be felt in the shoulder or chest, among other areas. Superficial pain originates in the skin or subcutaneous tissue. Phantom pain may occur in a person who has had a body part amputated, either surgically or traumatically.

. **a, b, f.** Physiologic responses are involuntary body responses; behavioral responses reflect body movements; affective responses reflect mood and emotions. Protecting or guarding a painful area, moaning and crying, and moving away from painful stimuli are behavioral responses. Examples of a physiologic or involuntary response would be increased blood pressure or dilation of the pupils. Affective responses, such as anger, withdrawal, and depression, are psychological in nature.

. **a.** Receptors in the skin and superficial organs may be stimulated by mechanical, thermal, chemical, and electrical agents. Friction from bed linens causing pressure sores is a mechanical stimulant. Sunburn is a thermal stimulant. An acid burn is the result of a chemical stimulant. An electrical shock is an electrical stimulant.

. **c.** Endorphins are produced at neural synapses at various points along the CNS pathway. They are powerful pain-blocking chemicals that have prolonged analgesic effects and produce euphoria. It is thought that endorphins are released through pain relief measures, such as relaxation techniques. Prostaglandins, substance P, and serotonin (a hormone that can act to stimulate smooth muscles, inhibit gastric secretion, and produce vasoconstriction) are neurotransmitters or substances that either excite or inhibit target nerve cells.

. **d.** While many analgesics are ordered on a PRN (as needed) basis, patients should be taught that it is more difficult to relieve pain that prevent it. The patient should not wait until pain is severe or unbearable to request pain medication. Few people become addicted to the medications if used for a short period of time. Pain following surgery can be controlled and should not be considered a natural part of the experience that will lessen in time.

. **b**. The gate control theory states that a limited amount of sensory information can be processed by the nervous system at any given moment. When too much information is sent through, certain cells in the spinal column interrupt the signal as if closing a gate, interfering with pain perception. Nursing measures such as applying warmth to the lower back stimulate the large nerve fibers to close the gate and block the pain. The other choices do not involve attempts to stimulate large nerve fibers that interfere with pain transmission as explained by the gate control theory.

. **a.** The CRIES Pain Scale is a tool intended for use with neonates and infants from 0 to 6 months. The COMFORT Scale, used to assess pain and distress in critically ill pediatric patients, relies on six behavioral and two physiologic factors that determine the level of analgesia needed to adequately relieve pain in these children. The FLACC Scale (F—Faces, L—Legs, A—Activity, C—Cry, C—Consolability) was designed for infants and children from age 2 months to 7 years who are unable to validate the presence or severity of pain. The FACES Scale is used for children who can compare their pain to the faces depicted on the scale.

. **a, b, c, d.** While it seems the patient’s immediate problem is unrelieved pain because the patient refuses to take pain medication, through further assessment, the nurse can plan to address fears of medication, teach about use of the

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

pump, determine if anxiety is interfering with pain, or an infection is causing increased pain. While decreased oral intake may be a response to pain, the patient's dietary intake will not uncover the underlying reason for refusing medications. Use of the incentive spirometer is not included in pain assessment; rather, it is an intervention to prevent atelectasis.

. **c.** Nonpharmacologic and nonopioid pharmacologic therapies (multimodal) are the preferred choices for chronic pain that is unrelated to active cancer, palliative care, or end-of-life care. If progression to opioids becomes necessary, the lowest effective dose of an immediate-release opioid should be initiated first. Ongoing assessment and careful monitoring should guide the prescription of opioids for the management of chronic pain (Dowell et al., 2016). A PRN (as needed) drug regimen has not been proven effective for people experiencing chronic or acute pain. When caring for a patient with acute pain, such as postoperative pain, medication should be offered or requested before pain becomes severe or unbearable. Once pain is adequately treated, such as later in the postoperative course, a PRN schedule may be effective.

. **b.** Health care personnel are placing awareness of pain relief in children as a priority. The evidence supports the fact that children do indeed feel pain, and reliable assessment tools are available specifically for use with children. Opioid analgesics may be safely used with children as long as they are carefully monitored.

. **d.** An opioid drug given by way of an epidural catheter or a displaced catheter may result in the occurrence of respiratory depression. Pruritus, urinary retention, and vomiting may occur but are not life threatening.

. **b.** Sedation levels predict respiratory depression. The sedation scale uses: S = sleep, easy to arouse: no action necessary; 1 = awake and alert; no action necessary; 2 = occasionally drowsy but easy to arouse; requires no action; 3 = frequently drowsy and drifts off to sleep during conversation; decrease the opioid dose; and 4 = somnolent with minimal or no response to stimuli; discontinue the opioid and consider use of naloxone. A respiratory level of 11 with normal depth of breathing is usually not a cause for alarm. Mild forgetfulness or confusion may result from opioids; additional observation is necessary. Constipation is not life threatening; it should be reported to the health care provider but is not the priority.

. **b.** The NSAIDs are contraindicated in patients with bleeding disorders (their action may interfere with platelet function). The nurse will hold the medication and collaborate with the provider to adjust the patient's prescriptions.

. **b.** Unauthorized family members or caregivers (instead of the patient) who administer PCA by pushing the dosage button can cause serious analgesic overdoses resulting in oversedation, respiratory depression, and death. This is known as PCA by proxy. Institutions should have protocols in place to protect against unauthorized PCA delivery and clear warning labels attached to PCA pumps stating, "WARNING: BUTTON TO BE PRESSED ONLY BY THE PATIENT" (ISMP).

. **c.** Social determinants of health greatly impact on pain management outcomes. Patients residing in low-income settings and minority populations are less likely to receive the recommended treatments for pain in health care settings. Minority patients often experience pain for a lengthy period of time before seeking treatment for it. Language barriers, culturally inappropriate pain assessment tools, and prejudice and misconceptions may contribute to unsatisfactory pain outcomes. Initiatives to address health care access and treatment disparities begin at the local and community level.

Nutrition

Susan Oakland

Susan Oakland, a 21-year-old student, is pregnant with her first child. Susan is in the ninth week of her pregnancy. She is experiencing persistent nausea, vomiting, and fatigue. She has had difficulty eating, with a resulting weight loss of 3 lb since her first prenatal visit at 5 weeks' gestation.

William Johnston

William Johnston, a 42-year-old executive, is newly diagnosed with high blood pressure and high cholesterol. He confides that his health has been the last thing on his mind and that his health habits are less than admirable. "I usually eat on the run, often fast food, or big dinners with lots of alcohol. I can't remember the last time I worked out or did any exercise, unless running from my car to the train counts! I guess it's no wonder I've gained a few pounds over the years!"

Charles Gallagher

Charles Gallagher is the husband of a 67-year-old woman, Claire, who is in the end stages of advanced dementia. Mrs. Gallagher had a percutaneous endoscopic gastrostomy (PEG) inserted during her last hospitalization 6 weeks ago due to recurrent episodes of aspiration pneumonia from an inability to

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

swallow. Mr. Gallagher states, “I was talking to the chaplain (here, at the long-term care facility) and he questioned the wisdom of this tube. I respect him but we really don’t have an option here, do we? I mean, if they take the tube out, she’ll starve to death—right?”

Learning Outcomes

After completing the chapter, you will be able to accomplish the following:

. Identify six classes of nutrients, explaining the significance of each.
. Identify risk factors for poor nutritional status.
. Describe how nutrition influences growth and development throughout the life cycle.
. Discuss the components of a nutritional assessment.
. Formulate diagnoses/patient problems that related to nutrition amenable to nursing intervention.
. Describe nursing interventions to help patients achieve their nutritional goals.
. Plan, implement, and evaluate nursing care relate to actual and potential health problems and needs associated with alterations in and related to nutrition.
. Identify nursing interventions to safely deliver enteral nutrition.
. Identify nursing interventions to safely deliver parenteral nutrition.

Good nutrition is vital for life and health. Poor nutrition can seriously decrease a person's level of wellness, which makes nutrition a vital component of nursing. This chapter provides information about the basic principles of nutrition, focusing on nutrients, energy balance, choices for an adequate diet, and factors affecting nutrition. In addition, components of simple screening and nutritional assessments are outlined. Potential and actual health problems and needs are provided, and patient outcomes for healthy nutrition are discussed. The accompanying Evolving Case Study 37-1 on page 1441 provides an opportunity to develop and apply clinical reasoning and clinical judgment skills. The dietician is the primary nutrition authority, but optimal nutrition care requires collaboration among all health care team professionals (Dudek, 2022). Nurses incorporate nutrition into all aspects of thoughtful, person-centered nursing care and are involved in all aspects of nutritional care. Refer to the accompanying Reflective Practice box on page 1390.

PRINCIPLES OF NUTRITION

The science of **nutrition** is the study of the intake of food and how food nourishes the body. It encompasses the study of nutrients and how they are handled by the body as well as the impact of human behavior and environment on related to food choices and the process of nourishment. As such, nutrition involves chemistry, biology/physiology, psychology, and socioeconomics. Nutrition and health are closely related (U.S. Department of Health and Human Services [DHHS] & U.S. Department of Agriculture [USDA], 2020).

Food is a complex mix of essential and nonessential nutrients (Dudek, 2022). **Nutrients** are specific biochemical substances used by the body for growth, development, activity, reproduction, lactation, health maintenance, and recovery from illness or injury. The metabolic processes involved in these functions are complex. Subsequently, most nutrients work better together than they do alone. Nutrient needs change throughout the life cycle in response to changes in body size, activity, growth, development, and state of health.

Some nutrients are considered *essential* because either they are not synthesized in the body or are made in insufficient amounts. Essential nutrients must be provided in the diet or through supplements. Essential nutrients that supply energy and build tissue (such as carbohydrates, fats, protein) are referred to as *macronutrients*. *Micronutrients,* such as vitamins and minerals, are required in much smaller amounts to regulate and control body processes.

Nonessential nutrients do not have to be supplied through dietary sources because they either are not required for body functioning or are synthesized in the body in adequate amounts. Some nutrients can be converted to others in the body. For instance, the body converts excess carbohydrates and protein into fat and stores them as triglycerides.

Of the six classes of nutrients, three supply energy (carbohydrates, protein, lipids [fats]) and three are needed to regulate body processes (vitamins, minerals, water).

Current dietary guideline recommendations integrate findings from scientific research, food pattern modeling, and analysis of current intake of the U.S. population (U.S. DHHS & USDA, 2020). Foods are not consumed in isolation, but in various combinations over time, generating an eating pattern (dietary pattern) (U.S. DHHS & USDA, 2020). Dietary patterns are the combination of foods and beverages that make up an individual's dietary intake over time (U.S. DHHS & USDA, 2020). Eating patterns are recognized as having an important role in nutrition; dietary patterns, including nutrient density and diet quality, are linked to health promotion and prevention of disease (Dudek, 2022). Healthy eating patterns are associated with positive healthy outcomes and meet Recommended Dietary Allowances (RDA) and Adequate Intakes for essential nutrients (U.S. DHHS & USDA, 2020). Healthy eating patterns are discussed later in the chapter in the Adequate Diet Selection section on page 1397.

Energy Balance

The body needs energy to function. Energy is derived or obtained from foods consumed. Energy in the diet is measured in the form of kilocalories, commonly abbreviated as calories, or cal. Only carbohydrates, protein, and fat provide energy. Vitamins and minerals, needed for the metabolism of energy, do not provide calories.

QSEN Reflective Practice: Cultivating QSEN Competencies

CHALLENGE TO LEGAL AND ETHICAL SKILLS

Mrs. Constance Gallagher is only 67 years old, but she is in the end stages of advanced dementia. She can no longer swallow and has had several hospitalizations in the past year for aspiration pneumonia. She lives in a long-term care facility (where I am doing a clinical rotation for my gerontologic nursing experience) and has a devoted family—husband, son, and daughter—who all visit regularly. For the last 6 weeks, she has received enteral feedings from a percutaneous endoscopic gastrostomy (PEG) tube that was placed during her last hospitalization. Mrs. Gallagher's husband confided to me that the chaplain at the long-term care facility, whom he respects and likes, questioned the wisdom of the feeding tube. He then asked me, "But we really don't have an option here, do we? I mean, if they take the tube out, she'll starve to death, no?" I had no idea how to respond.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

Thinking Outside the Box: Possible Courses of Action

- Simply refer Mr. Gallagher to someone more experienced about these things (since I am clearly over my head).
- Find out more about this myself and then get back to him.
- Request an ethics consult to explore how we can best respond to the husband's questions about what is in his wife's best interests, taking into consideration the role the long-term care facility's chaplain is playing.

Evaluating a Good Outcome: How Do I Define Success?

- The patient's health goals are met, including, if the family/caregiver wishes, a dignified death.
- The Gallagher family feels at peace with their decisions and the results of these decisions.
- An ethically justified decision is made about continuing or withdrawing artificial nutrition and hydration that is respectful of Mrs. Gallagher's wishes (to the extent that these are known) and compatible with her beliefs and interests.
- I develop skill in assisting with tough end-of-life decisions and learn more about how an ethics consult functions.

Personal Learning: Here's to the Future!

When I reported my exchange with Mr. Gallagher to the charge nurse, she said we might want to call an ethics consult because there were actually a few similar situations pending and not everyone on the unit seemed comfortable with the lead role the chaplain was taking in recommending the withdrawal of nutritional support.

The consult was a great experience. All of the patient's family members attended, plus the medical director of the home, the nurses on the patient's unit, the chaplain, the social worker, the long-term care facility's ethicist, and myself. After the medical director described the natural progression of advanced dementia, the ethicist noted that there is a difference between dying of starvation (which only happens if food is withdrawn but fluids continue to hydrate) and dying of dehydration (which will happen if we pull the PEG tube and discontinue all enteral feedings, and which is not believed to be painful). The ethicist then asked the family if they knew how the patient would respond if she could be asked if the benefits of continuing nutritional support outweighed the accompanying burdens of having her wrists restrained so she wouldn't pull out the tube, skin problems, and the like. After some discussion, they were in agreement that she would not want to live this way. Since the Gallaghers were Catholic, the Catholic chaplain was invited to describe what the Roman Catholic Church teaches about this. After a rather lengthy discussion, a decision was made to withdraw enteral feedings. The family seemed at peace with their decision.

Through this experience, I learned how an ethics consult works and can see the advantages of utilizing this resource in the future.

QSEN SELF-REFLECTION ON QUALITY AND SAFETY COMPETENCIES DEVELOPING KNOWLEDGE, SKILLS, AND ATTITUDES FOR CONTINUOUS IMPROVEMENT

How do you think you would respond in a similar situation? Why? What does this tell you about yourself and about the adequacy of your skills for professional practice? Do you agree with the criteria that the nursing student used to evaluate a successful outcome? Are there any other criteria that would be appropriate to use? Did the nursing student meet the criteria? Why or why not? What *knowledge, skills,* and *attitudes* do you need to develop to continuously improve the quality and safety of care for patients like Mrs. Gallagher?

Patient-Centered Care: What resources could you or the nurses offer to provide compassionate and coordinated care based on respect for the patient's preferences, values, and needs? How did the ethics consult facilitate decision making? What ethical and legal principles were maintained? How did the nursing student act as a patient advocate? Was the human dignity of the patient and the patient's family maintained?

Teamwork and Collaboration/Quality Improvement: What communication skills do you need to improve to ensure that you function as a member of the patient-care team? What skills do you need to implement effective strategies for communicating and resolving conflict? What skills do you need to assert your own position/perspective in discussions about patient care? What other services or resources might be available to aid in this type of decision-making process?

Safety/Evidence-Based Practice: What skills do you need to improve to ensure that patients in your care

receive the best nursing care possible? What evidence in nursing literature provides guidance for decision making regarding care of this patient?

Informatics: Can you identify the essential information that must be available in Mrs. Gallagher's electronic health record to support safe patient care and coordination of care? Can you identify the appropriate process to protect confidentiality of protected health information in the patient's health records? Can you think of other ways to respond to or approach the situation?

Energy in the body is used to carry on any kind of activity, whether voluntary or involuntary. A person's total daily energy expenditure is the sum of all the calories used to perform physical activity, maintain basal metabolism, and digest, absorb, and metabolize food.

Total energy intake for a meal, a day, or longer can be calculated using food composition tables. The values given for total calories for each food item eaten can simply be added, or the grams of carbohydrate, protein, and fat for each food item eaten can be added and multiplied by the appropriate calorie level (4, 4, and 9 calories, respectively). If a person's daily energy intake is equal to total daily energy expenditure, the person's weight will remain stable. However, if the energy intake is less than the energy expended, the person's weight will decrease. If the energy intake exceeds energy expenditure, weight will increase. Healthy body weight is achieved by balancing calorie intact with calorie expenditure (Dudek, 2022).

Metabolic Requirements

Basal metabolism (**basal metabolic rate [BMR]**) is the energy (number of calories) required to fuel the involuntary activities of the body at rest after a 12-hour fast—the energy needed to sustain the metabolic activities of cells and tissues (Dudek, 2022; Hinkle et al., 2022; Norris, 2020). These activities include actions such as maintaining body temperature and muscle tone, producing and releasing secretions, propelling food through the gastrointestinal (GI) tract, inflating the lungs, and contracting the heart muscle. Sex assigned at birth impacts BMR; men usually have a greater proportion of muscle mass than women of the same age and weight, resulting in a higher BMR (MFMER, 2020d). The less active a person is, the greater the proportion of calories used for BMR (Dudek, 2022).

Think back to **William Johnston**, the middle-aged man with hypertension and high cholesterol. Based on the patient's sex assigned at birth, the nurse would anticipate his BMR may be greater than that for a woman. The nurse would need to consider this fact when planning the patient's care.

Other factors that increase BMR include growth, infections, fever, emotional tension, extreme environmental temperatures, and elevated levels of certain hormones, especially epinephrine and thyroid hormones. Aging, prolonged fasting, and sleep all decrease BMR. Fasting or following a very–low-calorie diet may defeat a weight-loss plan because the body interprets this eating pattern as starvation and compensates by slowing down the resting metabolic rate, making it even more difficult to lose weight.

Body Weight Standards

As previously discussed, if a person's energy intake does not equal energy expenditure, weight will fluctuate. Healthy body weight (ideal body weight [IBW]) is an estimate of optimal weight for optimal health. Height and weight tables are commonly used for infants and children. However, the preferred methods to establish weight status include body mass index (BMI) for adults and children and measurement of waist circumference for adults (NHBLI, n.d.a).

BODY MASS INDEX

The **body mass index (BMI)** is a ratio of weight (in kilograms) to height (in meters squared). The BMI provides an estimate of body fat and can be used as an initial assessment of nutritional status. BMI can be calculated with a mathematical formula but is more conveniently determined using a BMI table. One such table from the National Heart, Lung, and Blood Institute (NHLBI, n.d.c) can be accessed at https://www.nhlbi.nih.gov/health/educational/lose_wt/BMI/bmi_tbl.htm. An online calculator is also available from the NHLBI (n.d.e) at https://www.nhlbi.nih.gov/health/educational/lose_wt/BMI/bmicalc.htm. According to the BMI guidelines published by the NHLBI (n.d.b), a person with a BMI below 18.5 is underweight, a BMI of 18.5 to 24.9 is a healthy weight, a BMI of 25 to 29.9 indicates an overweight person, a BMI of 30 to 39.9 indicates **obesity**, and a BMI of 40 or greater indicates extreme obesity.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

BMI also provides an estimation of relative risk for diseases that can occur with more body fat, such as heart disease, type 2 diabetes, hypertension, and certain cancers (NHLBI, n.d.d). However, it is important to note that BMI may not be accurate for certain groups of people, such as athletes, people with a muscular build, people with edema or dehydration, and older people and others who have lost muscle mass (Dudek, 2022; NHLBI, n.d.d). In addition, ethnic differences exist in the relationship between BMI and health risks (Tinajero et al., 2021).

Overweight and obesity are defined differently for children and teens than for adults. Children are still growing, and boys and girls mature at different rates. BMIs for children and teens compare their heights and weights against growth charts that take age and sex assigned at birth into account. This is called BMI-for-age percentile. A child or teen's BMI-for-age percentile shows how the individual's BMI compares with children of the same age and biologic sex (NHLBI, n.d.a). Additional information about BMI-for-age and growth charts for children ages 2 through 19 years can be found at the BMI-for-age calculator from the Centers for Disease Control and Prevention (CDC, 2020a). Refer to Box 37-1 for information to interpret the results of a BMI-for-age calculation.

Box 37-1 BMI-for-Age Percentile (Children and Teens)

Percentile Range	Weight Status Category
Less than 5th percentile	Underweight
5th percentile to less than the 85th percentile	Healthy weight
85th percentile to less than the 95th percentile	Overweight
95th percentile or greater	Obese

Source: Centers for Disease Control and Prevention (CDC). (2018, July 3). *Overweight & obesity. Defining childhood obesity. BMI for children and teens*. https://www.cdc.gov/obesity/childhood/defining.html

A significant intentional or unintentional change in the patient's weight can also indicate poor nutritional status and/or health problems. Most clinical screening tools include content addressing recent weight loss, current BMI, recent food intake, and disease severity (Reber et al., 2019).

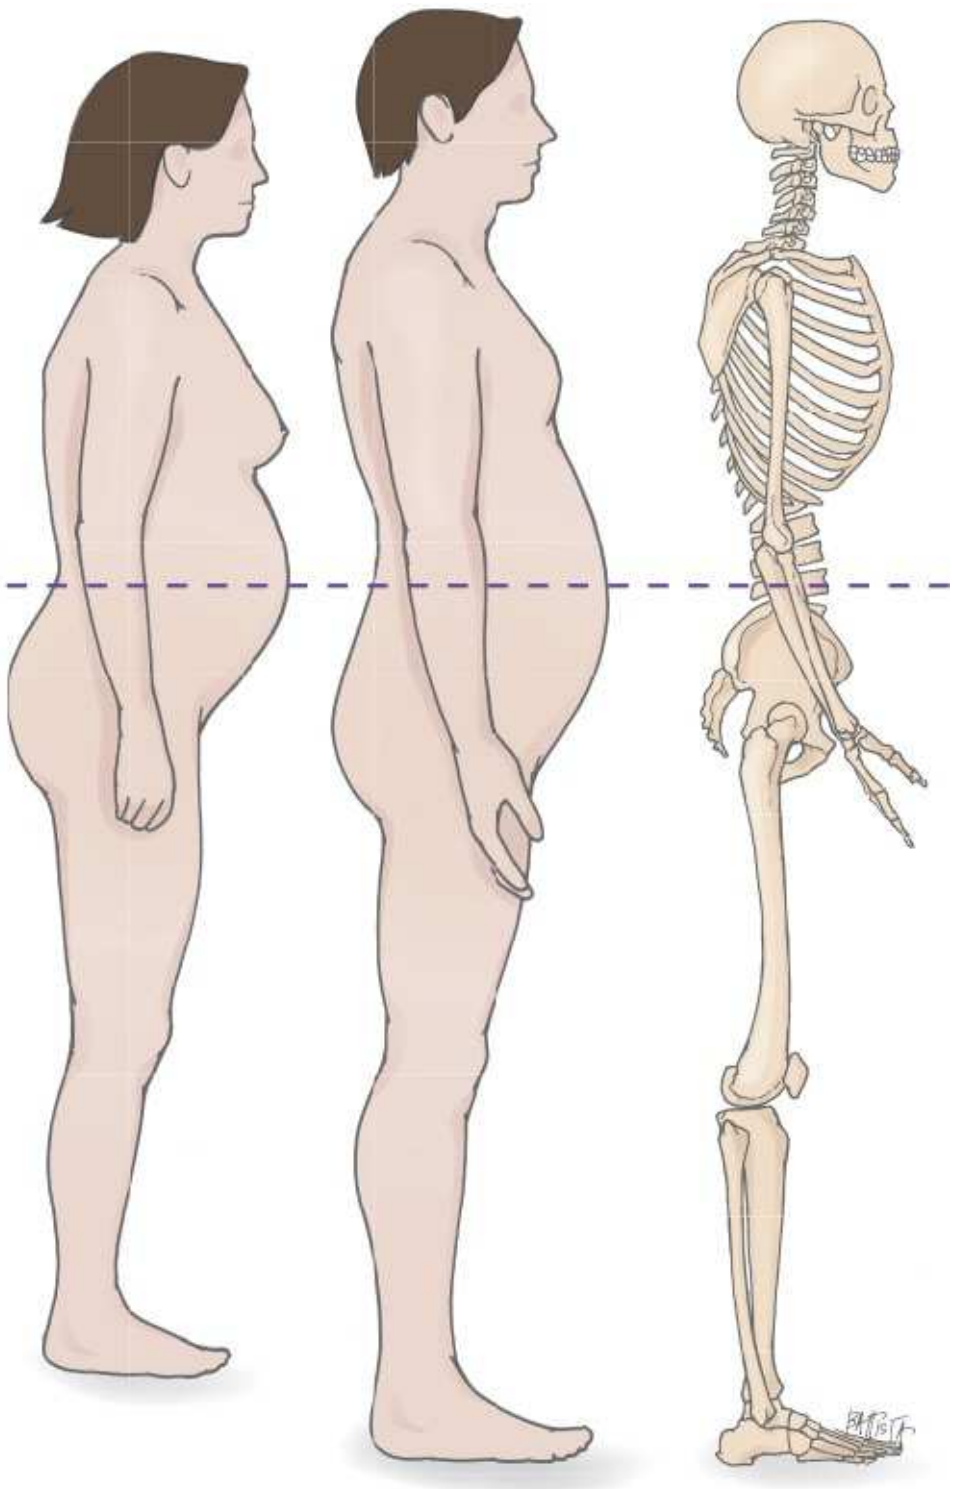

FIGURE 37-1. Positioning of measuring tape at the level of the umbilicus for waist circumference.

BODY FAT DISTRIBUTION

Where excess body fat is deposited is thought to be an important and reliable indicator of risk for disease, such as type 2 diabetes, hypertension, stroke, dyslipidemia, and cardiovascular disease (Ashwell & Gibson, 2014; CDC, 2020b). Central or abdominal obesity (centrally located distribution of fat) poses greater risk for cardiovascular disease and diabetes (Johns Hopkins Medicine, 2021). **Waist circumference** is a good indicator of abdominal fat. Waist circumference is measured by placing a measuring tape snugly around the patient's waist, just above the hipbones (CDC, 2020b) (Fig. 37-1). Risk increases with a waist measurement of 40 inches or more for men and 35 inches or more for women (NHLBI, n.d.d). As with BMI, ethnic groups differ in regard to where risk begins in relation to waist circumference (Dudek, 2022). Table 37-1 displays the relationship of the risks of obesity-associated diseases and conditions by BMI and waist circumference. Waist-to-hip ratio (WHR) is another screening tool to identify central obesity. The WHR is calculated by dividing the patient's waist circumference by the hip circumference (Maastricht University Medical Center, 2020). Females should have a waist-to-hip ratio of <0.8 and males <0.95 (Maastricht University Medical Center, 2020).

Table 37-1 Classification of Overweight and Obesity by Body Mass Index, Waist Circumference, and Associated Disease Risks

		DISEASE RISK[a] RELATIVE TO NORMAL WEIGHT AND WAIST CIRCUMFERENCE	
	BODY MASS INDEX (BMI) (kg/m²)	Men ≤40 inches (102 cm) Women ≤35 inches (88 cm)	Men >40 inches (102 cm) Women >35 inches (88 cm)
Underweight	<18.5	–	–

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

Normal	18.5–24.9	–	–
Overweight	25.0–29.9	Increased	High
Obesity (Class I)	30.0–34.9	High	Very high
(Class II)	35.0–39.9	Very high	Very high
Extreme obesity (Class III)	40.0[b]	Extremely high	Extremely high

[a]Disease risk for type 2 diabetes, hypertension, and CVD.

[b]Increased waist circumference also can be a marker for increased risk, even in persons of normal weight.

Source: National Heart, Lung, and Blood Institute (NHLBI). (n.d.b). *Aim for a health weight. Classification of overweight and obesity by BMI, waist circumference, and associated disease risks*. Retrieved September 26, 2020, from https://www.nhlbi.nih.gov/health/educational/lose_wt/BMI/bmi_dis.htm

Caloric Requirements

Just as healthy body weight or IBW can be determined in a variety of ways, so can a person's calorie requirements. The total number of calories a person needs each day varies depending on multiple factors, including the person's age, sex, height, weight, and level of physical activity (U.S. DHHS & USDA, 2020). A need to lose, maintain or gain weight also influences the total number of calories that should be consumed. The *Dietary Guidelines for Americans 2020–2025* (U.S. DHHS & USDA, 2020) provides estimated amounts of calories needed to maintain calorie balance based on age, sex assigned at birth, level of physical activity, using average reference heights and weights for each age-sex group. Estimated ranges are provided in Appendix 2 of the 2020–2025 Dietary Guidelines and can be accessed at https://www.dietaryguidelines.gov/.

Consider **William Johnston**, the man with poor health habits. The nurse would work with Mr. Johnston and the registered dietician to develop an appropriate weight-loss plan that would contain adequate calories yet still foster a weight loss of 1 to 2 lb/wk. Doing so would promote weight loss while still allowing for adequate nutritional intake.

Energy Nutrients

Carbohydrates, protein, and fats are potential sources of energy for the body.

Carbohydrates

Carbohydrates, commonly known as sugars and starches, are organic compounds composed of carbon, hydrogen, and oxygen. They serve as the structural framework of plants. The only animal source of carbohydrate in the diet is lactose, the sugar present in milk.

Carbohydrates are relatively easy to produce and store, making them the most abundant and least expensive source of calories in the diet worldwide. In countries where grains are the dietary staple, carbohydrates may contribute as much as 90% of total calories. Carbohydrate intake is often correlated to income. As income increases, carbohydrate intake decreases and protein intake, a more expensive form of energy, increases (Kim et al., 2020; Seidelmann et al., 2018). Refer to this text's online resources to view a table that summarizes the sources, functions, and significance of dietary carbohydrates.

CLASSIFICATION AND METABOLISM

The number of molecules within the structure determines the classification of carbohydrates. They are classified as simple (monosaccharide and disaccharide) or complex (polysaccharide) sugars.

Carbohydrates are more easily and quickly digested than protein and fat. Ninety percent of carbohydrate intake is digested. This percentage decreases as fiber intake increases. All carbohydrates are converted to glucose for transport through the blood or for use as energy. Glucose is an efficient fuel that certain tissues, particularly the central nervous system, rely on almost exclusively for energy. Glucose is transported from the GI tract, through the portal vein, to the liver. The liver stores glucose and regulates its entry into the blood. Hormones, especially insulin and glucagon, are responsible for keeping serum glucose levels fairly constant during both feasting and fasting.

Through a series of steps, cells oxidize (burn) glucose to provide energy, carbon dioxide, and water. Depending on a

person's state of energy balance, the period between when a carbohydrate is consumed and when it is used for energy may vary from minutes to months or longer. Unlike protein and fat, glucose is burned efficiently and completely and does not leave a toxic product for the kidneys to excrete.

When the supply of glucose exceeds what is needed for energy and for maintaining serum levels, it is stored. If muscle or liver glycogen stores are deficient, glucose is converted to glycogen and stored (glycogenesis). Conversely, glycogen is broken down in time of need to supply a ready source of glucose (glycogenolysis). When glycogen stores are adequate, the body converts excess glucose to fat and stores it as triglycerides in adipose tissue.

FUNCTIONS AND RECOMMENDED DIETARY INTAKE

The primary function of carbohydrates is to supply energy. Except for indigestible fiber, all carbohydrates provide 4 calories per gram, regardless of the source. It is recommended that carbohydrates provide 45% to 65% of total calories for adults, focusing on complex carbohydrates, such as whole grains (U.S. DHHS & USDA, 2020). Sugars added to foods supply calories but few or no nutrients and should be limited. The online Dietary Reference Intake calculator for Healthcare Professionals provides a means to calculate daily nutrient recommendations, including carbohydrates, based on the Dietary Reference Intakes (DRIs) and is available at https://www.nal.usda.gov/fnic/dri-calculator/ (USDA & NAL, n.d.a). Refer to the discussion of DRIs on page 1397.

Protein

Protein is a vital component of every living cell. Within the human body, more than 1,000 different proteins are made by combining various amounts and proportions of the 22 basic building blocks known as amino acids. Proteins are required for the formation of all body structures, including genes, enzymes, muscle, bone matrix, skin, and blood. Refer to this text's online resources to view a table that summarizes the sources, functions, and significance of dietary protein.

CLASSIFICATION AND METABOLISM

Dietary proteins may be labeled complete (high quality) or incomplete (low quality), based on their amino acid composition. Complete proteins contain sufficient amounts and proportions of all the essential amino acids to support growth, whereas incomplete proteins are deficient in one or more essential amino acids. In general, animal proteins (eggs, dairy products, meats) are complete, and plant proteins (grains, legumes, vegetables) are incomplete. There are some plant exceptions; soy and quinoa, for example, are plant proteins that are considered complete proteins (Cedars Sinai, 2019). Because different sources of plant proteins lack different amino acids, a plant protein can be complemented by combining it with a different plant protein or by adding a small amount of an animal protein to supply a complete protein. Examples of complementary vegetable proteins include corn tortilla with refried beans and lentil rice soup. Complementary proteins that use a small amount of animal protein include cereal with milk, rice pudding, and a cheese sandwich. It is not necessary to eat complementary proteins at the same meal; eating a variety of proteins throughout the day will achieve adequate protein intake (Dudek, 2022).

Concept Mastery Alert

Complete protein = animal protein *or* plant protein + small amount of animal protein or two complementary vegetable proteins.

Dietary protein is broken down into amino acid particles by pancreatic enzymes in the small intestine. These are absorbed through the intestinal mucosa to be transported to the liver. In the liver, amino acids are recombined into new proteins or are released into the bloodstream for use in protein synthesis by tissues and cells. Excess amino acids are converted to fatty acids, ketone bodies, or glucose and are stored or used as metabolic fuel.

The body's protein tissues are in a constant state of flux. Tissues are continuously being broken down (catabolism) and replaced (anabolism). Nitrogen balance, a comparison between catabolism and anabolism, can be measured by comparing nitrogen intake (protein intake) and nitrogen excretion (nitrogen lost in urine, urea, feces, hair, nails, skin). When catabolism and anabolism are occurring at the same rate, as in healthy adults, the body is in a state of neutral nitrogen balance (i.e., nitrogen intake equals nitrogen excretion). A positive nitrogen balance occurs when nitrogen intake is greater than excretion, and indicates tissue growth—for example, during childhood, pregnancy, lactation, and recovery from illness. A negative nitrogen balance occurs when more nitrogen is excreted than is ingested, and indicates tissue is breaking down faster than it is being replaced. This undesirable state occurs in situations such as starvation and the catabolism that immediately follows surgery, illness, trauma, and stress. This can result in the wasting of muscle tissue as it is converted to glucose for energy.

FUNCTIONS AND RECOMMENDED DIETARY INTAKE

The major function of protein is to maintain body tissues that break down from normal wear and tear and to support the growth of new tissue. Using protein for energy is more expensive both financially and physiologically than using carbohydrates. The nitrogen remaining after protein is metabolized burdens the kidneys. In addition, energy must be used to excrete the nitrogen. Like carbohydrates, protein consumed in excess of need can be converted to and stored as

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

fat. Protein intake should contribute 10% to 35% of total caloric intake for healthy adults and include a variety of protein foods (U.S. DHHS & USDA, 2020). The online Dietary Reference Intake calculator for Healthcare Professionals provides a means to calculate daily nutrient recommendations, including protein, based on the Dietary Reference Intakes (DRIs) and is available at https://www.nal.usda.gov/fnic/dri-calculator/ (USDA & NAL, n.d.a). Refer to the discussion of DRIs on page 1397.

Fats

Fats in the diet, or lipids, are insoluble in water and, therefore, insoluble in blood. Like carbohydrates, they are composed of carbon, hydrogen, and oxygen. Ninety-five percent of the lipids in the diet are in the form of triglycerides, the predominant form of fat in food and the major storage form of fat in the body. Compound lipids (such as phospholipids, in which a lipid is combined with another substance) and derived lipids (such as cholesterol) constitute the remainder of the lipids ingested. Refer to this text's online resources to view a table that summarizes the sources, functions, and significance of dietary fat.

CLASSIFICATION AND METABOLISM

Food fats contain mixtures of saturated and unsaturated fatty acids. The difference in degree of saturation depends on the amount of hydrogen in fat molecules. Saturated fats contain more hydrogen than unsaturated fats. Most animal fats are considered saturated and have a solid consistency at room temperature. Conversely, most vegetable fats are considered unsaturated, remain liquid at room temperature, and are referred to as oils. Saturated fats tend to raise serum cholesterol levels, whereas unsaturated fats lower serum cholesterol levels. Trans fats (trans-fatty acids) are a form of dietary fat that raise LDL ("bad") cholesterol and lower HDL ("good") cholesterol (MFMER, 2020a). Naturally occurring trans fats are produced by some animals and small amounts of these trans fats made be present in some meat (e.g., beef, lamb) and dairy products (e.g., milk) (American Heart Association, 2017). Most of the trans fat in food is formed when manufacturers partially hydrogenate vegetable (liquid; PHO) oils to solidify the oil and increase stability at room temperature and are found in many manufactured foods (American Heart Association, 2017; MFMER, 2020a). Eating trans fats increases the risk of developing heart disease and stroke and is associated with a higher risk of developing type 2 diabetes (American Heart Association, 2017). Because consumption of trans fat is so unhealthy, the U.S. Food and Drug Administration (FDA) has prohibited food manufacturers from adding major sources of artificial trans fat to foods and beverages, in an attempt to prevent the risks of cardiovascular and other associated diseases (U.S. FDA, 2018; MFMER, 2020a). Trans fats are listed on food nutrition labels so that consumers can make healthy choices in their diet. In the United States, a food with less than 0.5 g of trans fat in a serving can be identified as 0 g of trans fat (MFMER, 2020a).

Cholesterol is a fatlike substance found only in animal products. It is not an essential nutrient; the body makes sufficient amounts (Dudek, 2022). Cholesterol is an important component of cell membranes and is especially abundant in brain and nerve cells. It also is used to synthesize bile acids and is a precursor of the steroid hormones and vitamin D. Although cholesterol serves many important functions in the body, high serum levels are clearly associated with an increased risk for atherosclerosis. To help lower serum cholesterol levels, researchers recommend limiting cholesterol intake, eating less total fat—especially saturated and trans fat—eating more unsaturated fat, and increasing fiber intake, which increases fecal excretion of cholesterol.

Remember **William Johnston**, the middle-aged executive with hypertension and high cholesterol? Due to Mr. Johnston's "on-the-run" lifestyle, developing an individualized nutritional plan might be somewhat challenging. Based on an assessment of Mr. Johnston's eating habits, likes, and dislikes, the nurse would work with him to develop a plan that promotes weight loss and includes limiting cholesterol and total fat intake and consuming more foods containing unsaturated fats and fiber. Adapting the plan will help to promote adherence to it, thereby increasing the chances for success.

Fat digestion occurs largely in the small intestine. Bile, secreted by the gallbladder, emulsifies fat to increase the surface area so that pancreatic lipase can break down fat more effectively. Through a complex series of events, most fats are absorbed into the lymphatic circulation with the help of a protein carrier and are transported to the liver. Almost all fat consumed is absorbed (about 95%) in the small intestine; a small amount is excreted in the feces (Dudek, 2022).

FUNCTIONS AND RECOMMENDED DIETARY INTAKE

Fats are the most concentrated source of energy in the diet, providing 9 calories for every gram. Fat increases the palatability of the diet (e.g., to most people, filet mignon tastes better than flank steak) and has a high satiety value

because it delays gastric emptying time. In the body, fat aids in the **absorption** (the transfer of digested nutrients into the circulation) of the fat-soluble vitamins and provides insulation, structure, and temperature control. The *Dietary Guidelines for Americans 2020–2025* recommends that individuals should limit intake of saturated fats and trans fats, with less than 10% of calories per day from saturated fats and intake of trans fats to as low as possible (U.S. DHHS & USDA, 2020). The online Dietary Reference Intake calculator for Healthcare Professionals provides a means to calculate daily nutrient recommendations, including fats, based on the Dietary Reference Intakes (DRIs) and is available at https://www.nal.usda.gov/fnic/dri-calculator/ (USDA & NAL, n.d.a). Refer to the discussion of DRIs on page 1397.

Regulatory Nutrients

Vitamins, minerals, and water are regulatory nutrients. The body needs them for facilitation of the biochemical reactions within cells to regulate body processes, such as growth and metabolism (Dudek, 2022).

Vitamins

Vitamins are organic compounds needed by the body in small amounts. Most vitamins are active in the form of coenzymes, which, together with enzymes, facilitate thousands of chemical reactions in the body. Although vitamins do not provide energy (calories), they are needed for the metabolism of carbohydrates, protein, and fat. Vitamins are essential in the diet because most are not synthesized in the body or are made in insufficient quantities. The absence or insufficient use of vitamins in the body causes specific deficiency syndromes.

Vitamins are present in foods in only small amounts. Fresh foods are higher in vitamins than processed foods because vitamins may be destroyed by light, heat, air, and during preparation. The exception is when vitamins not naturally occurring in a food are added, such as vitamin D–fortified milk. This process is called fortification.

In the United States, severe vitamin deficiencies are uncommon. Mild or subclinical deficiencies of vitamin A, vitamin C, folate, and vitamin B_6, however, may affect a significant proportion of the population, especially those who (1) are members of certain age groups or patient groups (infants, adolescents, pregnant and lactating women, older people); (2) smoke, abuse alcohol, or use medications on a long-term basis; (3) are chronically ill, either physically or psychologically; or (4) are poor or finicky eaters, such as chronic dieters and food faddists.

Vitamins are classified as either water soluble or fat soluble. Water-soluble vitamins include vitamin C and the B-complex vitamins (ascorbic acid, thiamine, riboflavin, niacin, pyridoxine, biotin pantothenic acid, folate, and cobalamin). They are absorbed through the intestinal wall directly into the bloodstream. Although some tissues are able to hold limited amounts of water-soluble vitamins, they usually are not stored in the body. Deficiency symptoms are apt to develop quickly when intake is inadequate; therefore, a daily intake is recommended. However, because water-soluble vitamins are not stored, amounts consumed in excess of need are excreted in the urine. Toxicities are not likely, although megadoses of certain water-soluble vitamins can be harmful.

Vitamins A, D, E, and K, the fat-soluble vitamins, are absorbed with fat into the lymphatic circulation. Like fat, they must be attached to a protein to be transported through the blood. Secondary deficiencies of the fat-soluble vitamins can occur anytime fat digestion or absorption is altered, such as during malabsorption syndromes and pancreatic and biliary diseases. The body stores excesses of the fat-soluble vitamins mostly in the liver and adipose tissue. Because they are stored, a daily intake is not imperative and deficiency symptoms may take weeks, months, or years to develop. Excessive intake, particularly of vitamins A and D, is toxic.

Although scrutiny and research continue about vitamin supplements and their long-term effects, most nutritionists agree that vitamins will never be a substitute for good nutrition and healthy lifestyle practices (USDA & DHHS, 2020). The *Dietary Guidelines for Americans 2020–2025* (USDA & DHHS, 2020) recommends that nutrient needs be met primarily through consuming foods. However, although the majority of Americans consume sufficient amounts of most nutrients, some vitamins and other nutrients are consumed by many individuals in amounts below the Estimated Average Requirement or Adequate Intake levels (see discussion later in chapter) (USDA & DHHS, 2020). Low intake occurs due to low consumption of the food groups that contain these nutrients (USDA & DHHS, 2020). Supplements may be useful when they fill a specific identified nutrient gap that cannot or is not otherwise being met by the person's intake of food (Dudek, 2022; USDA & DHHS, 2020). Groups that may not be "well nourished" and may benefit from vitamin supplements include dieters consuming less than 1,200 calories/day, vegans, people with alcohol use disorder, older adults, people who are food insecure, and patients with chronic illness (Dudek, 2022, p. 116). Supplementation can also ensure adequate intakes of specific nutrients in patients with physiologic limitations or changes. For example, folate (folic acid) supplementation prior to conception and during pregnancy reduces the risk of neural tube defects (USDA & DHHS, 2020). Refer to this text's online resources to view a table that summarizes water- and fat-soluble vitamins

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

Think back to **Susan Oakland**, the young woman who is pregnant. She will be advised to take a daily multivitamin supplement as part of her prenatal care. Supplements are used in conjunction with an optimal diet to meet the increased nutrient requirements of pregnancy.

Minerals

Minerals are inorganic elements found in all body fluids and tissues in the form of salts (e.g., sodium chloride) or combined with organic compounds (e.g., iron in hemoglobin). Some minerals function to provide structure within the body, whereas others help to regulate body processes. Minerals, which are elements, are not broken down or rearranged in the body but, rather, are contained in the ash that remains after digestion. Excessive soaking and cooking in water can cause loss of minerals from food. However, minerals are commonly not destroyed by food processing.

Major minerals are present in the body in amounts greater than 5 g and include calcium, phosphorus (phosphates), sulfur (sulfate), sodium, chloride, potassium, and magnesium (Dudek, 2022). Trace elements are minerals present in the body in amounts less than 5 g; trace minerals ae not less important than major minerals and include iron, zinc, manganese, chromium, copper, molybdenum, selenium, fluoride, and iodine (Dudek, 2022). Refer to this text's online resources to view a table that summarizes the macrominerals and microminerals that have recommended intake guidelines.

Water

As the major body constituent present in every body cell, water accounts for between 50% and 60% of the adult's total weight. Infants have proportionately more water accounting for body weight. About two thirds of the body's water is contained within the cells (intracellular fluid [ICF]); the remainder is called extracellular fluid (ECF), which includes all other body fluids, such as plasma and interstitial fluid. Total body water and ECF decrease with age; ICF increases with an increase in body mass. Refer to Chapter 41 for more information on water in the body.

Water is more vital to life than food because it provides the fluid medium necessary for all chemical reactions, it participates in many reactions, and it is not stored in the body. Water acts as a solvent that dissolves many solutes, thereby aiding digestion, absorption, circulation, and excretion. Through evaporation from the skin, water helps to regulate body temperature. As a lubricant, water is needed both for mucous secretions and for movement between joints.

Think back to **Charles Gallagher**, husband of the woman with advanced dementia receiving enteral nutrition. During the group meeting about continuing or withdrawing the enteral nutrition, Mr. Gallagher learns that withdrawal of the feedings would also involve limited water intake. This information is important in helping Mr. Gallagher and his family arrive at an informed decision about whether to continue the enteral feedings.

Sources of water in the diet include not only beverages but also solid foods, which contain between 10% and 98% water. Water is also produced through the metabolism of carbohydrates, protein, and fat. It leaves the body through urine, feces, expired air, and perspiration. Water intake (an average of 2,600 mL/day for adults [Dudek, 2022]) usually equals water output. Water balance may be seriously affected when intake (such as in older adults or people in comatose states) or output (such as in patients with altered renal function, profuse perspiration, diarrhea, vomiting, fistulas, drainage tubes, hemorrhage, severe burns) is altered.

Digestion

The food consumed by a person supplies the essential nutrients needed for cells to perform their necessary functions, but

the cells cannot use food in its consumed form. The GI system breaks down the food into particles small enough to pass into the cells and be used by the cells. This breakdown process is called **digestion**. Digestion begins in the mouth where food is taken in, mixes with saliva, is pushed into the pharynx by the tongue, and then continues into the esophagus. Peristalsis moves the food through the esophagus and into the stomach. The stomach churns the ingested food, mixing it with substances to break down the food and convert it to a semiliquid mixture. The food leaves the stomach and enters the small intestine. The small intestine secrets enzymes, which, along with secretions from the liver and pancreas, digest the food. The digested nutrients are then transferred into the person's circulation (absorption), to be transported throughout the body. Most absorption of digested food and minerals, and some absorption of water, occurs through the walls of the small intestine. Undigested waste materials continue through the GI tract and are eliminated. Elimination of these waste products is discussed in Chapter 39. Figure 39-1 on page 1519 illustrates the organs of the GI tract.

Box 37-2 **Key Recommendations of the Dietary Guidelines for Americans 2020–2025**

Consume a healthy eating pattern across the lifespan that accounts for nutrient-dense food and beverage choices to reflect personal preferences, cultural traditions, and budgetary considerations within an appropriate calorie level.

A healthy eating pattern includes:

- A variety of vegetables
- Fruits
- Grains, at least half of which are whole grains
- Fat-free or low-fat dairy
- A variety of protein foods
- Oils

A healthy eating pattern limits:

- Saturated fats, trans fats, added sugars, and sodium
- Calories/day from added sugars to less than 10%
- Calories/day from saturated fats to less than 10%
- Sodium to less than 2,300 mg/day
- Alcohol to moderate consumption

Guidelines for physical activity include:

- Engage in regular physical activity and reduce sedentary activities to promote health, psychological well-being, and a healthy body weight.
- To achieve and maintain a healthy body weight, adults should do the equivalent of 150 to 300 minutes of moderate-intensity aerobic activity each week. If necessary, adults should increase their weekly minutes of aerobic physical activity gradually over time and decrease calorie intake to a point at which they can achieve calorie balance and a healthy weight. Adults should also include muscle-strengthening activities, such as lifting weights or doing push-ups, at least 2 days each week.

Source: Adapted from U.S. Department of Health and Human Services & U.S. Department of Agriculture. (2020). *Dietary guidelines for Americans 2020–2025*. https://www.dietaryguidelines.gov/

Adequate Diet Selection

An adequate diet provides a balanced intake of all essential nutrients in appropriate amounts. In the past, defining an adequate diet or healthy eating was less obvious and sometimes difficult. Tools for planning or evaluating a diet for adequacy include dietary recommendations and guidelines issued from health and U.S. governmental facilities, and the Dietary Reference Intakes (DRIs). The task of promoting health through proper nutrition has been made easier by labeling regulations that mandate specific information about food contents and their comparison to recommended daily intakes.

Dietary Recommendations

The *Dietary Guidelines for Americans* (USDA & DHHS, 2020) are science-based strategies compiled by the U.S. Department of Health and Human Services and the U.S. Department of Agriculture. A new edition of the *Guidelines* is published every 5 years to reflect current scientific knowledge and provide sound food-based guidance to promote health (USDA & DHHS, 2020). People are encouraged to choose a healthy eating pattern at an appropriate calorie level to help achieve and maintain a healthy body weight, support nutrient adequacy, and reduce the risk of chronic disease. Key recommendations of the *Dietary Guidelines for Americans* 2020–2025 appear in Box 37-2. The complete guidelines are available at https://www.dietaryguidelines.gov/ (USDA & DHHS, 2020).

Dietary Reference Intakes

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

The Dietary Reference Intakes (DRIs) provide recommended nutrient intakes that estimate nutrient intakes necessary to ensure that healthy populations meet nutrient needs to maintain health and prevent deficiency diseases (Institute of Medicine, 2006) and are viewed as an average daily intake over at least one week (Dudek, 2022). The DRIs are a set of reference values. The DRIs include:

- **Recommended Dietary Allowance (RDA)** is the average daily dietary intake of a nutrient that is sufficient to meet the requirement of nearly all (97% to 98%) healthy people.
- Adequate Intake (AI) for a nutrient is established when an RDA cannot be determined. Therefore, a nutrient either has an RDA or an AI. The AI is based on observed intakes of the nutrient by a group of healthy people.
- Tolerable Upper Intake Level (UL) is the highest daily intake of a nutrient that is likely to pose no risks of toxicity for almost all individuals. As intake above the UL increases, risk increases.
- Estimated Average Requirement (EAR) is the amount of a nutrient that is estimated to meet the requirement of half of all healthy people in the population.
- Chronic Disease Risk Reduction (CDRR) is the level above which intake reduction is expected to reduce chronic disease risk. At this time, sodium is the only nutrient to be assigned a CDRR (National Academies of Sciences, Engineering, and Medicine, 2019).

Each of these reference values distinguishes between biologic sex and different life stages, providing estimates of nutrient needs for healthy people. Links to information about the DRIs as well as other healthy eating resources can be found at https://www.nutrition.gov/topics/basic-nutrition/healthy-eating (USDA, n.d.a). The online Dietary Reference Intake calculator for Healthcare Professionals provides a means to calculate daily nutrient recommendations based on the Dietary Reference Intakes (DRIs) and is available at https://www.nal.usda.gov/fnic/dri-calculator/ (USDA & NAL, n.d.a).

MyPlate Food Guide

MyPlate food guidance graphic is part of a communication initiative based on the *Dietary Guidelines for Americans* to help consumers make better food choices to follow a healthy heating pattern across the lifespan (USDA & DHHS, 2020; USDA, n.d.b). MyPlate is designed to remind Americans to eat healthfully. MyPlate illustrates the five food groups using a familiar mealtime visual, a place setting (Fig. 37-2). The goals of the recommendations are to balance calories by encouraging consumers to enjoy food, but eat less, and avoid oversized portions. Consumers are also advised to increase the intake a variety of nutrient-dense foods across and within all food groups (USDA & DHHS, 2020). Consumers are encouraged to reduce sodium consumption by comparing sodium in foods such as soup, bread, and frozen meals and choose foods with lower numbers. MyPlate also encourages the consumption of water instead of sugary drinks.

The importance of activity and exercise are also emphasized, including the recommendations for children and adolescents to be physically active for 60 minutes or more a day and adults to engage in activity that requires moderate effort, such as brisk walking for 2 1/2 hours or more a week (USDA, n.d.b). Visitors to the website can personalize nutritional and physical activity plans, track foods consumed and physical activities, and get support to help make healthier choices. The ChooseMyPlate initiative also offers a free mobile app to help patients with daily food goals and track real-time progress (USDA, n.d.b). The MyPlate guidelines are available at https://www.choosemyplate.gov/ (USDA, n.d.b).

FIGURE 37-2. The MyPlate food guidance graphic. (*Source:* U.S. Department of Agriculture [USDA]. [n.d.]. https://www.choosemyplate.gov/)

Food Labeling

Food labels provide a significant amount of nutritional information for the consumer. Regulations that control food

labels have always been controversial. In 1975, the FDA, a federal facility charged with protecting the U.S. food and drug supply, enacted legislation for a standardized label format that was considered a positive step toward educating the consumer about nutrition. Confusion and misinformation resulted as food manufacturers oversimplified or exaggerated health claims for their products. In 1990, Congress passed the Nutritional Labeling and Education Act, which required all foods, including fruits and vegetables, to be clearly labeled. Four broad categories are addressed in this legislation and include nutrition labeling, serving sizes, descriptors, and health claims. In 2006, labels were required to include information related to the amount of trans fat (trans-fatty acids) on nutrition fact labels. Consumers should be easily able to identify the serving size and servings per container; the calories per serving; the amount of total fat, saturated fat and trans fat; the amount of cholesterol and sodium; the total amount of carbohydrates, including dietary fiber and sugars (total sugars and added sugars); and the total amount of protein in the product (U.S. FDA, 2020c). The label also provides information related to vitamin D and potassium because Americans do not always get the recommended amounts (U.S. FDA, 2020c). Diets higher in vitamin D and potassium can reduce the risk of osteoporosis and high blood pressure, respectively (U.S. FDA, 2020c, para. 5). Calcium and iron are also included on the label because Americans do not always get the recommended amounts (U.S. FDA, 2020c). Diets higher in calcium and iron can reduce the risk of osteoporosis and anemia, respectively (U.S. FDA, 2020c, para 5). Figure 37-3 illustrates a sample label with explanation of terms. The food label is a tool to educate the public about nutrition and aid in making informed food decisions to choose a healthy diet (U.S. FDA, 2020b).

FACTORS AFFECTING NUTRITION

A person's food patterns and habits have a great impact on overall food intake. Food habits are a product of many evolving variables, such as physiologic and physical factors that influence nutrient requirements (e.g., stage of development, state of health, medications). Social determinants of health, the conditions (economic stability, health care access and quality, social and community context, education access and quality, neighborhood and built environments) in the environments in which people live their lives (U. S. Department of Health and Human Services. Office of Disease Prevention and Health Promotion, n.d.), culture, religion, food ideology (the meaning of food for an individual), and learned aversions also have an impact on food habits.

These variables alone or in combination also can affect food intake and overall nutrition.

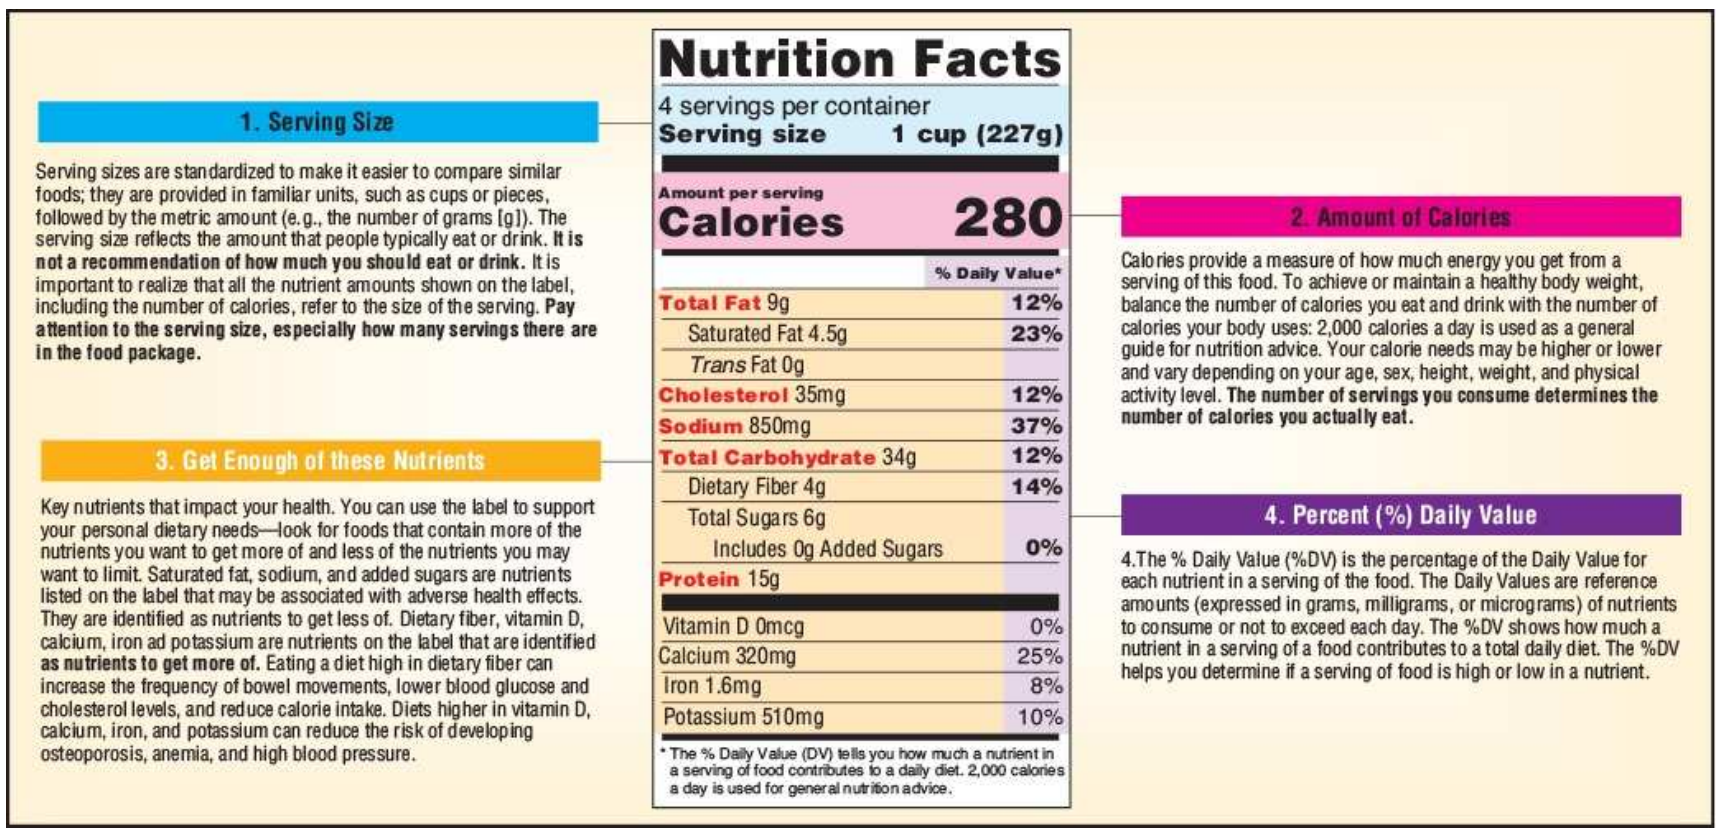

FIGURE 37-3. Sample nutritional label with explanation of terms. (*Source:* U.S. Food and Drug Administration [FDA]. [2020, March 11]. *How to understand and use the nutrition facts label.* https://www.fda.gov/food/new-nutrition-facts-label/how-understand-and-use-nutrition-facts-label)

Physiologic and Physical Factors That Influence Nutrient Requirements

There are various reasons a person's nutrient requirements may differ. Some are permanent, such as chronic illness, whereas others are temporary, such as pregnancy.

Developmental Considerations

Throughout the life cycle, nutrient needs change in relation to growth, development, activity, and age-related changes in metabolism and body composition. Periods of intense growth and development, such as during infancy, adolescence, pregnancy, and lactation, cause an increase in nutrient needs. Nutrient needs stabilize during adulthood, although older people may need more or less of some nutrients. Age influences not only nutrient requirements, but also food intake. The consistency of food consumed, eating patterns, and the significance of food change with physical and psychosocial

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

development.

Remember **Susan Oakland**, the student who is pregnant, and William Johnston, the executive with hypertension and high cholesterol, described at the beginning of the chapter. The nurse would need to incorporate knowledge of each patient's developmental level when planning care.

INFANTS

The period from birth to age 1 year is the most rapid period of growth. Birth weight doubles in 4 to 6 months and triples by age 1 year. Length increases 50% in the first year. Muscle control and the development of hand–eye coordination allow the infant to progress to sitting upright and self-feeding. The iron stores present at birth start to become depleted between ages 3 and 4 months. The immune system matures between ages 4 and 6 months.

Nutritional needs per unit of body weight are greater during infancy and childhood than at any other developmental stage (Physicians Committee for Responsible Medicine, n.d.). Breastfeeding is recommended as the major source of nutrition for the first 6 to 12 months of life (NAPNAP, 2019). If the infant is not breastfed, the infant should receive one of the commercially prepared iron-fortified infant formulas. Cow's milk is not recommended for infants younger than age 1 year. Supplemental vitamins may be prescribed. In general, solid foods are not introduced before the infant is developmentally ready, usually at about age 6 months. At this age, the infant gains control of the head, neck, jaw, and tongue; develops hand–eye coordination; and the ability to sit, chew, and drink. New foods should be introduced one at a time for a period of 2 to 3 days so that any allergic reaction, such as rashes, fussiness, vomiting, diarrhea, or constipation, can be easily identified (Dudek, 2022). By age 1 year, infants should be eating a variety of table foods and various textures (Dudek, 2022). Iron-fortified foods are recommended (Dudek, 2022).

TODDLERS AND PRESCHOOLERS

There is continued growth and development during this stage, but the growth rate slows (Kyle & Carman, 2021). Mobility, autonomy, and coordination increase, as do muscle mass and bone density. Language skills improve, and the 3- to 5-year-old child also develops attitudes toward food.

Toddlers and preschoolers can feed themselves, verbalize food likes and dislikes, and occasionally use food to manipulate their parents (Fig. 37-4). Appetite dramatically decreases and becomes erratic. Inappropriate use of food (e.g., to punish, reward, bribe, convey love) may lead to inappropriate food attitudes. Children in this age group often experience an inadequate intake of fruits and vegetables and/or excessive intake of sweetened fruit drinks.

FIGURE 37-4. Toddlers and preschoolers can feed themselves and verbalize food likes and dislikes.

SCHOOL-AGE CHILDREN

The 6- to 12-year-old child has an uneven, individualized, sometimes erratic slow progressive physical growth pattern (Kyle & Carman, 2021). Permanent teeth erupt as the digestive system matures. Socialization and independence increase. At this stage, the body accumulates reserves in preparation for the upcoming adolescent growth spurt.

Nutritional implications for the school-age child focus on health promotion. Increasing energy requirements need to

be balanced with foods of high nutritional value. The appetite improves but still may be irregular. The parents' role as the primary regulator of food intake diminishes, and advertising has more of an impact on the child's food choices.

ADOLESCENTS

Adolescence (ages 11 to 20 years) is a period of rapid physical, emotional, social, and sexual maturation. The growth spurt begins at different ages among individuals. Girls begin menstruation and experience fat deposition, whereas males experience an increase in muscle mass, lean body tissue, and bones. Adolescence is also marked by intense psychosocial growth, family/caregiver conflict, and social and peer pressure. Childhood nutrition problems often worsen during adolescence. Adolescents tend to skip breakfast, contributing to a lower-quality diet and decreased performance in school. Children in this age group tend to consume inadequate amounts of fruits, vegetables, whole grains, and dairy products (USDA & DHHS, 2020).

Nutrient needs, especially for calories, protein, calcium, and iron, increase to support growth. Weight consciousness may become compulsive in teenaged girls, resulting in anorexia nervosa, an eating disorder characterized by extreme weight loss, muscle wasting, arrested sexual development, refusal to eat, and bizarre eating habits. Bulimia, another eating disorder characterized by gorging followed by purging with self-induced vomiting, diuretics, and laxatives, also becomes more common in this age group. Although contrasts exist, there is also some overlap between these diseases. Both conditions are serious health and nutritional problems; individuals with these disorders require professional medical help and counseling. Other unhealthy diet practices include fasting, the use of diet pills, and laxative abuse.

Adolescents often eat their food rapidly, leading to overconsumption before satiety is experienced. Food is often eaten away from home, consisting of products from fast food restaurants, convenience stores, and vending machines—foods high in fat, sugar, and salt. These factors need to be considered when planning dietary interventions for adolescents.

Both the pregnant person and child are at increased nutritional risk during teenage pregnancy due to competition for the nutrients between the adolescent's body and that of the fetus. Nutritional needs may be harder to meet because fewer meals are eaten at home, and peer influence and busy schedules have an impact. Adequate nutrition and appropriate weight gain improve birth outcomes and decrease the incidence of low–birth-weight infants and improve the health of infants born to adolescents (Dudek, 2022; Kyle & Carman, 2021).

ADULTS

With adulthood, growth ceases. This age is also marked by a decline in the BMR with each decade. Adults may become more aware of the preventive role of exercise, or pressures of work and family may lead to a decline in physical activity and exercise.

Nutritional needs level off in adulthood, and fewer calories are required because of the decrease in BMR. Weight gain results if adjustments in caloric intake are not made.

PREGNANT AND LACTATING PERSONS

During pregnancy, the fetus, maternal tissues, and placenta grow dramatically. Weight gain occurs, and GI changes as a result of the pregnancy may result in nausea, vomiting, heartburn, or constipation. The quantity of breast milk produced depends on an adequate supply of nutrients.

Nutrient needs during pregnancy increase to support growth and maintain maternal homeostasis, particularly during the second and third trimesters. During the second trimester, normal-weight pregnant persons need approximately 340 extra calories per day and 450 extra calories per day in the third trimester than when not pregnant (Academy of Nutrition and Dietetics, 2020a). Key nutrient needs include protein, calories, iron, and folic acid. Caloric needs are higher for lactation (approximately 500 cal/day) than nonpregnant calorie needs (Dudek, 2022), and the nutritional quality of breast milk is maintained at the expense of the lactating person's nutrition if dietary intake is inadequate. People who did not gain enough weight during pregnancy may need to increase their calorie intake (Dudek, 2022).

OLDER ADULTS

Because of the decreases in BMR and physical activity and loss of lean body mass, energy expenditure decreases. Loss of teeth and periodontal disease may make chewing more difficult. A decrease in peristalsis can result in constipation. Loss of taste between sweet and salty begins between ages 55 and 59 years, but discrimination between bitter and sour remains intact. The sensation of thirst also decreases. Degenerative diseases and the use of medications are more common with aging. It is not uncommon for social isolation, poor self-esteem, or loss of independence to affect nutritional intake negatively.

Because of the changes related to aging, the caloric needs of the body decrease. The need for nutrients, however, increases, especially protein, calcium, B_{12}, and vitamin D (Academy of Nutrition and Dietetics, 2020b; Dudek, 2022). Foods that are difficult to chew may need to be eliminated, whereas an increase in fiber and fluid intake can relieve constipation. Older adults are also prone to dehydration, and lack of interest in eating is common. Nutrient intake, digestion, absorption, metabolism, or excretion may be altered because of the physiologic changes common to this age. Dietary restrictions related to chronic illness, limited income, isolation, and age-related physiologic changes place persons in this age group at risk for malnutrition (Bernstein & Munoz, 2020; Touhy & Jett, 2018).

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

Sex Assigned at Birth

Males differ from females in their nutrient requirements due to differences in body composition and reproductive function. Their larger muscle mass translates into higher caloric and protein requirements (therefore, slightly higher needs for B vitamins that metabolize calories and protein) because muscle is more metabolically active than adipose tissue (females have proportionately more adipose tissue). Females of childbearing age have higher iron requirements related to menstruation. In addition, evidence indicates there are biologic sex—associated differences in metabolism of some nutrients, including fatty acids, proteins, and carbohydrates (Comitato et al., 2015).

State of Health

The alteration in nutrient requirements that results from illness and trauma varies with the intensity and duration of the stress. For instance, fevers increase the need for calories and water. Unlike fevers related to septicemia, however, fevers caused by a mild case of the flu require few dietary adjustments.

Trauma, such as major surgery, burns, and crush injuries, is followed by hormonal changes that profoundly affect the body's use of nutrients. To preserve or replenish body nutrient stores and to promote healing and recovery, nutrient requirements increase dramatically in the adaptive phase after stress. In some cases of severe trauma, such as major burns, the rehabilitative phase of recovery, characterized by the gradual normalization of nutrient needs, may last for years.

Chronic disorders—for example, diabetes, renal disease, hypertension, heart disease, GI disorders, and cancer—can alter nutrient requirements by influencing nutrient intake, digestion, absorption, metabolism, utilization, or excretion.

Mental health problems, such as depression and confusion, can cause a patient to forget to eat or lack the motivation to eat, leading to malnutrition.

Alcohol Use Disorder

Alcohol use disorder is a pattern of alcohol use that includes any alcohol that puts your health or safety at risk or causes other alcohol-related problems and includes binge drinking (a pattern of drinking where a minimum of 4 to 5 drinks are consumed within 2 hours) (MFMER, 2018). Alcohol can alter the body's use of nutrients, and thereby its nutrient requirements, by numerous mechanisms (Gramlich et al., 2021). The toxic effect of alcohol on the intestinal mucosa interferes with normal nutrient absorption; thus, requirements increase as the efficiency of absorption decreases. The need for B vitamins increases because they are used to metabolize alcohol. Alcohol can also influence nutrient metabolism by impairing nutrient storage, increasing nutrient catabolism, and increasing nutrient excretion. Alcohol abuse that results in liver damage has profound effects on the body's nutrient metabolism and requirements.

Medications

Many drugs have the potential to influence nutrient requirements. Nutrient absorption may be altered by drugs that (1) change the pH of the GI tract, (2) increase GI motility, (3) damage the intestinal mucosa, or (4) bind with nutrients, rendering them unavailable to the body. Nutrient metabolism can be altered by drugs that (1) act as nutrient antagonists, (2) alter the enzyme systems that metabolize nutrients, or (3) alter nutrient degradation. Some drugs alter the renal reabsorption of nutrients and, therefore, may increase or decrease nutrient excretion.

Megadoses of Nutrient Supplements

Because some nutrients compete against each other for absorption, an excess of one nutrient can lead to a deficiency (or increase the requirement) of another, especially if one is absorbed preferentially. For instance, a delicate balance exists between zinc and copper. People who take therapeutic levels of zinc run the risk of developing a copper deficiency—which is otherwise rare—unless they also increase their intake of copper.

https://www.nutrition.gov/topics/whats-food/vitamins-and-mineralsDietary supplements can have druglike effects and may interact with food and medications (Karch, 2020). Accurate information regarding the patient's use of dietary supplements is imperative to provide safe and appropriate care. The use of herbs, vitamins, minerals, and other supplements can impact a patient's plan of care and must be considered by all members of the health care team. For example, a patient taking ginkgo biloba (an herbal) and aspirin may have to have surgery postponed due to an increased risk for excessive bleeding, because each of these substances have anticoagulant properties. A list of accurate, reliable sources for the latest information about specific herbs and supplements based on scientific evidence can be found .

Physical, Sociocultural, and Psychosocial Factors That Influence Food Choices

Dietary choices or restrictions also are influenced by social determinants of health (e.g., economics, social supports, literacy, language), culture, religion, and personal feelings and meanings associated with food. The financial income of the patient or the patient's household can directly impact the ability to purchase sufficient food and/or food of high nutritional value. Diverse lifestyles and eating habits directly impact a person's nutritional health and well-being. Religious restrictions and beliefs or cultural practices may affect the patient's acceptance of, response to, and engagement in nutrition therapies. Health care providers need an understanding of a patient's cultural values, beliefs, and practices to provide culturally acceptable care.

Social Determinants of Health

Economic resources and stability affect dietary choices and patterns. Employment and income coupled with the increasing cost of food may result in a decrease in the nutritional quality of the diet. Many variables influence the types of foods purchased. Creative use of the food dollar means using unit pricing to determine cost per serving (e.g., comparing the unit price of 39¢ per serving with a similar product's 45¢ per serving), selecting foods that contain adequate nutrients, and buying seasonal foods that are more economical and can be prepared easily at home. Avoiding convenience foods and meals purchased away from home can save food dollars.

Additional sociocultural factors affecting nutritional intake include:

- Language barriers
- Knowledge of nutrition
- Literacy
- Lack of caregiver or social support
- Social isolation
- Limited access to food market and ability to obtain food (food deserts)
- Lack of or inadequate cooking and/or food preparation arrangements

Religion

Dietary restrictions associated with religions might affect a patient's nutritional requirements. Many religions eschew certain types of food products. For example, Mormon individuals do not use coffee, tea, or alcohol, and are encouraged to limit meat consumption. Many Hindu people are vegetarian, adhering to the concept of nonviolence as applied to all living being (Andrews et al., 2020; Dudek, 2022). Therefore, alternative food choices or meal patterns may be necessary. Kosher dietary laws require special food preparation techniques and prohibit intake of pork and shellfish (Andrews et al., 2020). Thus, a patient's religious affiliation may affect that individual's nutritional regimen. Question regarding any preferences or restrictions should be included in a nutritional assessment. Vegetarian, kosher, and other special diets are available in hospitals, long-term care facilities, retirement homes, and programs, such as Meals on Wheels.

Meaning of Food

Food means different things to different people, with food playing multiple roles in the lives of most people. In addition to satisfying hunger and providing nutrition, food may signify a celebration, a social gathering, or a reward. Some people use various foods to indicate caring or to give comfort and reassurance during times of stress or unhappiness. Mealtime may evoke memories of family discussions, laughter, and enjoyable times. Some may remember conflicts associated with eating or avoid eating because it reminds them of their loneliness and isolation. Others, because of society's emphasis on being thin, may resort to fad or crash weight-reduction diets to resolve eating conflicts and lose weight rapidly. This initial weight reduction seldom is sustained for an extended period, and a cycle of "yo-yo" dieting frequently results. Drastic weight loss is followed by an eating binge that causes the dieter to regain all the lost weight and, possibly, some additional weight each time the sequence occurs. Nutritional deficiencies may occur and place the person at risk for other diseases. Losing weight and keeping it off require a change in eating habits as part of the overall commitment to health.

Culture

Nutritional diversity is common among cultural or ethnic groups. The variety and selections are unique to each group and represent their personal beliefs and customs. Culture influences what is eaten or considered edible, how it is prepared, and what combinations of food are permitted. Herbal treatments that are popular in some cultures may interfere with or counteract the action of prescribed medication. The variations in food choices within a culture also depend on income levels and availability of foods. General and specific cultural knowledge allows the health care provider to ask the right questions when interacting with patients of varying backgrounds. The U.S. Department of Agriculture and the National Agricultural Library (n.d.b) provides extensive resources for working with various ethnic and cultural groups at https://www.nal.usda.gov/fnic/ethnic-and-cultural-resources-0. Nurses who are aware of the specific needs and beliefs of culturally diverse patient populations are better able to communicate effectively and provide optimal care. Box 37-3 suggests guidelines for effective communication about nutrition with culturally diverse patients.

If a patient of a different culture is to be placed on a specific diet, discussing food choice options is necessary to customize the diet to meet the person's cultural demands. Discussing ways to integrate cultural food preferences into current nutrition guidelines is an important part of nursing care.

Food Intake

At times, a combination of physiologic and physical factors that influence nutrient requirements and, or in combination with, sociocultural and psychosocial factors can affect a person's nutritional intake. Subsequently, these factors can result in a decrease or increase in food intake.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

Box 37-3 **Communicating Effectively About Nutrition With Culturally Diverse Patients**

- Acquire basic information about health beliefs and practices of various cultural groups in your health care setting. This provides a basis for assessing patients' beliefs and practices. Recognize, however, that within all cultures and ethnic groups, there are members who do not hold all the values of the group.
- Ask specifically about the use of folk or home remedies prescribed by a nontraditional healer.
- Determine the patient's language preferences for spoken and written communication.
- Utilize printed or audiovisual information that is in the language spoken by your patients.
- Promote healthy food choices by identifying healthy traditional food practices and encourage their use.
- Encourage cultural sensitivity in health care workers in your particular setting.
- Recognize that diversity exists within cultural groups. For example, the Hispanic/Latino population includes Mexican American, Mexican, Cuban, Puerto Rican, and other groups.
- Emphasize threads or messages in health teaching that are common to all cultures (e.g., concern about family, faith, home).
- Help culturally diverse patients to value and understand the importance of communicating concerns and asking questions about prescribed dietary practices.

Source: Adapted from Andrews, M., Boyle, J. S., & Collins, J. (2020). *Transcultural concepts in nursing care* (8th ed.). Wolters Kluwer; Dudek, S. (2022). *Nutrition essentials for nursing practice* (9th ed.). Wolters Kluwer.

Decreased Food Intake

Food intake may decrease for various reasons. Patients with a BMI of less than 18.5 are considered underweight. **Anorexia**, or the lack of appetite, may be related to systemic and local diseases; numerous psychosocial causes, such as fear, anxiety, depression, or pain; and impaired ability to smell and taste—or it may occur secondary to drug therapy or medical treatments (Dudek, 2022; Jarvis & Eckhardt, 2020). Others who may have limited food intake include those who have difficulty chewing and swallowing, those who experience chronic GI problems or undergo certain surgical procedures, those with certain chronic illnesses (such as cancer), and those with inadequate food budgets.

Concept Mastery Alert

Anorexia is different from anorexia nervosa. *Anorexia* is a general term that involves a lack of appetite that results from numerous causes. *Anorexia nervosa* is an eating disorder that involves varied issues including extreme weight loss, muscle wasting, arrested sexual development, refusal to eat, and bizarre eating habits.

Consider **Charles Gallagher**, whose wife is receiving enteral feedings. The underlying reason for insertion of the PEG tube was her inability to swallow and subsequent development of aspiration pneumonia that required numerous hospitalizations. The nurse would need to communicate this information to Mr. Gallagher to ensure that he understands the rationale for the feeding. This understanding is important for decision making.

Increased Food Intake

Increased food intake may lead to overweight and obesity. Obesity presents a serious health problem physically, socially, and emotionally. Obesity in adults is defined as body weight that is higher than what is considered as healthy weight for a given height or having a BMI of 30 or more (CDC, 2020c; NHLBI, n.d.b). In children and teens, overweight is defined as a BMI at or above the 85th percentile and below the 95th percentile for children and teens of the same age and sex assigned at birth (CDC, 2020c). Obesity in children and teens is defined as a BMI at or above the 95th percentile for children and teens of the same age and sex assigned at birth (CDC, 2018). More than two thirds of adults in the United States are considered to be overweight or have obesity (NIDDK, 2017). In addition, approximately 17% of young people between ages 2 and 19 years are considered to be obese, and about 6% are considered to be extremely obese (NIDDK, 2017).

An imbalance between calories consumed and calories expended, resulting from an excess caloric intake and/or a

decrease in energy expenditure, leads to the gradual accumulation of weight (NHLBI, n.d.a). In addition, an increased intake of energy-dense foods that are high in fat and sugars and an increase in physical inactivity due to the increasingly sedentary nature of many forms of work, changing modes of transportation and increasing urbanization are thought to play a role in causing obesity (World Health Organization, 2020). This excess weight increases the risk for numerous health problems, such as metabolic syndrome, cardiovascular diseases, certain cancers, and respiratory problems such as sleep apnea and obesity hypoventilation syndrome (NHLBI, n.d.a); increases the risks associated with surgery (American Society of Anesthesiologists, n.d.); and increases the risk for complications during pregnancy, labor, and delivery (Silbert-Flagg & Pillitteri, 2018). People who are overweight or obese may be the subject of weight bias and stigma and this could lead to feelings of rejection, shame or guilt, depression, isolation, and to perceive oneself as a failure (MFMER, 2020c; NIDDK, n.d.). Obesity is resistant to treatment, and weight loss is temporary at best unless behavior modification and exercise are incorporated into the dietary plan (MFMER, 2020c).

NURSING PROCESS FOR NUTRITION

Assessing

Nutritional status has a significant role in both health. For well patients, good nutritional status can help to maintain health, promote normal growth and development, and protect against disease. During illness, good nutritional status can reduce the risk for complications and speed recovery time. Conversely, poor nutritional status can increase the risk for illness or death.

Like other aspects of nursing care, nutritional assessment is a systematic approach used to identify the patient's actual or potential needs, formulate a plan to meet those needs, initiate the plan or assign others to implement it, and evaluate the effectiveness of the plan. The level of assessment may range from simple screening to a comprehensive, in-depth assessment, depending on individual circumstances. Regardless of the level of assessment, nutritional assessment is appropriate for all patients. Nurses can collect assessment data through history taking (dietary, medical, socioeconomic data), physical assessments (anthropometric and clinical data), and laboratory data. Patients found to be at risk for malnutrition are often referred to a dietitian for comprehensive assessment of their nutritional status (Anderson, 2019a; Dudek, 2022).

Nurses working with patients to promote appropriate behaviors related to nutrition should examine their own behaviors as factors in the success of the plan. Nurses who role model good health behaviors are more effective teachers. Use the display, Promoting Health 37-1: Nutrition, for yourself before using it with others.

Nutritional Data

Collect nutritional data from the patient or family or caregivers and evaluate it according to the *Dietary Guidelines*, DRI, or the MyPlate food guide, depending on the purpose of the assessment and within the context of the patient's health status.

NUTRITIONAL SCREENING

Nutritional screening is an important part of the nursing assessment. Screening looks for cues associated with nutrition problems to determine if a person is malnourished or at risk for malnutrition. The Mini Nutritional Assessment tool (MNA) is one example of a tool frequently used to screen older adults (Fig. 37-5) and is available and regularly updated at www.mna-elderly.com. The MNA is a combination of diverse screening questions, anthropometric measurements, nutritional habits, general condition, and self-evaluation (Reber et al., 2019). The MNA short-form (MNS-SF) is also available and consists of six items, takes less than 5 minutes to complete, and is as effective as the long version (Reber et al., 2019).

After a screening tool identifies a patient at risk it is imperative to complete a nutritional assessment as a follow-up. These patients are usually referred to a dietitian for further nutrition assessment, diagnosis, and intervention (Anderson, 2019a; Dudek, 2022). When this is combined with other methods of assessing nutritional status, the nurse is better prepared to coordinate a focused strategy to combat malnutrition.

Promoting Health 37-1

NUTRITION

Use the assessment checklist to determine how well you are meeting your needs related to nutrition practices. Then develop a prescription for self-care by choosing appropriate behaviors from the list of suggestions.

Assessment Checklist

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

☐ almost always ☐ sometimes ☐ almost never

☐ ☐ ☐ 1. I know and use the recommended dietary guidelines and servings.

☐ ☐ ☐ 2. My weight is within 10% of the ideal for my height and body frame.

☐ ☐ ☐ 3. I maintain an appropriate balance between exercise and food intake.

☐ ☐ ☐ 4. I limit my fat, sugar, salt, and red meat intake.

☐ ☐ ☐ 5. I limit my caffeine intake.

☐ ☐ ☐ 6. I use alcoholic beverages in moderation.

☐ ☐ ☐ 7. I make an effort to eat high-fiber foods.

Self-Care Behaviors

1. Maintain desirable weight, eating a variety of foods in adequate amounts from each of the food groups.
2. Eat slowly, take smaller portions, and avoid second helpings if trying to control overeating.
3. Eat a variety of foods low in calories and high in nutrients to lose weight.
4. Obtain clearance from a health care provider before starting a weight-loss program.
5. Avoid too many foods high in cholesterol (milk, egg yolk, organ meats, fats, oils); instead choose lean meat, fish, poultry, and beans.
6. Eat foods high in fiber: whole-grain breads and cereals, fruits, vegetables, dry beans.
7. Avoid excess use of salt and sugar.
8. Begin an exercise program and maintain it.
9. Learn healthy eating habits; read labels, become familiar with healthy fast-food and restaurant menus; and drink alcohol moderately (if at all).
10. Substitute healthy rewards for yourself that do not include high-calorie, low-nutrition snacks, and beverages.

Information to promote effective nutrition, dietary supplement use and safety; nutrient recommendations; and database resources are available online.

Mini Nutritional Assessment
MNA®

Nestlé Nutrition Institute

Last name: First name:

Sex: Age: Weight, kg: Height, cm: Date:

Complete the screen by filling in the boxes with the appropriate numbers.
Add the numbers for the screen. If score is 11 or less, continue with the assessment to gain a Malnutrition Indicator Score.

A Has food intake declined over the past 3 months due to loss of appetite, digestive problems, chewing or swallowing difficulties?
0 = severe decrease in food intake
1 = moderate decrease in food intake
2 = no decrease in food intake ☐

B Weight loss during the last 3 months
0 = weight loss greater than 3kg (6.6lbs)
1 = does not know
2 = weight loss between 1 and 3kg (2.2 and 6.6 lbs)
3 = no weight loss ☐

C Mobility
0 = bed or chair bound
1 = able to get out of bed / chair but does not go out
2 = goes out ☐

D Has suffered psychological stress or acute disease in the past 3 months?
0 = yes 2 = no ☐

E Neuropsychological problems
0 = severe dementia or depression
1 = mild dementia
2 = no psychological problems ☐

F Body Mass Index (BMI) = weight in kg / (height in m)² ☐
0 = BMI less than 19
1 = BMI 19 to less than 21
2 = BMI 21 to less than 23
3 = BMI 23 or greater ☐

Screening score (subtotal max. 14 points) ☐☐
12-14 points: Normal nutritional status
8-11 points: At risk of malnutrition
0-7 points: Malnourished
For a more in-depth assessment, continue with questions G-R

G Lives independently (not in nursing home or hospital)
1 = yes 0 = no ☐

H Takes more than 3 prescription drugs per day
0 = yes 1 = no ☐

I Pressure sores or skin ulcers
0 = yes 1 = no ☐

J How many full meals does the patient eat daily?
0 = 1 meal
1 = 2 meals
2 = 3 meals ☐

K Selected consumption markers for protein intake
- At least one serving of dairy products (milk, cheese, yoghurt) per day — yes ☐ no ☐
- Two or more servings of legumes or eggs per week — yes ☐ no ☐
- Meat, fish or poultry every day — yes ☐ no ☐

0.0 = if 0 or 1 yes
0.5 = if 2 yes
1.0 = if 3 yes ☐☐

L Consumes two or more servings of fruit or vegetables per day?
0 = no 1 = yes ☐

M How much fluid (water, juice, coffee, tea, milk...) is consumed per day?
0.0 = less than 3 cups
0.5 = 3 to 5 cups
1.0 = more than 5 cups ☐.☐

N Mode of feeding
0 = unable to eat without assistance
1 = self-fed with some difficulty
2 = self-fed without any problem ☐

O Self view of nutritional status
0 = views self as being malnourished
1 = is uncertain of nutritional state
2 = views self as having no nutritional problem ☐

P In comparison with other people of the same age, how does the patient consider his / her health status?
0.0 = not as good
0.5 = does not know
1.0 = as good
2.0 = better ☐.☐

Q Mid-arm circumference (MAC) in cm
0.0 = MAC less than 21
0.5 = MAC 21 to 22
1.0 = MAC greater than 22 ☐.☐

R Calf circumference (CC) in cm
0 = CC less than 31
1 = CC 31 or greater ☐

Assessment (max. 16 points) ☐☐.☐
Screening score ☐☐.☐
Total Assessment (max. 30 points) ☐☐.☐

Malnutrition Indicator Score
24 to 30 points ☐ Normal nutritional status
17 to 23.5 points ☐ At risk of malnutrition
Less than 17 points ☐ Malnourished

ASSESSING DIETARY INTAKE

Many different methods can be used to assess actual dietary intake.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

24-Hour Recall Method

The easiest way to collect dietary data is to obtain a 24-hour recall of all food and beverages the patient normally consumes during an average day. Ask the patient to recall details related to nutritional intake from the prior 24 hours. This method includes the patient's portion sizes, meal and snack patterns, meal timing, and location where food is eaten. Because this method relies on memory and accurate interpretation of portion sizes, the information may not be reliable.

Food Diaries/Calorie Counts

Food diaries and calorie counts require documentation of actual intake for a specified period of time. In an outpatient setting, ask the patient to record everything the patient has had to eat or drink, including portion size, over a set period of time. In the hospital or other facility settings, documentation is usually completed by the nursing staff. These tools may provide a better overall picture of nutrient intake because all food and beverages consumed in a specified period, usually 3 to 7 days, are recorded.

Food Frequency Record

Food frequency records give a general picture of nutritional consumption. Ask patients questions to elicit an average number of times certain foods or food groups are consumed in a given period of time: per day, per week, or per month. For example, ask, "How many times in the last week have you eaten fresh fruit or fish?" or "How many times in the last week have you had a glass of milk?"

Focused Assessment Guide 37-1

NUTRITION

Factors to Assess	Questions and Approaches
Usual dietary intake	Does your current intake differ from your usual intake? If so, is the reason a loss of appetite, changes in smell or taste, difficulty chewing and swallowing, hospitalization, a modified diet? With whom do you usually eat meals?
Food allergies or intolerances	Do you have any food allergies or intolerances?
Food preparation and storage	Who does the food shopping? Who prepares the meals? How is the food normally prepared? For instance, is food usually fried, baked, or broiled? Do you have adequate food storage space and preparation equipment?
Type of dietary practices	Do you now or have you in the past followed a modified diet prescribed by a health care provider? Do you now or have you in the past used a fad diet, health foods, or self-prescribed supplements?
Eating disorder patterns	Do you view yourself as overweight? Do you weigh yourself frequently during 1 day? How is your appetite? Do you binge on large amounts of food in a short period? Have you ever caused yourself to vomit after eating a meal? Have you used laxatives, diuretics, herbal supplements, or over-the-counter weight-loss pills to lose weight?

Diet History

A more comprehensive approach to diet assessment is a full diet history. In addition to a 24-hour food recall, calorie counts/food diaries, and food-frequency record, interview questions are geared to provide information on past and present food intake and habits. Sample questions are included in the accompanying Focused Assessment Guide 37-1.

Consider **William Johnston**, the man who has less-than-healthful dietary and health habits. The nurse could use a diet history to obtain specific information about Mr. Johnston's actual intake. Analysis of this information would reveal his actual dietary intake and identify potential and actual nutritional problems.

MEDICAL AND SOCIOECONOMIC DATA

Medical, social determinants of health, as well as cultural and psychological influences, require evaluation for their impact on nutritional requirements and food choices. A nutritional assessment should include the following health, social, and economic information (Dudek, 2022).

Medical data include:

- Current illness as well as health, medical and surgical history
- Past and current drug history
- Medications, supplement use, herbal supplement use, complementary, and integrative therapy use
- History of drug dependence or abuse
- Ability to chew and swallow, including condition of mouth, missing teeth, or dentures
- Appetite, food intolerance and allergies, and bowel habits

Social data include:

- Age, sex assigned at birth, family history, lifestyle (e.g., those at extremes in age are most at risk)
- Social determinants of health
  - Educational background
  - Socioeconomic status: occupation, sources of income, food budget
  - Illiteracy
  - Language barriers
  - Caregiver and/or social support
  - Knowledge of nutrition
  - Access to reliable, healthy food options
- Information about exercise, and sleep patterns
- Religious affiliation, cultural and ethnic background
- Use of alcohol and tobacco

ANTHROPOMETRIC DATA

Anthropometric measurements (measurement of the size and proportion of the human body) are used to determine body dimensions. In children, anthropometric measurements are used to assess growth rate and weight gain; in adults, they can give indirect measurements of body protein and fat stores. For the data to be accurate and reliable, use standardized equipment and procedures, and compare the data with the appropriate reference standards for the patient's age and sex assigned at birth.

Obtain height and weight, the most common anthropometric measurements, when the patient is admitted to the health care facility and periodically thereafter and are assessed in community care environments as well. Weigh a patient on the same scale each time and at the same time of day, preferably before breakfast. Height and weight are used to calculate the patient's BMI. Because actual weight may be increased if the patient has edema, consider hydration status. Although self-reported weight may be recorded when actual weight is unobtainable, it is highly inaccurate and must be noted. Record an actual weight as soon as feasibly possible. Self-reported height in the older adult can be inaccurate related to shortening of the spine (MedlinePlus, 2020). Record an actual height as soon as possible.

BODY MASS INDEX AND WAIST CIRCUMFERENCE

Calculate the patient's BMI and measure waist circumference, as discussed earlier in the chapter on page 1391. Compare results with the established guidelines to determine the patient's status and identify potential health risks. Refer to Table 37-1 on page 1392.

CLINICAL DATA

Although signs and symptoms of altered nutrition may be observed during a physical assessment (Table 37-2 on page 1408), they usually do not appear until the condition is advanced. In addition, further investigation is necessary to determine whether abnormal findings are actually caused by a nutritional deficiency, are possibly related to a nutritional deficiency, or are unrelated to nutritional status.

Assess for physical barriers to eating. **Dysphagia** (difficulty swallowing or the inability to swallow) can be the result of poor dental health, cancer, or a neurologic disease, such as stroke, Parkinson disease, or dementia, and may reduce the patient's nutritional intake. Dysphagia also is associated with an increased risk for **aspiration**, the

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

misdirection of oropharyngeal secretions or gastric contents into the larynx and lower respiratory tract (Nazarko, 2020). Dysphagia should be considered if a patient has one or more signs or symptoms of dysphagia or related issues (Holdoway & Smith, 2020; Nazarko, 2020). Refer to Box 37-4 (on page 1409) for signs and symptoms of and risk factors for dysphagia. Assessment tools have been developed to measure patient dysphagia symptoms. These tools may be used to determine the safety of oral feeding, document symptom severity and to monitor the effectiveness of treatment (Oliveirea et al., 2019; Johnson et al., 2018).

Dental problems are associated with impaired chewing and avoidance of foods that may be difficult to chew, such as meat, fruit, and vegetables. Patients who experience weakness and fatigue may find eating to be a chore to avoid. Diminished sensor abilities, such as sight, taste, smell, and hearing, may also impact a patient's nutritional intake.

BIOCHEMICAL DATA

Laboratory tests, which measure blood and urine levels of nutrients or biochemical functions that depend on an adequate supply of nutrients, may be used as part of a nutritional assessment. Most routine biochemical tests measure protein status; measures of body vitamin, mineral, and trace element status are also available. Some evidence suggests, however, that these traditional nutrition indicators do not accurately quantify the degree of malnutrition (Hartwell et al., 2018) and should be avoided as part of assessment of hospitalized patients and patients in critical care settings, in particular, as they do not take the importance of disease severity and inflammation and stress into account (McClave, Taylor, et al., 2016; McClave, DiBaise, et al., 2016).

Hemoglobin, the oxygen-carrying protein of the red blood cells, and hematocrit, the volume of red blood cells packed by centrifugation in a given volume of blood, are measures of plasma protein that also reflect a person's iron status. Protein status can also be determined by measuring serum prealbumin and transferrin levels and by a total lymphocyte count. In the past, serum albumin levels were considered as a marker for malnutrition (Fischbach et al., 2022). However, prealbumin has been suggested as the better reflection of the current nutritional status of within the patient's body (Fischbach et al., 2022). Prealbumin levels provide a timelier picture of a change in dietary status reflecting the current nutritional status within a patient's body (Fischbach et al., 2022). Transferrin acts as an iron-transporting protein, but because it is related to iron levels may not always be an accurate indicator of nutritional status. The total lymphocyte count reflects immune status and is directly affected by impaired nutritional states.

Table 37-2 Clinical Observations for Nutritional Assessment

BODY AREA	SIGNS OF GOOD NUTRITIONAL STATUS	SIGNS OF POOR NUTRITIONAL STATUS
General appearance	Alert, responsive	Listless, apathetic, and cachectic
General vitality	Has endurance, energetic, sleeps well, vigorous	Easily fatigued, no energy, falls asleep easily, looks tired, apathetic, depressed mood
Weight	Normal for height, age, body build; BMI	Overweight or underweight
Hair	Shiny, lustrous, firm, not easily plucked, healthy scalp	Dull and dry, brittle, loss of color, easily plucked, thin and sparse
Face	Uniform skin color; healthy appearance, not swollen	Dark skin over cheeks and under eyes, flaky skin, facial edema (moon face), pale skin color
Eyes	Bright, clear, moist, no sores at corners of eyelids, membranes moist and healthy pink color, no prominent blood vessels	Pale eye membranes, dry eyes (xerophthalmia); Bitot spots, increased vascularity, cornea soft (keratomalacia), small yellowish lumps around eyes (xanthelasma), dull or scarred cornea
Lips	Good pink color, smooth, moist, not chapped or swollen	Swollen and puffy (cheilosis), angular lesion at corners of mouth or fissures or scars (stomatitis)
Tongue	Deep red, surface papillae present	Smooth appearance, beefy red or magenta colored, swollen, hypertrophy or atrophy
Teeth	Straight, no crowding, no cavities, no	Cavities, mottled appearance (fluorosis),

	pain, bright, no discoloration, well-shaped jaw	malpositioned, missing teeth
Gums	Firm, good pink color, no swelling or bleeding	Spongy, bleed easily, marginal redness, recessed, swollen, and inflamed
Glands	No enlargement of the thyroid, face not swollen	Enlargement of the thyroid (goiter), enlargement of the parotid (swollen cheeks)
Skin	Smooth, good color, slightly moist, no signs of rashes, swelling, or color irregularities	Rough, dry, flaky, swollen, pale, pigmented, lack of fat under the skin, fat deposits around the joints (xanthomas), bruises, petechiae
Nails	Firm, pink	Spoon shaped (koilonychia), brittle, pale, ridged
Skeleton	Good posture, no malformations	Poor posture, beading of the ribs, bowed legs or knock-knees, prominent scapulas, chest deformity at diaphragm
Muscles	Well developed, firm, good tone, some fat under the skin	Flaccid, poor tone, wasted, underdeveloped, difficulty walking
Extremities	No tenderness	Weak and tender, edema of lower extremities
Abdomen	Flat	Swollen
Nervous system	Normal reflexes, psychological stability	Decrease in or loss of ankle and knee reflexes, psychomotor changes, mental confusion, depression, sensory loss, motor weakness, loss of sense of position, loss of vibration, burning and tingling of the hands and feet (paresthesia)
Cardiovascular system	Normal heart rate and rhythm, no murmurs, normal blood pressure for age	Cardiac enlargement, tachycardia, abnormal blood pressure
GI system	No palpable organs or masses (liver edge may be palpable in children)	Enlarged liver or spleen

Source: Adapted from Dudek, S. G. (2022). Nutrition essentials for nursing practice (9th ed.). Wolters Kluwer; Jarvis, C., & Echkardt, A. (2020). Physical examination & health assessment (8th ed.). Elsevier.

Blood glucose, blood cholesterol, and blood triglycerides are additional laboratory tests relative to nutritional status. Twenty-four-hour urine tests used to measure protein metabolism include urine creatinine excretion and urine urea nitrogen. Urea, a breakdown product of amino acids, can be measured in the urine and blood. It reflects protein intake and the body's ability to detoxify and excrete this metabolic byproduct. Creatinine levels are directly proportional to the body's muscle mass; a reduction in this value reflects severe malnutrition. These biochemical indicators with nutritional implications are summarized in Box 37-5.

Box 37-4 **Signs and Symptoms and Risk Factors for Dysphagia**

Signs and Symptoms

- Difficulty swallowing foods or fluids; may only be certain foods or liquids
- Coughing or choking when eating or drinking
- Unintentional weight loss
- Frequent throat clearing
- Wet gurgling voice after eating
- Feeling of food or liquids "stuck" in throat
- Leakage of food or saliva from mouth

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

Risk Factors

- Neurologic condition (e.g., stroke, head injury, brain injury, progressive neurologic disorder [e.g., Parkinson disease, multiple sclerosis])
- Dementia
- Obstructive condition (e.g., head and neck cancer, gastroesophageal reflux disease)
- COPD
- Aging
- Malnutrition
- Childhood syndromes (e.g., Down syndrome, cerebral palsy)

Source: Adapted from Holdoway, A., & Smith, A. (2020). Meeting nutritional need and managing patients with dysphagia. *Journal of Community Nursing*, *34*(2), 52–59; Nazarko, L. (2020). Dysphagia: A guide for nurses in general practice. *Practice Nursing*, *31*(4), 162–168. https://doi.org/10.12968/pnur.2020.31.4.162.

Diagnosing Actual or Potential Health Problems and Needs

An assessment of a patient's nutrition status may lead to the identification of one or more actual or potential health problems and needs related to nutrition. Following the formulation of the actual or potential health problems and needs, the nurse communicates findings to other nursing and health care professionals through the use of the written and spoken word. The written actual or potential health problem or need becomes a permanent part of the patient's health record. Examples of health problems and needs with related etiology and signs and symptoms can be found in the box Examples of Actual or Potential Health Problems and Needs: Nutrition on page 1410.

Box 37-5 **Biochemical Data With Nutritional Implications**

Values for Adults

- Hemoglobin (normal = 12–18 g/dL)
  decreased → anemia
- Hematocrit (normal = 46–52%)
  decreased → anemia
- Prealbumin (normal = 19–38 mg/dL)
  decreased → protein depletion, malnutrition
- Transferrin (normal = 250–425 mg/dL)
  decreased → anemia, protein deficiency or loss from burns or malnutrition
- Blood urea nitrogen (normal = 6–20 mg/dL)
  increased → starvation, high-protein intake, severe dehydration
  decreased → malnutrition, low-protein diet, overhydration
- Serum creatinine (normal = 0.6–1.2 mg/dL)
  increased → dehydration
  decreased → reduction in total muscle mass, severe malnutrition

Source: Adapted Fischbach, F. T., Fischbach, M. A., & Stout, K. (2022). *Fischbach's a manual of laboratory and diagnostic tests* (11th ed.). Wolters Kluwer.

Outcome Identification and Planning

Expected outcomes are derived from the actual or potential nutritional problems identified. The goal is to maintain or restore optimal nutritional status using foods the patient likes and tolerates as appropriate for their situation. Goals should also include those to alleviate symptoms or side effects of disease or treatment and to prevent complications or diet-related chronic diseases. General patient outcomes are listed here. Actual patient outcomes should list specific behaviors and criteria individualized for the patient situation. The patient will:

- Attain and maintain ideal body weight, as indicated by BMI and waist circumference.
- Eat a diet adequate but not excessive in all nutrients, based on the *Dietary Guidelines for Americans 2020–2025*, the MyPlate food guideline system, and the DRIs.
- Eat a variety of food in each of three or more meals.
- Follow the appropriate modified diet, when necessary, to restore health, avoid disease recurrences, and prevent or delay potential complications.

Remember **Charles Gallagher**, the husband of the woman receiving enteral nutrition. Initially, outcomes would focus on maintaining his wife's nutritional status. However, the informed decision made to withdraw the nutritional support would lead the nurse to revise the outcomes. Therefore, the outcomes then would focus on emotional comfort for the Gallagher family and a peaceful, dignified death for Mrs. Gallagher.

Implementing

Providing proper and adequate nourishment to the patient is a collaborative effort implemented in a variety of settings. Diet interventions are prescribed in the inpatient setting based on input from the dietitian, the nurse and other health care providers; nurses often provide dietary education and support for the patient. The nurse may also be responsible for screening patients at home who are at nutritional risk, observing intake and appetite, evaluating the patient's tolerance, and assisting the patient with eating. Other nursing interventions related to meeting patients' nutritional needs may include administering enteral and parenteral feedings, consulting with the dietitian and the health care team when dietary problems arise, addressing the potential for drug–nutrient reactions, obtaining more food or snacks for the patient when appropriate, monitoring food brought by visitors or prepared by family members/caregivers, monitoring food accessibility, and participating in nutrition education efforts.

Examples of Actual or Potential Health Problems and Needs

NUTRITION

Actual or Potential Health Problems and Needs	Possible Etiologic Factors	Potential Signs and Symptoms
Impaired Nutritional Status	Insufficient dietary intake, increased metabolic demands	• "Foods just don't taste good anymore." • Reports losing 15 lb within the past 3 weeks. • Several ulcers present on buccal mucosa. • Reports "frequent loose stools" every day for past 2 weeks. • Patient appears fatigued and undernourished; muscle wasting is evident. Laboratory data reveal protein deficiency.
Impaired Swallowing	Neuromuscular impairment, weakness	• "Food seems to get stuck." "Sometimes I can't finish eating because I cough too much." • Swallowing evaluation study reports abnormality in oral and pharyngeal phases. Patient observed to have difficulty chewing; delayed swallow; gags and coughs during meal; gurgly voice quality noted after meal.
Body Weight Problem: Overweight	Excessive food intake in relation to physical activity Sedentary behavior occurring for >2 hours/day BMI 24; waist circumference 39	—

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

inches

Source: International Council of Nurses (ICN). (2019). Nursing diagnosis and outcome statements. https://www.icn.ch/sites/default/files/inline-files/ICNP2019-DC.pdf

Patients with increased nutritional requirements, those who are unable to meet their nutritional requirements orally, and those who will be NPO for more than 48 to 72 hours (Jordan & Moore, 2020) may require nutritional support from **enteral nutrition**, administering nutrients directly into the stomach, or **parenteral nutrition (PN)**, providing nutrition via intravenous (IV) therapy, based on individual circumstances.

QSEN TEAMWORK AND COLLABORATION

Patients, nurses, dieticians, physicians, and other members of the health care team each have key roles in assessing, addressing, and monitoring nutrition and nutrition-related care issues and concerns. Communication and collaboration between the nurse, patient, and other health care professionals result in thoughtful, person-centered nutritional care.

Teaching Nutritional Information

For the greatest chance of success, tailor nutrition instructions individually to the patient's lifestyle, culture, literacy level, and level of motivation. Although strict guidelines and printed handouts may seem ideal, in practice, simplicity and compromise are often the keys to patient engagement. Educational interventions should reinforce the importance of and rationale for adequate nutrition. Nurses should include basic principles of the prescribed nutritional plan and emphasize positive actions, "things to do" instead of what the patient should not do and/or cannot eat (Tappenden et al., 2013).

In the hospital, shortened stays limit the time available for nutritional screening and intervention. Patients are often acutely ill and may be unable to absorb and retain any nutritional instruction. Educational sessions may be limited and should focus on immediate needs. It may also be difficult to include a family member or caregiver responsible for food preparation in scheduled teaching sessions.

Often, more extensive education is more realistic in community settings. In many situations, the home health care nurse has the opportunity to have a significant impact on nutritional health. Provide instruction in a relaxed setting that allows insight into a patient's cultural orientation and family/caregiver patterns and traditions. This type of environment also encourages modification and adjustments in the nurse's approach to nutritional instruction. Investigate the variety of community services and programs that are available to provide nutritional support to patients at home. The accompanying Focus on the Older Adult includes teaching content and strategies for the specific nutritional challenges facing the older adult. Refer to Chapter 9 for additional information and guidelines related to teaching and counseling.

Focus on the Older Adult

NURSING STRATEGIES TO ADDRESS AGE-RELATED CHANGES AFFECTING NUTRITION

Age-Related Changes	Nursing Strategies
Altered ability to chew related to loss of teeth, ill-fitting dentures, and gingivitis	• Encourage and instruct patient to care for and retain own teeth and dentures. • Encourage proper tooth brushing and use of special toothpaste if gums and teeth are sensitive. • Chop, shred, or puree foods that are difficult to chew. • Select ground meat, fish, or poultry as protein sources more easily chewed.
Loss of senses of smell and taste	• Serve food that is attractive and at proper temperature. • Serve one food at a time rather than mixing foods. • Serve foods with different textures and aromas.
Decreased peristalsis in the esophagus	• Avoid cold liquids. • Avoid emotional upsets and stress-producing situations. • Take anticholinergic drugs as prescribed.
Gastroesophageal reflux	• Avoid overeating.

	• Avoid juices, chocolate, and fat. • Avoid alcohol and smoking. • Elevate the head of the bed 30 to 40 degrees when sleeping. • Lose weight if necessary. • Avoid bending over. • Take antacids or other medications as prescribed. • Avoid eating right before bedtime.
Decreased gastric secretions	• Chew food thoroughly. • Eat meals on a regular schedule. • Use antacids or other medications as prescribed. • Be alert for symptoms of deficiency of nutrients, particularly iron, calcium, fat, protein, and vitamin B_{12}.
Slowed intestinal peristalsis	• Eat a high-fiber diet. • Remain as active as possible. • Increase fluid intake. • Avoid laxative use. • Eat meals at a regular time. • Drink prune juice or eat prunes every morning.
Lowered glucose tolerance	• Eat more complex carbohydrates. • Avoid sugar-rich foods.
Reduction in appetite and thirst sensation	• Offer fluids at regular intervals and at preferred temperature. • Be alert for symptoms of dehydration and electrolyte imbalance. • Offer small meals at frequent intervals.
Nutritional deficiencies related to alcohol intake	• Encourage diet high in protein and carbohydrates. • Offer small, frequent meals to maintain caloric intake. • Restrict sodium and fluids if edema is present. • Take multivitamin supplements, as prescribed.
Loss of appetite associated with depression and loneliness	• Promote mealtime as a social event. • Set an attractive table in a pleasant setting. • Eat outdoors whenever possible. • Invite guests as often as possible. • Participate in special programs for senior citizens.
Physical disability	• Open cartons and assist with setup of meal. • Arrange for home-delivered meals. • Conserve energy when preparing meals (sit on a stool, etc.). • Provide transportation and assistance to obtain food.
Low income	• Buy specials when available at food store. • Use generic brands. • Use coupons. • Cook larger quantities than necessary and freeze the leftovers for future use. • Substitute eggs, skim milk powder, and beans for meat. • Check for any community resources available to older adult.
Malnutrition	• Eat essential foods first. • Select nutrient-dense foods. • Monitor for signs of nutritional deficiencies. • Encourage eating by planning special events.
Increased risk for drug–nutrient interactions	• Avoid unnecessary drugs; monitor for polypharmacy. • Be aware of drug actions and interactions.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

- Check with pharmacist to determine if medication may or may not be taken with food.
- Assess for confusion and inability to manage medication regimen.

Recall **William Johnston**, the patient with hypertension and high cholesterol. The nurse would need to consider Mr. Johnston's lifestyle when developing a teaching plan for him. As a result of his "on-the-run" lifestyle, the nurse would need to adapt the teaching plan, making sure that it is realistic for his needs. For example, the nurse might teach Mr. Johnston about reading food labels to ensure that his selections, when he is "on the run" are low in fat and cholesterol. In addition, the nurse would also provide Mr. Johnston with appropriate suggestions for choices when dining out. Doing so will help communicate to him that the plan is workable, enhancing the chances of Mr. Johnston complying with the plan, thereby achieving success.

Include information about food safety issues in patient teaching. This includes safe handling of foods, food storage, and preventing food-borne illness. Encourage patients to wash hands and clean food contact surfaces frequently when handling and preparing foods (U.S. DHHS, 2020). Wash fruits and vegetables before eating or preparation but not meat, poultry or eggs (U.S. DHHS, 2020). This helps prevent contamination of food with bacteria and viruses. Teach patients to cook foods to a safe temperature to kill microorganisms. Also, explain that raw, cooked, and ready-to-eat foods should be separated during shopping and preparation and should be stored separately (U.S. DHHS, 2020). This prevents cross-contamination with microorganisms. Chill (refrigerate) perishable food within 2 hours and keep cold foods at 40°F or lower in the refrigerator and 0°F in the freezer to prevent the growth of pathogens. Teach patients to cook food to an internal temperature that is high enough to kill pathogens and keep foods hot (140°F or above) after cooking (U.S. DHHS, 2020). Refer patients and their family/caregivers to a Minimum Cooking Temperature reference to ensure foods are cooked to a safe temperature. The U.S. Department of Health and Human Services (2019) provides one such reference at https://www.foodsafety.gov/food-safety-charts/safe-minimum-cooking-temperature.

Monitoring Nutritional Status

Responsibilities of nurses related to monitoring the patient's nutritional status include (Anderson, 2019a; Dudek, 2022; Tappenden et al., 2013):

- Assessment/observation of food and supplement intake in relation to identified outcomes
- Documentation of appetite and initiating appropriate interventions when the patient does not eat
- Collaborating with the health care team to implement supplements if the patient's intake is low or the patient has increased nutritional requirements
- Collaborating with the health care team to initiate a nutritional consult
- Assess the patient's tolerance of the prescribed diet
- Monitor the patient's weight
- Monitor progression of nothing by mouth (NPO) status and prescribed restrictive diets
- Monitor the patient's understanding of nutritional information and engagement
- Monitor the patient's progress in meeting goals identified in the plan of care for nutrition

Nurses are often involved in the process of diet progression. The decision to advance a patient's diet is based on the return of GI function, the absence of symptoms related to a particular disease process, or the resolution of whatever prompted the dietary restriction. Often, prescribed interventions are written to begin the patient on one diet and advance to another diet as tolerated. This allows the nurse to assess the patient's tolerance of the beginning diet and change, or advance, the diet based on the assessments. Diet tolerance can be assessed by the following: absence of nausea, vomiting, and diarrhea; absence of feelings of fullness; absence of abdominal pain and distention; feelings of hunger; and the ability to consume at least 50% to 75% of the food on the meal tray. For example, a postoperative patient may have an order to begin a clear liquid at breakfast and advance to a house diet as tolerated. The patient would receive a clear liquid diet for breakfast. The nurse would assess the patient's ability to ingest the clear liquids and then make a decision regarding progression of the diet.

Stimulating Appetite

Pain, illness, anxiety, and medications can contribute to anorexia and poor intake when in a health care facility or in the home. To the hospitalized patient, food and eating may take on much greater meaning. Loss of control over food choices, the way food is prepared, when and how food is served, and eating alone may do little to encourage normal eating. Make every effort to ensure that the proper food is not only served, but also eaten. The additional time and attention spent when encouraging a person to eat may have a positive effect on dietary intake. The following measures may help to stimulate appetite in any setting:

- Serve small, frequent meals to avoid overwhelming the person with large amounts of food.
- Solicit food preferences and encourage favorite foods from home or prepared when at home, if possible.
- Provide encouragement and a pleasant eating environment.
- Be sure that any prepared food looks attractive.
- Schedule procedures and medications at times when they are least likely to interfere with appetite.
- Control pain, nausea, or depression with medications.
- Offer alternatives for items that a person cannot or will not eat.
- Encourage or provide good oral hygiene. Ensure that the patient's dentures are well-fitting and in place, if applicable.
- Remove clutter from the eating area.
- Keep eating area free from irritating odors.
- Arrange food tray so that a person can easily reach food.
- Provide a comfortable position.
- Ask about any rituals during mealtimes at home and include them if possible.
- If patients are absent from their rooms during mealtime, order a late food tray or keep food warm until they return.
- Do not disturb mealtime; don't interrupt patients for nonurgent procedures during mealtime.

Technology Alert

Health information technology (HIT) has broadened the ways by which patients can participate and engage in nutrition care, improving dietary intake and outcomes (Roberts et al., 2020). One HIT aims to improve patients' nutrition intakes by engaging patients and enabling patient participation in nutrition care while in the hospital. Patients are provided with patient education related to the importance of meeting energy/protein requirements and training on how to use the HIT, the hospital's electronic foodservice system, access via bedside computer screens. Patients also record their food intake after each meal on the bedside computer and track their intakes relative to their nutritional goals, combined with daily goal-setting sessions with a health care professional (Roberts et al., 2020).

Assisting With Eating

The loss of independence that comes with the inability to self-feed can be a severe blow to a person's self-esteem. The following measures may help a person maintain dignity while being fed:

FIGURE 37-6. Creating a relaxed, person-centered atmosphere. (*Source: Photo by Alexander Raths/Shutterstock*.)

- Involve the person as much as possible. Solicit the patient's preferences regarding the order of items eaten and the eating pace.
- Provide appropriate drinks.
- Sit at the patient's eye level and make eye contact to create a more relaxed, person-centered atmosphere (Fig. 37-

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

6).

- Engage the person in pleasant conversation to ease tension.
- Place a napkin, not a bib, over the person's clothes for protection.
- Use straws or special eating utensils whenever possible.
- Ensure that if a person wears dentures, hearing aids, or glasses, they are in place before mealtime.
- Open containers, cut meat, or apply condiments to the prepared food only if the person wishes.

When assisting visually impaired patients:

- Explain placement of foods on plates and food tray. Relating items on plate to the location on a clock face may be helpful.
- Provide special plate guards, utensils, double handles, and compartmentalized plates.
- Place foods and dishes in similar locations at each meal.
- Use straws for beverages, if not contraindicated by the presence of dysphagia.
- Provide supervision as needed.

Box 37-6 (on page 1414) outlines special considerations and interventions for feeding patients with dementia or other alterations in cognition. Box 37-7 (on page 1414) highlights nursing considerations for feeding patients with dysphagia.

Providing Oral Nutrition

A variety of oral diets are available in health care settings and may be prescribed for use at home. Oral diets may be categorized as regular, modified consistency, or therapeutic (Dudek, 2022). Regular, regular vegetarian, and modified consistency diets are outlined here. Information regarding common therapeutic diets is outlined in Table 37-3 on page 1415.

NORMAL OR HOUSE DIETS

Normal, regular, or house diets are designed to achieve or maintain optimal nutritional status by providing adequate amounts of all nutrients. The diet's actual composition and nutritional value varies with the quantity and types of food selected by the patient. No foods are excluded. Portion sizes are not limited. Regular diets are adjusted to meet age-specific needs throughout the life cycle and may also be altered to meet vegetarian, kosher, or other eating preferences for an individual patient (Dudek, 2022).

Box 37-6 Special Considerations and Interventions for Feeding Patients With Dementia or Other Alterations in Cognition

- Change the environment in which meals occur.
- Assess the area where meals are served. Create a homelike environment by preparing food close to the place where it will be served to stimulate senses.
- Observe as many former rituals as possible, such as handwashing and saying a blessing.
- Avoid clutter and limit distractions.
- Maintain a pleasant, well-lighted room. Play calming music.
- Keep food as close to its original form as possible; try "finger foods" that are easy to pick up.
- Serve meals in the same place at the same time and in the company of others.
- Provide longer and continuous facilitation at mealtimes.
- Check food temperatures to prevent accidental mouth burns.
- Assist as needed. Be alert for cues from the patient. Turning away may signal that the patient has had enough to eat or that the patient needs to slow down. Leaning forward with an open mouth usually means the patient is ready for more food.
- Stroking the underside of the chin may help promote swallowing.
- Provide one or two food items at a time. Offer small, frequent eating opportunities. A whole tray of food may be overwhelming.
- Ensure that the patient's glasses and hearing aid are working properly.
- Demonstrate what you want the patient to do. State the goal clearly, and then mimic the action with exaggerated motions.
- Provide foods and between-meal snacks that are easy to consume using the hands.
- Use adaptive feeding equipment as needed such as weighted utensils, large-handled cups, and larger or smaller silverware than standard.
- Promote family/caregiver involvement to encourage eating.

Eating performance in relation to intake of solid and liquid food in nursing home residents with dementia: A secondary behavioral analysis of mealtime videos. *International Journal of Nursing Studies*, *96*, 18–26. https://doi.org/10.1016/j.ijnurstu.2018.12.010; and Mendes, A. (2018). Optimising nutritional intake in people with dementia on hospital wards. *British Journal of Nursing*, *27*(20), 1206. https://doi.org/10.12968/bjon.2018.27.20.1206

Box 37-7 **Special Considerations and Interventions for Feeding Patients With Dysphagia**

- Provide at least a 30-minute rest period prior to mealtime. A rested person will likely have less difficulty swallowing.
- Sit the patient upright, preferably in a chair. If bedrest is mandatory, elevate the head of the bed to a 90-degree angle. Maintain upright position for 30 minutes after the meal.
- Provide mouth care immediately before meals to enhance the sense of taste.
- Avoid rushed or forced feeding.
- Provide small, frequent meals to help maximize intake.
- Adjust the rate of feeding and size of bites to the patient's tolerance. Allow patient to control the eating process if possible.
- Collaborate to obtain a speech therapy consult for swallowing evaluation.
- Initiate a nutrition consult for appropriate diet modification such as chopping, mincing, or pureeing of foods and liquid consistency (thin, nectar-thick, honeylike, spoon-thick).
- Keep in mind that some patients may find thickened liquids unpalatable and thus drink insufficient fluids.
- Reduce or eliminate distractions at mealtime so that the patient can focus attention on swallowing; discourage chatting during the meal.
- Alternate solids and liquids.
- Assess for signs of aspiration during eating: sudden appearance of severe coughing; choking; cyanosis; voice change, hoarseness, and/or gurgling after swallowing; frequent throat clearing after meals; or regurgitation through the nose or mouth.
- Inspect oral cavity for retained food.
- Avoid or minimize the use of sedatives and hypnotics since these agents may impair the cough reflex and swallowing.

VEGETARIAN DIETS

Some patients may prefer a vegetarian diet for a variety of reasons, such as religious preference, ethical belief that killing animals for food is unjust, fear of contamination with pesticides, or health concerns about the cholesterol and saturated fats found in meats. There are many different forms of vegetarianism, ranging from avoidance of red meat to complete elimination of all animal products. Meats are usually replaced with legumes, grains, and vegetables, and, if well planned, this type of diet can satisfy all nutritional requirements. Because fewer or no animal products are consumed, vegetarians consume less saturated fat, cholesterol, and animal protein and greater amounts of carbohydrates, fiber, and other important nutrients. Vitamin B_{12}, vitamin A, and iron are nutrients that may require supplementation in some vegetarian diets, but most vegetarian diets are not deficient in any nutrients. Support patients who follow a vegetarian diet by assisting them or their caregiver to select nutritious food items from the large variety of foods available within their dietary framework.

Table 37-3 **Selected Therapeutic Diets**

DIET AND DESCRIPTION	INDICATIONS
Consistent-carbohydrate diet: Total daily carbohydrate content is consistent; emphasizes general nutritional balance. Calories based on attaining and maintaining healthy weight. High-	Type 1 and type 2 diabetes, gestational diabetes, impaired glucose tolerance

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

fiber and heart-healthy fats encouraged; sodium and saturated fats are limited.	
Fat-restricted diet: Low-fat diets are intended to lower the patient's total intake of fat.	Chronic cholecystitis (inflammation of the gallbladder) to decrease gallbladder stimulation; cardiovascular disease, to help prevent atherosclerosis
High-fiber diet: Emphasis on increased intake of foods high in fiber.	Prevent or treat constipation; irritable bowel syndrome; diverticulosis
Low-fiber diet: Fiber limited to <10 g/day.	Before surgery; ulcerative colitis; diverticulitis; Crohn disease
Sodium-restricted diet: Sodium limit may be set at 500–3,000 mg/day	Hypertension; heart failure; acute and chronic renal disease, liver disease
Renal diet: Reduce workload on kidneys to delay or prevent further damage; control accumulation of uremic toxins. Protein restriction 0.6–1 g/kg/day; sodium restriction 1,000–3,000 mg/day; potassium and fluid restrictions dependent on patient situation	Nephrotic syndrome; chronic kidney disease; diabetic kidney disease

MODIFIED CONSISTENCY DIETS

Liquid diets are used most often as transitional diets when eating resumes after acute illness, surgery, or parenteral nutrition. Because clear-liquid diets are inadequate in calories, protein, and most nutrients, progression to more nutritious alternatives is recommended as soon as possible.

Full-liquid diets contain all the items on a clear-liquid diet. Additional items allowed include milk and milk drinks, puddings, custards, plain frozen desserts, pasteurized eggs, cereal gruels, vegetable juices, and milk and egg substitutes. A full-liquid diet contains liquids that can be poured at room temperature. High-calorie, high-protein supplements are recommended if a full-liquid diet is used for more than 3 days.

Mechanically altered diets are adequate in calories and nutrients and may be used on a long-term basis. Additional information regarding modified-consistency diets (modified-texture diets, texture-modified diets) can be found in Table 37-4.

Table 37-4 Modified Consistency Diets

DIET AND DESCRIPTION	INDICATIONS
Clear liquid diet: Composed only of clear fluids or foods that become fluid at body temperature. Requires minimal digestion and leaves minimal residue. Includes clear broth, coffee, tea, clear fruit juices (apple, cranberry, grape), gelatin, popsicles, commercially prepared clear liquid supplements.	Preparation for bowel surgery and lower endoscopy; acute gastrointestinal disorders; initial postoperative diet
Puréed diet: Also known as a blenderized liquid diet because the diet is made up of liquids and foods blenderized to liquid form. All foods are allowed.	After oral or facial surgery; chewing and swallowing difficulties
Mechanically altered diet: Regular diet with modifications for texture. Excludes most raw fruits and vegetables and foods with seeds, nuts, and dried fruits. Foods are chopped, ground, mashed, or soft.	Chewing and swallowing difficulties; after surgery to the head, neck, or mouth

ORAL NUTRITIONAL SUPPLEMENTS

Oral nutritional supplements (ONSs), foods rich in energy, protein, and macro- and micronutrients are used as part of the plan of care for patients who are unable to meet their nutritional requirements through oral diet alone (Ballesteros-Pomar et al., 2020). Patients whose intake of food is insufficient to meet their requirements, such as patients who are unable or unwilling to eat, or whose nutritional needs are so great that a normal volume of food is insufficient, are often prescribed ONS (Dudek, 2022). ONSs are also indicated as a primary intervention for patients identified at risk of malnutrition (Anderson, 2019a; Holdoway & Anderson, 2019). ONSs are available in a wide range of styles, including clear liquids, milk/dairy-based drinks, specially prepared foods (puddings, yogurts, shakes, gelatins, nutrition bars), and powders (Dudek, 2022; Holdoway & Anderson, 2019). Patient preferences should be considered when implementing the use of ONSs, and education about the benefits of use should be reinforced to enhance patient understanding and engagement (Dudek, 2022).

NOTHING BY MOUTH

Patients may be prescribed nothing by mouth (**NPO**) for a period of time prior to surgery or before certain diagnostic tests. NPO may also be necessary for patients experiencing severe nausea and vomiting, an inability to chew or swallow, or various acute or chronic GI abnormalities; for those who are comatose; and for women during labor and delivery.

The following measures may provide comfort to patients who are ordered NPO:

- Encourage or provide good oral hygiene.
- Provide the patient with ice chips or sips of water as allowed.
- Urge the patient to avoid watching others eat. Suggest alternate activities at mealtimes.

Well-nourished patients can easily withstand the stress of NPO for a short period, but being NPO for an extended period of time poses a nutritional challenge for many people. Patients who will be NPO for more than 48 to 72 hours may require nutritional support from enteral nutrition (EN) or parenteral nutrition (PN), depending on individual circumstances (Delgado, 2018; Jordan & Moore, 2019). These therapies are discussed in the following sections.

Providing Enteral Nutrition

Oral feeding is the preferred and most effective method of feeding patients. However, at times, a patient may be unable to meet their nutritional needs through oral intake of an adequate diet. In this circumstance, an alternate feeding method may be necessary. Placement of an enteral feeding tube into the stomach (gastric) or small intestine (jejunum) to provide a formula containing adequate nutrients may be appropriate; enteral nutrition is the preferred method of feeding after the oral route for patients who have at least a partially functional GI tract (Dudek, 2022; Hartwell et al., 2018; Pars & Çavuşoğlu, 2019). Enteral nutrition (EN) may be used to supplement an oral diet or provide the only source of nutrition (Dudek, 2022).

Gastric feedings have the advantage of allowing the stomach to be used as a natural reservoir, regulating the amount of foods and liquids released into the small intestine. This alternate feeding method may deliver total or supplemental nutrition over a short-term period or for longer intervals. EN is contraindicated when the GI tract is nonfunctional, in severe short bowel syndrome, intractable vomiting and/or diarrhea, GI ischemia, bowel obstruction, peritonitis, and paralytic ileus (Dudek, 2022). Consider factors related to selection of a feeding tube, including aspiration risk, the anticipated duration of the feeding tube, the function of the GI tract, and the patient's overall condition and prognosis. Also, it is important to consider the ethical implications surrounding initiation of tube feedings, which entail knowledge of the patient's wishes concerning this intervention.

The decision to place, maintain, and/or discontinue feeding tubes can be a source of much turmoil in the lives of patients and their families (Hartwell et al., 2018). There are many emotional, physical, psychological, cultural, and quality-of-life aspects to the institution, maintenance, and withdrawal of nutrition (Bischoff et al., 2020). Nurses can be a source of great support and information to aid patients and their families in making nutrition-related health care decisions.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

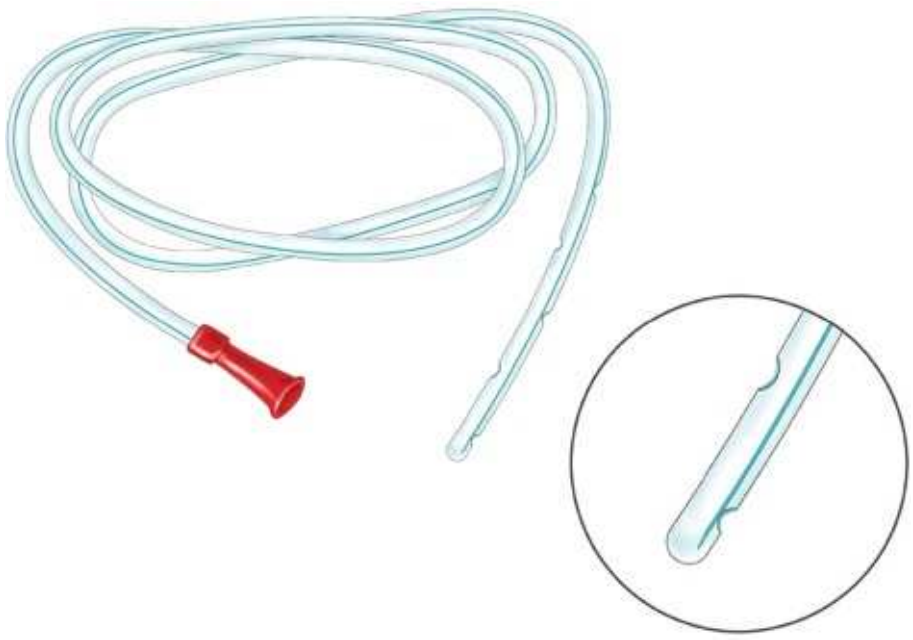

FIGURE 37-7. Levin tube.

SHORT-TERM NUTRITIONAL SUPPORT

For short-term use (<4 weeks [Bischoff et al., 2020; Dudek, 2022]), a nasogastric or nasointestinal route may be selected. A **nasogastric (NG) tube** is inserted through the nose and into the stomach. However, the patient is at risk for aspirating the tube feeding solution into the lungs, a disadvantage for using this route.

FIGURE 37-8. Dobbhoff tube.

Nasogastric tubes may be firm and large in diameter. One example is a Levin tube. A Levin tube is a flexible rubber or plastic single-lumen tube with holes at the stomach end and a connector at the opposing end (Fig. 37-7). The connector allows for attachment to a feeding apparatus and medication administration. These tubes are fairly inflexible and are associated with patient discomfort (Anderson, 2018a). Smaller, softer, more pliable polyurethane tubes may also be inserted via the nose into the stomach or small intestine. This type of tube is advantageous, providing greater patient comfort and less trauma to the nares (Anderson, 2018a). A Dobbhoff tube is an example of this type of tube (Fig. 37-8). However, the smaller tube diameter makes checking tube placement and medication administration more difficult than with the larger-diameter tubes. The methods of inserting and removing a nasogastric tube are described in Skills 39-2 on pages 1560–1565 and 39-3 on pages 1566–1568.

Less commonly, a **nasointestinal (NI) tube** is passed through the nose and into the upper portion of the small intestine (nasoduodenal and nasojejunal). NI may be indicated for a patient with high risk for aspiration or who have shown intolerance to gastric EN (Bischoff et al., 2020; McClave, Taylor, et al., 2016). Some health conditions (e.g., delayed gastroduodenal motility, gastric outlet stenosis) also necessitate the use of a nasointestinal tube (Bischoff et al., 2020; Turner et al., 2020).

CONFIRMATION OF NASOGASTRIC FEEDING TUBE PLACEMENT

Verify correct placement of the nasogastric tube after the initial insertion, before beginning a feeding or instilling medications or liquids, and at regular intervals during continuous feedings. This decreases the risk that the tip of the tube is situated in the stomach or intestine, preventing inadvertent administration of substances into the wrong place. A misplaced feeding tube in the lungs or pulmonary tissue places the patient at risk for aspiration, pneumonia, and even death (Lamont et al., 2011, as cited in Anderson, 2018a). Radiographic examination, measurement of tube length and measurement of tube marking, measurement of aspirate pH, and monitoring of carbon dioxide have been suggested to confirm feeding tube placement (Anderson, 2018a; Irving et al., 2018; Methany et al., 2019). The use of two or more of these techniques in conjunction with each other increases the likelihood of correct tube placement

(AACN, 2020; Anderson, 2019b; Anderson, 2018a; Dias et al., 2019; Rahimi et al., 2015). An old technique of auscultation of air injected into a feeding tube has been proved unreliable and is not suggested for use (AACN, 2020; Anderson, 2018a; Boeykens et al., 2014; Boullata et al., 2017; Irving et al., 2018; Metheny et al., 2019). Recommendations for use of visual inspection of gastric aspirate are conflicting; this method should be used cautiously if part of policy and procedure guidelines and with consideration to the potential for inaccuracy (AACN, 2020; Dias et al., 2019; Mak & Tam, 2020; Metheny et al., 2019).

When bedside methods to check placement suggest the tube has been displaced, a radiograph should be requested to determine the tube's location (AACN, 2020).

Technology Alert

The use of ultrasound has been suggested to verify correct positioning of gastric tubes as an alternative for radiologic examination. This visualization technique has shown promise in aiding in confirmation of correct placement of gastric tubes in newborns, pediatric and adult patients, in both inpatient and outpatient settings (Atalay et al., 2016; Dias et al., 2019 ; Mak & Tam, 2020; Tsujimoto et al., 2017). The use of ultrasound to provide accurate imaging of nasogastric tube position and avoid the use of x-ray holds potential to complement other means of verification of placement as well as provide critical information where x-rays are not readily available (Mak & Tam, 2020).

Radiographic Examination

Radiographic examination (x-ray) is the standard procedure to verify initial placement of a feeding tube as it allows the visualization of the entire course and the location of the tip of the tube (AACN, 2020; Boullata et al., 2017; Mueller et al., 2011). However, radiographs expose the patient to radiation, must be interpreted by a radiologist, are costly if done on a routine basis, and may be inaccessible. A radiograph only confirms the position of the tube at the time it was taken. The tube may have moved at any point thereafter. Also, as previously stated, placement must be checked frequently while the tube is in place, and repeated, frequent radiographs are not practical (Boullata et al., 2017). Routine chest and abdominal radiography reports can be reviewed to determine if the radiologist has referred to feeding tube location as part of monitoring tube location (AACN, 2020).

Measurement of Tube Length and Verification of Tube Marking

Another way to verify tube placement is to measure the length of the exposed tube after insertion and document this measurement (AACN, 2020; Dias et al., 2019). Once placement has been confirmed by initial radiograph, mark the exit site of the feeding tube with an indelible marker at the nostril or note the centimeter marking on the tube (AACN, 2020; Irving et al., 2018; Judd, 2020). Observe for a change in the external tube length at regular intervals and before use (AACN, 2020). Any change in the length of the exposed tube may indicate dislodgement (AACN, 2020; Boullata et al., 2017). If a significant change in the external length is observed, use other bedside tests to help determine if the tube has become dislocated (Best, 2013; Boullata et al., 2017). If placement is in doubt, a radiograph should be obtained to verify tube placement (AACN, 2020; Boullata et al., 2017).

Assessment of Aspirate pH

Testing of the pH of gastric secretions aspirated from the tube is recommended to verify gastric tube placement (AACN, 2020; Dias et al., 2019; Irving et al., 2018; Metheny et al., 2019). Fasting gastric pH is usually 5 or less, even in patients receiving gastric-acid inhibitors (AACN, 2020). The pH of feeding tube aspirates is likely to approach fasting levels if nutritional feedings have been off for at least 1 hour (AACN, 2020; Irving et al., 2018). However, when continuous feedings are in use, pH may become less helpful, because the nutritional formula may buffer the pH of GI secretions (Judd, 2020). Refer to Guidelines for Nursing Care 37-1 (on page 1418). Gastric pH ≥6 is of no benefit in predicting tube location in the GI tract or in ruling out tracheopulmonary placement (Boullata et al., 2017).

Use of pH test strips calibrated in units of 0.5 and approved for use with human secretions should be used to ensure accuracy (Anderson, 2018; Metheny et al., 2019). There is considerable variation in the evidence guidelines related to the pH values to distinguish between gastric and respiratory aspirates (Metheny et al., 2019). The lower the pH, obviously, the stronger the evidence for placement in the stomach and not the respiratory tract (Metheny et al., 2019). Suggested limits for a safe range to identify gastric secretions vary from pHs of ≤4.0, ≤5.0, and ≤5.5 and a pH of ≥6.0 for respiratory secretions (AACN, 2020; Dias et al., 2019; Metheny et al., 2019). Nurses should be certain to follow facility policy, procedure, and practice guidelines. If placement is in doubt, a radiograph should be obtained to verify tube placement (AACN, 2020; Boullata et al., 2017).

▶ Guidelines for Nursing Care 37-1

Assessment and pH Measurement of Gastric Contents

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

Allow 1-hour interval after patient has received medication or completed an intermittent feeding before testing pH of gastric fluid. Feedings should never be interrupted solely for the purpose of pH testing; however, if a feeding is interrupted as part of preparation for a test or procedure, testing of the pH may be desired.

- Assemble supplies, and provide for privacy. Use of pH test strips calibrated in units of 0.5 and approved for use with human secretions should be used to ensure accuracy.
-  Explain the procedure to the patient, perform hand hygiene, and put on disposable gloves.
- Attach the syringe to the end of the tube and aspirate a small amount (5 to 10 mL) of gastric secretions.
- If unable to obtain specimen, reposition the patient and flush tube with an air bolus, then apply negative pressure to the plunger. It may be necessary to retry several times.
- Place a drop of gastric secretions onto pH test strip or place small amount in plastic cup and dip pH test strip into it. Within 30 seconds, compare color on test strip with chart supplied by the manufacturer.
- Document results on the patient's flow sheet. The following are indications of placement:

pH

- Stomach: Suggested limits for a safe range are from pH of ≤4.0, ≤5.0, and ≤5.5
- Intestines: pH 7.0 or higher
- Respiratory tract: pH of ≥6.0

This method will not effectively differentiate between intestinal fluid and pleural fluid.

Initial and ongoing verification of feeding tube placement in adults. https://www.aacn.org/; Anderson, L. (2018). Fine-bore nasogastric tube feeding: Reducing the risks. *British Journal of Nursing*, *27*(12), 674–675. https://doi.org/10.12968/bjon.2018.27.12.674; Dias, F. S. B., Almeida, B. P., Alvares, B. R., Jales, R. M., Caldas, J. P. S., & Carmona, E. V. (2019). Use of pH reagent strips to verify gastric tube placement in newborns. *Revista Latino-Americana de Enfermagem*, *27*, e3227. https://doi.org/10.1590/1518-8345.3150.3227; Metheny, N. A., Krieger, M. M., Healey, F., & Meert, K. L. (2019). A review of guidelines to distinguish between gastric and pulmonary placement of nasogastric tubes. *Heart & Lung*, *48*(3), 226–235. https://doi.org/10.1016/j.hrtlng.2019.01.003

Aspiration of fluid through the feeding tubes is sometimes difficult, especially if a smaller diameter tube is used. Because they are less rigid, they may be more likely to collapse when negative pressure is applied during aspiration. More than likely, the difficulty is a result of a blocked tube. In addition, the ports on the tip of the tube may not be positioned in fluid. Several attempts may be necessary to aspirate gastric contents. Inject air boluses into the tube with a large syringe and slowly apply negative pressure to withdraw fluid (AACN, 2020; Metheny et al., 2019). If repeated instillations of air and repositioning prove ineffective and placement is in doubt, a radiograph should be obtained to verify tube placement (AACN, 2020; Boullata et al., 2017).

Carbon Dioxide Monitoring

Monitoring for carbon dioxide to determine nasogastric tube position and/or dislodgement involves the use of a colorimetric end-tidal CO_2 detector to detect the presence of carbon dioxide, which would indicate tube positioning in the patient's airway (Hess et al., 2021). Monitoring for carbon dioxide may be helpful to detect placement of a feeding tube in the tracheobronchial tree (AACN, 2020; Boullata et al., 2017; Hess et al., 2021). However, inaccuracies are possible (Metheny et al., 2019). Carbon dioxide may be detected when the tube is in the mouth and not in the airway and carbon dioxide may not be detected when the tube is in the airway if the ports in the tube are occluded (Gilbert & Burns, 2010, as cited in AACN, 2020). A carbon dioxide sensor cannot determine where a feeding tube's tip ends in the GI tract (esophagus, stomach, or small bowel).

Confirming Nasointestinal Tube Placement

After an initial x-ray for placement, the nurse can validate that the tube is still in the small intestine by checking the pH of the aspirate (pH ≥ 6) and observing the aspirate appearance. During fasting, gastric fluid is typically clear and colorless or grassy green; small-bowel secretions are typically bile-stained, ranging in color from light to golden yellow or brownish green (Metheny et al., 1994, as cited in AACN, 2020). Refer to Guidelines for Nursing Care 37-1.

LONG-TERM NUTRITIONAL SUPPORT

When enteral feeding is required for a longer period (at least 4 to 6 weeks) (Bishcoff et al., 2020), an enterostomal tube may be placed through an opening created into the stomach (**gastrostomy**) or into the jejunum (jejunostomy) (Bischoff et al., 2020; Roveron et al., 2018; Shellnutt, 2019). A gastrostomy may be used for patients who have

impaired chewing and swallowing related to neurologic diseases (stroke, multiple sclerosis) or obstruction of the upper respiratory and/or digestive tract, as in head and neck cancers; patients with oncologic health problems associated with malnutrition; and patients with other health issues that lead to malnutrition, such as chronic renal failure, cystic fibrosis, or Crohn disease (Anderson, 2018b; Pars & Çavuşoğlu, 2019). Placement of a tube into the stomach can be accomplished by a surgeon or gastroenterologist via a **percutaneous endoscopic gastrostomy (PEG)**, a surgically (open or laparoscopically) placed **gastrostomy tube**, or gastrostomy placed via interventional radiologic methods (Anderson, 2019b; Roveron et al., 2018). Use of a PEG tube or other type of gastrostomy tube requires an intact, functional GI tract.

The use of a PEG tube is the preferred and most common method of gastrostomy tube insertion for long-term enteral nutrition (Bischoff et al., 2020; Pars & Çavuşoğlu, 2019; Shellnutt, 2019). Unlike a traditional, surgically placed gastrostomy tube, placement of a PEG usually does not require general anesthesia and has lower rate of major complications, such as blocking and dislodgement (Bischoff et al., 2020; Pars & Çavuşoğlu, 2019). Insertion of a PEG tube involves local anesthesia, sedation, passage of an endoscope into the stomach, a small incision or stab wound through the skin of the abdomen, pushing a cannula through the small incision, insertion of a guide wire or suture material through the cannula, and introduction and placement of the PEG tube through one of several methods. PEG tubes are held in place with an internal retention device (bumper or water-filled balloon) which holds it in place in the stomach and an external device (disc) that sits close to the abdominal surface (Anderson, 2019b; Roveron et al., 2018). Figure 37-9 illustrates a PEG tube in place in the stomach.

In long-term feeding situations in which gastric problems exist, the jejunostomy is an alternate method through which nutrition can be delivered. The small bowel may also be used for feeding for patients at high risk for aspiration (McClave, Taylor, et al., 2016). These tubes may be inserted surgically or with endoscopic or laparoscopic guidance. Figure 37-10 illustrates a PEG/J tube in the jejunum. Gastrostomy and jejunostomy tubes are not easily displaced or dislocated (Pars & Çavuşoğlu, 2019).

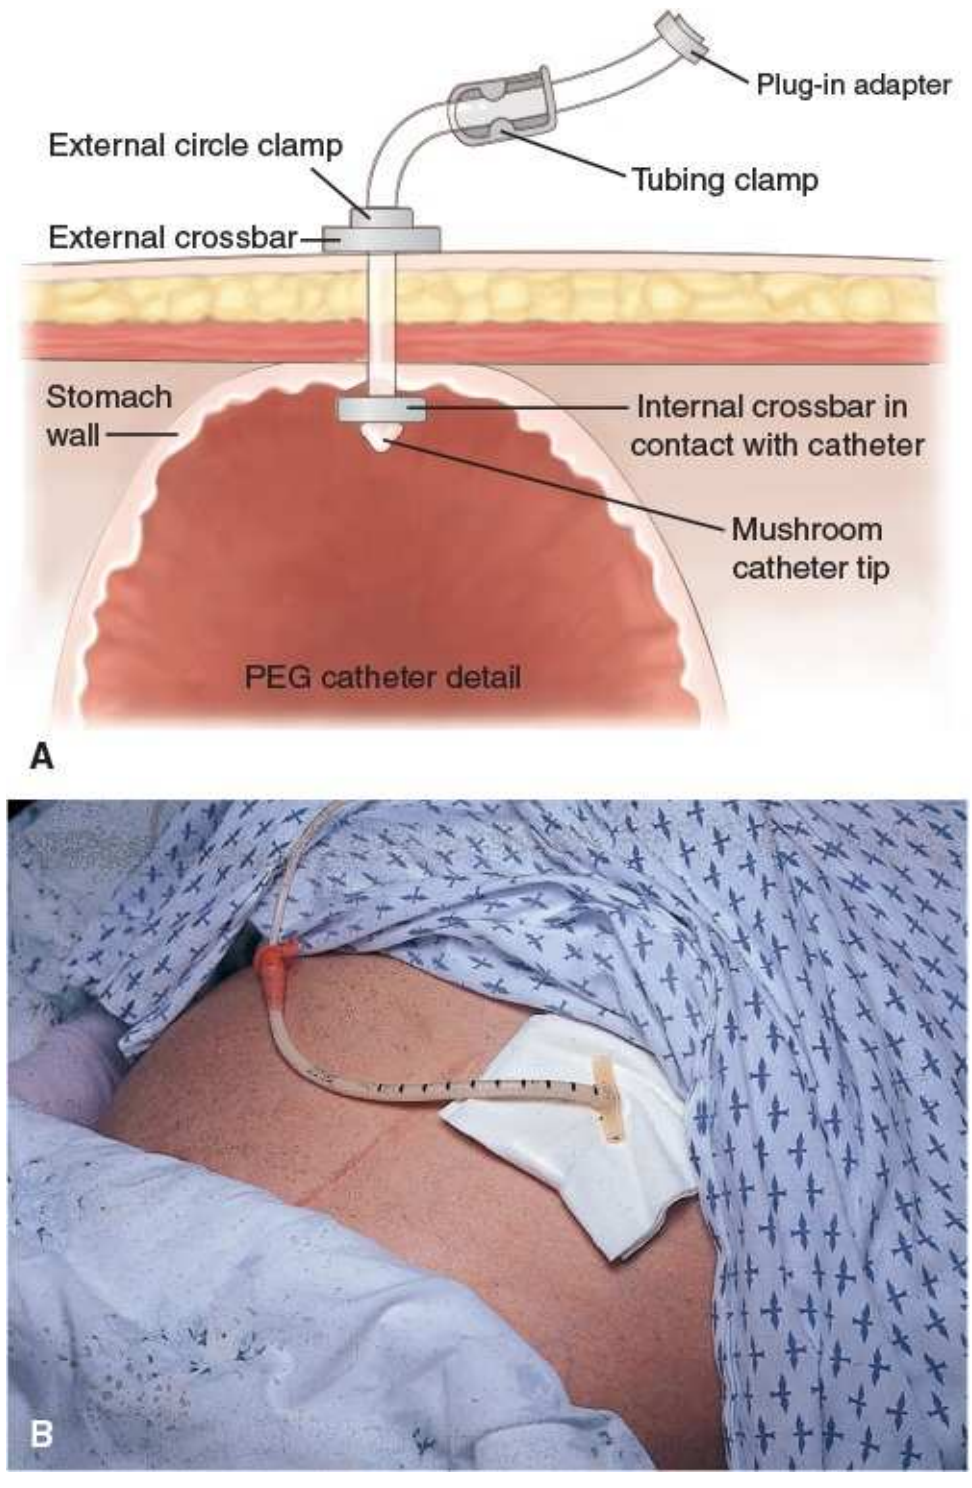

FIGURE 37-9. **A.** Percutaneous endoscopic gastrostomy tube in place in the stomach. **B.** Percutaneous endoscopic gastrostomy exiting the patient's abdomen.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

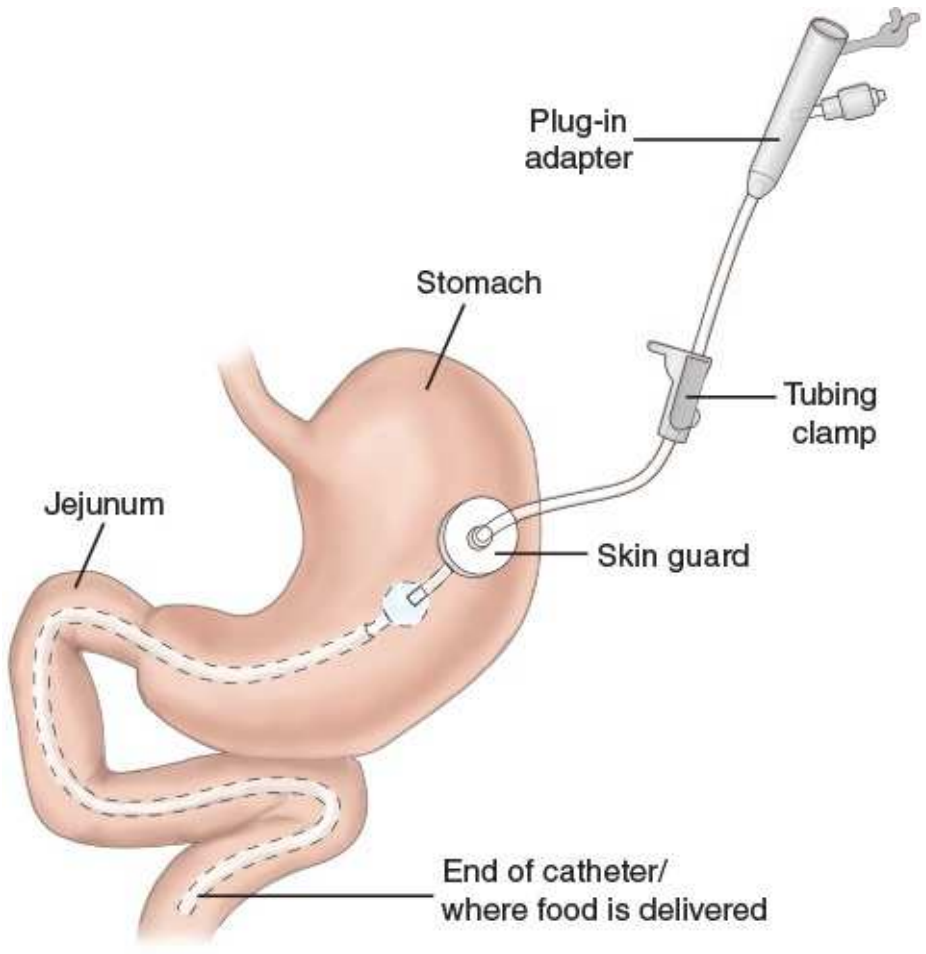

FIGURE 37-10. PEG/J tube inserted in the jejunum.

For patients who are active yet require long-term continuous or intermittent feedings, a low-profile gastrostomy device (LPGD) may be an option (Fig. 37-11 on page 1420). Children are also candidates for LPGDs (Abdelhadi et al., 2020). The external apparatus is minimal and consists of a button or skin disk that is stable, less irritating to the skin, and has no external tubing, making it easier to conceal with clothing (Kyle & Carman, 2021). Additional advantages include that it can be immersed in water, is less noticeable, and is less likely to migrate or become dislodged. The device has a cap, which is opened to access the feeding tube and connect with special connection tubing and an administration set.

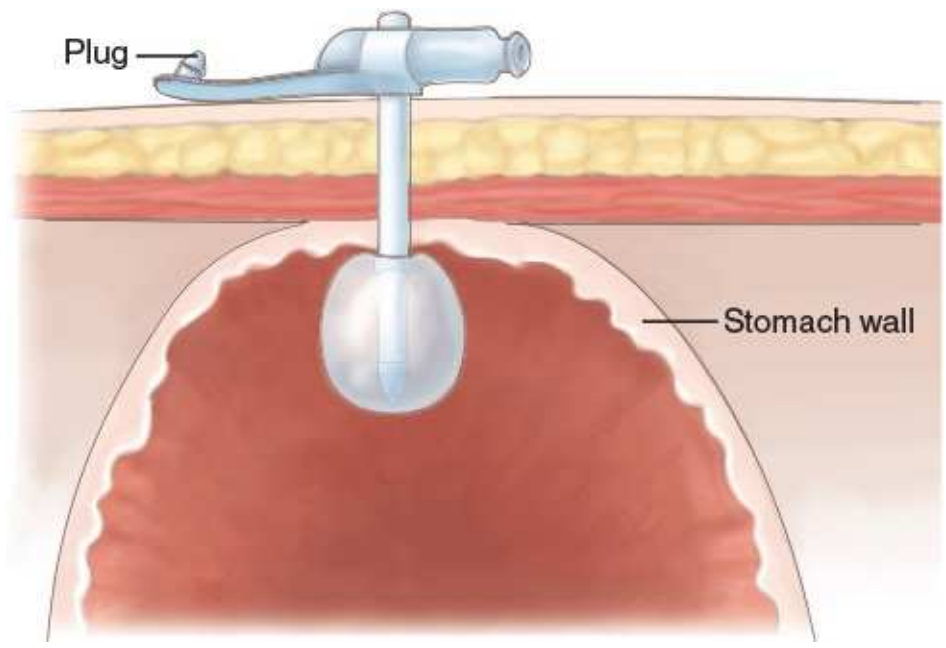

FIGURE 37-11. Low-profile gastrostomy device (LPGD).

Checking placement of a gastrostomy or jejunostomy tube requires regular comparisons (according to facility policy) of the tube length to the measurement (inches or centimeters) that was documented after placement and status of the external fixation disc (Roveron et al., 2018). An indelible marker can be used to identify the exit point of the tube from the abdominal wall.

ADMINISTRATION OF ENTERAL NUTRITION

Feeding Schedule

Based on the patient's physical, health, and nutritional condition, the nutritionist usually makes recommendations concerning the feeding pattern or schedule, with the intent to deliver a caloric and/or protein goal from enteral nutrition (Anderson, 2018b; Jordan & Moore, 2020). Enteral feeding and medication administration can be initiated using an NGT after insertion once placement is confirmed through radiographic imaging and interpretation by a radiologist (AACN, 2020; Boullata et al., 2017; Bischoff et al., 2020; Mueller et al., 2011). Use of a gastrostomy tube

for enteral feeding and medication administration can be initiated within 4 hours after the procedure (Bischoff et al., 2020; Roveron et al., 2018).

Enteral feedings are administered by bolus, intermittent continuous, or continuous infusion (Anderson, 2018b; Bischoff et al., 2020). Bolus formula administration involves administering a 200- to 400-mL volume over a 15- to 60-minute period, depending on patient tolerance, using a 50-mL syringe (no feeding pump) (Bischoff et al., 2020). The total feed volume is divided into four to six feedings throughout the day (Bischoff et al., 2020). Intermittent continuous feeding is the administration of nutritional formula and fluids by giving a volume of formula over a period of time at regular intervals using a feeding pump (Anderson, 2018b; Bischoff et al., 2020). Continuous feeding is the administration of a small volume of formula over a longer period of time, for as much as 12, 18, or 24 hours. Use of a feeding pump delivers nutritional formula and fluid at a set rate over a specified period of time (Anderson, 2018b).

Volume-based feeding protocols in which 24-hour or daily volumes are targeted instead of hourly rates have been shown to increase volume of nutrition delivered (Heyland et al., 2013, as cited in McClave, Taylor, et al., 2016). This type of method empowers nurses to increase feeding rates to make up for volume lost for scheduled and unscheduled interruptions or while enteral nutrition is held and increase attainment of nutritional goals, supporting optimal nutritional intake (Kinikin et al., 2020; McClave, Taylor, et al., 2016). Feedings into the intestine are always continuous and include initiation at a lower rate with a gradual increase in the rate until the target rate identified to meet nutritional goals is met (Bischoff et al., 2020).

For some patients, a combination of methods, such as overnight continuous feeding and bolus feeding during the day best meets their needs and allows for autonomy and lifestyle preferences (Bischoff et al., 2020). For other patients, cyclic feeding may be implemented. This involves administering continuous feeding for a portion of the 24-hour period. The usual routine is to feed the patient for 12 to 16 hours, most often overnight. Cyclic feeding allows the patient to attempt eating regular meals during the day, if this is possible, making ambulation and activity easier. Skill 37-1 on pages 1428–1433 describes the steps used to administer nutrition via a feeding tube.

Enteral Feeding Formulas

Many enteral feeding formulas are available. The nutritional composition of tube feedings depends on the feeding route, the patient's ability to digest and absorb nutrients, and the patient's nutrient and fluid requirements. Other considerations include the availability and cost of the formula, health conditions that require diet modifications, food intolerance, and allergies. Standard formulas contain intact molecules of protein, carbohydrates, and fats, requiring the patient to have normal digestion and absorption. Hydrolyzed formulas contain proteins and other nutrients in simple forms that require little or no digestion. These formulas are used with patients with impaired digestion or absorption. In addition to being nutritionally balanced, formulas may be high in calories; contain fiber; contain additional protein; or be especially formulated for patients with respiratory, renal, or other health problems. Modified enteral formulas are available with lower sugar content and slowly digestible carbohydrates for use by patients with diabetes (Bischoff et al., 2020). Detailed information about their composition and caloric value can be obtained from the product label.

Feedings are initiated at full strength. The previous practice of diluting feedings has not been shown to improve feeding tolerance and prolongs the period of inadequate nutrition support (Bischoff et al., 2020; Dudek, 2022). The rate of infusion begins at the recommended rate, based on guidelines from the dietician or nutrition nurse specialist, and the rate is advanced in increments until the desired rate is achieved (Anderson, 2018b); feeding should be advanced to goal within 48 to 72 hours of initiation (McClave, DiBaise, et al., 2016). Rate advancement is based on patient tolerance. Refer to the discussion Monitoring for Tolerance of Enteral Nutrition on page 1421.

Enteral Feeding Pumps

An enteral feeding pump regulates the amount of feeding solution that is delivered to the patient. A pump should be used when slow rates of enteral formula are required (Boullata et al., 2017; Bischoff et al., 2020). The newer pumps are user friendly, have built-in safeguards that protect the patient from complications, and can be used in both institutions and the home. Safety features include automatic tube flush, cassettes that prevent free flow of formula, safety tips that prevent accidental attachment to an IV setup, and various audible and visible alarms. Most pumps can operate for up to 8 hours on battery. However, manufacturers often recommend using the pump plugged into an electrical outlet for recharging whenever the patient is seated or resting for a period of time. Feeding pumps are also available for mobile use for community-based EN, attaching to a wheelchair or fitting in a specially designed backpack, for example (Bischoff et al., 2020).

NURSING CONSIDERATIONS FOR ENTERAL FEEDING

Nursing actions that contribute to successful enteral tube feedings focus on monitoring patient tolerance of EN, patient safety, monitoring for complications, comfort, and education. Implementation of evidence-based practice guidelines related to these actions provides a means to improve nutritional outcomes.

Monitoring for Tolerance of Enteral Nutrition

Patient tolerance of the volume and type of formula must be monitored daily (Boullata et al., 2017; McClave, Taylor,

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

et al., 2016). Criteria to consider when evaluating patient feeding tolerance include:

- Absence of nausea, vomiting
- Absence of diarrhea and constipation
- Absence of abdominal pain and feelings of fullness
  - Absence of distention
- Presence of bowel sounds within normal limits
  - Achievement of target goal nutrition administration

Evidence related to definition, measurement, monitoring, and management of **gastric residual volume** (feeding remaining in the stomach; GRV) varies. GRV has been used to monitor for tolerance of EN; however, there is little support for this intervention as routine measurement for most patients and is not considered best practice and should not be used as part of routine care to monitor EN (McClave, Taylor, et al., 2016; Ozen et al., 2018; Parker et al., 2019; Pars & Çavuşoğlu, 2019; Rysavy et al., 2020). GRV is not a suitable parameter to determine feeding intolerance (McClave, Taylor, et al., 2016; Pars & Çavuşoğlu, 2019). GRV has been shown to be a poor marker of true gastric volume, gastric emptying, risk of aspiration, pneumonia, and poor outcomes (Hartwell et al., 2018; McClave, DiBaise, et al., 2016). The use of GRVs as a monitor for tolerance increases the risk of tube clogging and decreases attainment of nutritional goals as a result of disruption of delivery of EN (McClave, DiBaise, et al., 2016). Some evidence for practice suggests measurement of GRV may only be necessary during EN initiation and advancement (Roveron et al., 2018; Singer et al., 2019).

If GRV checks are part of facility policy and procedure, automatic cessation of EN should be avoided for GRVs < 500 mL in the absence of other signs of intolerance (Boullata et al., 2017; McClave, Taylor, et al., 2016; Roveron et al., 2018). Evaluate the significance of a single high gastric residual volume in relation to other indicators of GI intolerance, including abdominal distention, abdominal discomfort, nausea, and vomiting (AACN, 2018). Tolerance to gastric feeding can be improved through the use of a prokinetic agent, continuous infusion, and elevation of the head of the bed (McClave, Taylor, et al., 2016).

Promoting Patient Safety

To promote patient safety when administering a tube feeding, be sure to include the following interventions as part of patient care:

- Check tube placement before administering any fluids, medications, or feeding, using multiple techniques: x-ray, external length, external verification marking, pH testing (refer to Guidelines for Nursing Care 37-1, page 1418), and carbon dioxide monitoring. Consistent inability to withdraw fluid from tube may indicate displacement of the tube from the stomach into the esophagus (AACN, 2020).
  - Assess for signs of respiratory distress; coughing, choking, dyspnea may occur when a tube is inadvertently positioned in the airway (AACN, 2020).
- Feeding tubes are prone to blockage, due to protein-rich formula solutions, the viscosity of the feeding formulas, and relatively small diameter of the feeding tube lumens, the use of the tubes for medication administration, and inadequate water flushes (Bischoff et al., 2020; Drummond Hayes & Hayes, 2018). Feeding tubes should be flushed with at least 30 mL of water before starting and after completion of bolus feedings; every 4 to 8 hours during continuous feeding (Bischoff et al., 2020; Boullata et al., 2017; Roveron et al., 2018); and before and after medication administration (Drummond Hayes & Hayes, 2018), based on the patient's fluid needs and restrictions (Boullata et al., 2017).
- Sterile water should be used for tube flushes in immunocompromised or critically ill patients, and for reconstituting powdered enteral formula (Allen, 2015; Boullata et al., 2017).
- Assess the abdomen for abnormalities. Assess for bowel sounds at least once per shift to check for the presence of peristalsis and a functional intestinal tract. Experts, however, have recently concluded that it is common for acutely ill patients to have delayed gastric emptying; therefore, delaying enteral feedings based on hypoactive bowel sounds may place a patient at risk for malnutrition (McClave, Taylor, et al., 2016; McClave, DiBaise, et al., 2016). Gastric distention, abdominal girth, nausea, vomiting, bloating, or pain are better indicators of how well a patient is tolerating a tube feeding (Bischoff et al., 2020; McClave, Taylor, et al., 2016; Pars & Çavuşoğlu, 2019).
- Make sure the patient is as upright as possible during feeding. Keep the head of the bed elevated at 30 to 45 degrees at all times during administration of enteral feedings and for 1 hour afterward to prevent reflux, aspiration, and pneumonia, unless contraindicated (McClave, Taylor, et al., 2016; Roveron et al., 2018). Patients for whom semi-recumbent position is contraindicated or who cannot tolerate a semi-Fowler position should be placed in a reverse- or anti-Trendelenburg position (Boullata et al., 2017; Roveron et al., 2018). Exceptions to upright supine positioning during feeding are necessary at times. Patients with pulmonary disease who are acutely ill, such as those with acute respiratory distress syndrome (ARDS) or COVID-19-related respiratory failure/ARDS, may be positioned in the prone position on a regular basis to promote improved oxygenation (Guttendorf, 2021; Morata et al., 2021; Siegmeister et al., 2021; Venus et al., 2020). Enteral nutrition during prone positioning is recommended to meet the nutritional needs of the critically ill patient (Behrens et al., 2021; Bruni et al., 2020; Savio et al., 2021).

Limited evidence suggests that administration of enteral nutrition while the patient is prone is not associated with substantial increase in complications compared to enteral nutrition administered in a supine position (Boullata et al., 2017; Bruni et al., 2020). Elevation of the head of the bed at 10 to 25 degrees (reverse Trendelenburg) is suggested (Behrens et al., 2021; Boullata et al., 2017; Powers, 2021). Closely monitor abdominal and bowel status at least every 4 hours for feeding tolerance and GI motility status (Boullata et al., 2017; Powers, 2021). Refer to the Research in Nursing display for a discussion of evidence related to enteral feeding in the prone position.

- There is no benefit from stopping feedings during short periods of lowering of the head of the bed (Boullata et al., 2017). If a prolonged procedure will require lowering of the head of the bed, feedings should be stopped during this period; feedings should be promptly restarted when the procedure is ended or as feasible.

Research in Nursing

Bridging the Gap to Evidence-Based Practice

Enteral Feeding in the Prone Position

Integration of evidence-based practice interventions is an important aspect of the provision of effective nursing care. Early enteral nutrition (Behrens et al., 2021; Bruni et al., 2020; Savio et al., 2021) and prone positioning (Guttendorf, 2021; Morata et al., 2021; Venus et al., 2020) may both improve outcomes for patients with pulmonary disease who are acutely ill (Bruni et al., 2020). Is enteral nutrition administration in the prone position safe? Is there increased concern for enteral nutrition intolerance, such as high residual gastric volume, regurgitation, and/or vomiting, during pronation?

Related Research

Bruni, A., Garofalo, E., Grande, L., Auletta, G., Cubello, D., Greco, M., Lombardo, N., Garieri, P., Papaleo, A., Doldo, P., Spagnuolo, R., & Longhini, F. (2020). Nursing issues in enteral nutrition during prone position in critically ill patients: A systematic review of the literature. *Intensive & Critical Care Nursing*, *60*, 102899. https://doi.org/10.1016/j.iccn.2020.102899

The purpose of this systematic review was to assess the occurrence of high residual gastric volume, regurgitation or vomiting in patients receiving enteral nutrition (EN) during pronation. Three databases, MEDLINE, EMBASE, and CINAHL, were searched using keywords and related MeSH terms, from inception until November 19, 2019. All relevant studies enrolling adult patients receiving mechanical ventilation and evaluating early EN during prone positioning were included; case reports or series, literature reviews, systematic reviews, and meta-analyses were excluded. Outcomes investigated included residual gastric volume, EN feeding volume, the need to discontinue EN, rate of episodes of vomiting or regurgitation, rate of ventilator-associated pneumonia (VAP) or secondary infections, ICU and hospital length of stay, and mortality. The search of the databases yielded 111 reports. Fifteen duplicate reports and 89 citations were excluded as a result of the initial screening. One of the remaining 7 reports was excluded as it was a narrative review. Six studies were included in the systematic review. Five of the 6 studies reported no differences with respect to gastric residual volume between supine and prone positioning. Results suggested that administration of EN over 24 hours instead of 18 hours resulted in greater tolerance. The need to hold/stop EN administration and vomiting episodes were higher during prone positioning, with similar rates of high gastric volume between supine and prone positions. The incidence of VAP, length of stay, and mortality were similar between supine and prone positions. One study reported lower mortality in patients receiving EN over 24 hours as compared to an 18-hour administration period. The researchers concluded protocols should be initiated and followed by health care providers to increase the enteral feeding volume, while avoiding EN intolerance. Nurses must be aware of the risk for regurgitation and vomiting during EN in the prone position and closely monitor enteral feeding. The researchers also suggested that, given the limited available evidence, randomized controlled trials are needed to assess if administration of early EN during prone positioning influences major clinical outcomes.

Relevance to Nursing Practice

Adherence to evidence-based guidelines for enteral nutrition contributes to improved nutrition outcomes. Nursing adherence to these guidelines is instrumental in attaining improved patient outcomes. Nurses and facilities should identify best-practice guidelines and incorporate interventions to improve knowledge of and adherence to these guidelines to improve patient outcomes.

- Prevent contamination during enteral feedings by maintaining the integrity of the feeding system and using proper technique. Closed systems, consisting of a sterile, prefilled, ready-to-hang container, reduce the opportunity for bacterial contamination of the feeding formula. An open system exists when formula from a can or bottle is added to a feeding setup. Always check the expiration date of formula. Perform hand hygiene and put on nonsterile gloves before preparing, assembling, and handling any part of the feeding system. Disinfect the opening and rim of

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

any cans to be opened before opening. Label all equipment with the patient's name, date, and time the feeding was hung, and cap or cover any disconnected tubing. Clean a reusable feeding system with soap and hot water every 24 hours; replace a disposable feeding apparatus for open systems every 24 hours. Closed systems can be used up to 48 hours; check the manufacturer's guidelines and facility policy.

- Medications may be administered through a feeding tube, but never give them while a feeding is being infused; feeding must be stopped prior to administration of medications (Boullata et al., 2017).
- Never add medications directly to the formula (Boullata et al., 2017); some drugs become ineffective when mixed with feeding formulas and medications mixed in feeding formulas may cause clogging of the feeding tube.
- Do not mix medications together; administer each medication separately and dilute appropriately prior to administration (Boullata et al., 2017).
- Administer liquid forms of medications whenever possible (Boullata et al., 2017).
- It is very important to flush the tube with water before, between, and after the administration of medications. Purified water (e.g., sterile water, although there is no need for the water to be sterile) should be used for medication administration, as the chemical contaminants in tap water can potentiate drug–drug interactions (Boullata et al., 2017).
- Resume enteral feeding as soon as possible to avoid compromising nutrition status; only hold feeding when time lapse is indicated to avoid potential drug–nutrient interaction in the GI lumen (Boullata et al., 2017).
- Administering medications through an enteral feeding tube is discussed in depth in Chapter 30.

Monitoring for Complications

Patients receiving tube feedings are at risk for several complications. Table 37-5 (on page 1424) summarizes nursing measures to prevent selected complications.

Providing Comfort Measures

Patients with nasogastric tubes often experience discomfort related to irritation to nasal and throat mucosa and drying of the oral mucous membranes. Implement several nursing interventions to ensure the patient's comfort and prevent alterations in the integrity of these tissues.

- Administer oral hygiene frequently (every 2 to 4 hours) to prevent drying of tissues and to relieve thirst. Offer the patient the opportunity to rinse the mouth with warm water and mouthwash solution frequently. Lubricate the lips generously.
- Keep the nares clean, especially around the tube, where secretions tend to accumulate. Using a lubricant after cleaning the nares is recommended.
- Help control local irritation from the tube in the throat. Analgesic throat lozenges or anesthetic sprays may be effective.
- Encourage the patient, if able, to verbalize concerns about tube feeding and presence of the tube. A visit from another person who has learned to cope with this alternate feeding method may prove helpful.
- Secure the nasogastric tube to the patient's nose and cheek, based on facility policy, to prevent tension and tugging on the tube, causing trauma to the nares, and inadvertent displacement or dislodgment (Morton & Fontaine, 2018). Displacement or dislodgement of a tube can lead to aspiration, pneumonia, and sepsis (Powers, 2019). Use of a commercial securement device is recommended (Schroeder & Sitzer, 2019). Refer to Box 37-8 (on page 1424) for methods to secure an NGT.
- Secure the gastrostomy tube to the patient's abdomen in a way that stabilizes the tube and avoids excessive traction (Boullata et al., 2017; Roveron et al., 2018). Excessive friction may result in development of peristomal hypergranulation tissue (Bischoff et al., 2020; Roveron et al., 2018). Excessive traction may contribute to enlargement of the stoma and the development of leakage around the tube (Roveron et al., 2018).

Recall **Charles Gallagher**, the husband of the woman with advanced dementia receiving enteral nutrition. The nurse could teach Mr. Gallagher how to provide oral hygiene for his wife, including lubricating her lips. Doing so would allow Mr. Gallagher to feel some control over the situation. In addition, he would be helping to meet his wife's comfort needs and his own needs.

Providing Education

Often, patients will continue to receive enteral feedings at home or another community setting. Teaching Tips 37-1 (on page 1425) outlines important points to review with patients and families/caregivers in the home/community setting. Provide individualized instructions in written form as a reference for the patient and family/caregivers. Be sure to include the following in the teaching plan:

- Information about the administration of feedings, amount of fluid to be administered, operation of the pump, formula, instructions regarding rate and frequency and how to check for tube placement, as well as what to do if the tube becomes blocked or dislodged

Table 37-5 Preventing Complications of Enteral Feeding

POTENTIAL COMPLICATION	PREVENTIVE INTERVENTIONS
Aspiration	• Use appropriate measures to check tube placement. • Elevate head of bed at least 30–45 degrees during feeding and for 1 hour afterward. • Give small, frequent feedings. • Avoid over sedation of patient. • Check residual volume per policy.
Clogged tube	• Flush tube before and after feeding, every 4 hours during continuous feeding, and after withdrawing aspirate. • Sterile water should be used for tube flushes in immunocompromised or critically ill patients (Allen, 2015; Boullata et al., 2017). • Attach a 30- or 60-mL piston syringe to the feeding tube and pull back the plunger to help dislodge the clog. Then, fill the syringe with warm water and attempt to flush. If met with resistance, use gentle back and forth motion of the plunger to help loosen the clog. If necessary, clamp the tube to allow the warm water to penetrate the clog for up to 20 minutes and then attempt to flush (Boullata et al., 2017).
Nasal erosion with nasogastric or nasointestinal tubes	• Check nostrils every shift for signs of pressure. • Clean and moisten nares every 4–8 hours. • Secure tube to avoid pulling or pressure
Diarrhea	• Prevent contamination in both open and closed systems. • Change delivery set every 12–24 hours according to facility policy. • Refrigerate opened cans of formula and discard after 24 hours. • Limit hang time to 4 hours when using open system. • Use aseptic technique for patients who are immunosuppressed or acutely ill. • Assess for fecal impaction.
Other GI symptoms (nausea, vomiting, distention)	• Avoid oversedating patient (delays gastric emptying). • Administer GI motility medications, as prescribed.
Unplanned extubation	• Anchor tube appropriately with commercial device, bridle, or tape. • Check on patient frequently. • Measure external length of tubing at regular intervals.
Gastrostomy site infection	• Cleanse stoma and peristomal skin with sterile saline and gauze 24 hours after placement and every day for the first week (Roveron et al., 2018). • Stoma and peristomal skin may be cleansed with skin cleanser/mild soap and warm water 7–10 days after placement (Roveron et al., 2018). • Avoid the use of creams or powders around the stoma (Roveron et al., 2018). • Assess for signs of infection. • Request a consult with a wound care specialist, as needed.

- How to administer medications through the tube
- Care of the tube insertion site and possible complications that need to be communicated to the health care team
- Proper preparation, cleaning, and disposal of equipment

Box 37-8 Methods to Secure a Nasogastric Tube

- Tape
  - Commonly used
  - Associated with the most displacement and dislodgments issues (Powers, 2019)
  - Tape wrapped too tightly around tube may pull tube toward nares and cause erosion or pressure injury
  - Tape in manner to prevent pulling or pressure on nares
- Commercial adhesive devices
- Hydrocolloid dressing and tape to patient's cheek
- Nasal securement devices, such as nasal bridles
  - Associated with significant reduction in dislodgment versus tape (Powers, 2019; Stabler et al., 2018; Taylor et al., 2018)

- Emergency telephone numbers, including the number for the home health care facility and the appropriate members of the health care team
- Arrangements for follow-up from the home health care nurse as soon as possible after discharge

The care of a patient with a gastrostomy tube is outlined in Skill 37-2 on pages 1434–1435.

REMOVAL OF A NASOGASTRIC TUBE

Removing the nasogastric tube as carefully as it is inserted when it is no longer required is important to avoid causing the patient undue discomfort. After the tube is removed, provide for oral hygiene to remove disagreeable tastes and odors. Directions for removing the nasogastric tube are given in Skill 39-3 in Chapter 39.

NASOENTERIC TUBES FOR DECOMPRESSION

In addition to providing enteral feedings, nasogastric tubes can be used for other purposes. They may be inserted to decompress or drain the stomach of fluid, unwanted stomach contents, such as poison or medication and air, allowing it to rest, or before or after surgery, to promote healing. Tubes used for these purposes and associated nursing care are discussed in detail in Chapter 39.

Teaching Tips 37-1

HOME ENTERAL FEEDINGS

Health Topic	Teaching Tip	Why Is This Important?
Cleaning around a gastric tube insertion site	Use of soap and water, making sure that area is adequately rinsed and dried.	If soap is left under the gastric tube guard, it can lead to skin irritation.
	Rotation of the guard after cleaning around it	The guard can put pressure on the skin, leading to skin breakdown.
Delivering tube feedings	Head elevation while delivering a gastric feeding and for approximately an hour after the feeding	Keeping the head elevated helps to prevent aspiration of gastric tube feedings.
	Method of administration such as delivering the feedings via continuous or bolus method, and steps for carrying out the feeding	The patient or caregiver should know how to operate the machinery if it is to be delivered via continuous method or how to set up for a bolus feeding.
Leaking of gastric contents	Method of checking for problems (is guard too loose or balloon not filled adequately) if gastric tube is leaking stomach contents around insertion site	If gastric tube is leaking acidic stomach contents, the area around the insertion site can quickly break down.

Placement check	Methods to check placement to ensure that tube has not migrated inward or outward	Gastrostomy tubes can be marked with an indelible marker. The mark should be checked to make sure it is at the level of the abdominal wall. If the mark is not visible, the tube may have migrated inward. If the mark is away from the abdominal wall, the tube may no longer be in the stomach. Patients may also measure the length of the tube from the skin and record the measurement. This measurement should be confirmed to ensure that the tube has not migrated.

Providing Parenteral Nutrition

Parenteral nutrition (PN) is the administration of nutritional support via the intravenous route. Use of the enteral route is preferred to the parenteral route for nutrition support whenever feasible (Gorski et al., 2021); patients who cannot meet their nutritional needs by the oral or enteral routes may require intravenous nutritional supplementation. Intravenous supplementation may be prescribed for high-risk patients under specific circumstances, when enteral nutrition is not feasible or sufficient to meet energy or protein goals (McClave, DiBaise, et al., 2016, p. 317). PN may be considered for patients already on EN only after 7 to 10 days, when unable to meet >60% of energy and/or protein requirements by the enteral route alone (McClave, DiBaise, et al., 2016, p. 328).

PN is a highly concentrated, hypertonic nutrient solution. PN provides calories; restores nitrogen balance; and replaces essential fluids, vitamins, electrolytes, minerals, and trace elements. PN can also promote tissue and wound healing and normal metabolic function. It provides the bowel a chance to heal and reduces activity in the gallbladder, pancreas, and small intestine. PN meets the patient's nutritional needs by way of nutrient-filled solutions administered intravenously through a central venous access device, such as a tunneled, multilumen, or nontunneled catheter into the subclavian vein or a peripherally inserted central catheter (PICC).

Peripheral parenteral nutrition (PPN) is a less concentrated nutrient solution that can be administered through a peripheral vein. Peripheral veins cannot tolerate highly concentrated solutions and high fluid volumes, thus the solution used to deliver PPN is not as nutrient dense (Boullata et al., 2014). PPN is associated with a high risk of phlebitis and loss of venous access sites (Boullata et al., 2014; Gorski et al., 2021; McClave, DiBaise, et al, 2016). As a result, the nutritional value of PPN is limited and is most appropriate for patients who need short-term nutritional support (≤7 to 10 days) and to prevent, not correct, nutritional deficits (Dudek, 2022).

PARENTERAL NUTRITION SOLUTIONS AND ADMINISTRATION

PN contains the three primary components necessary to maintain nutrition: amino acids (proteins), carbohydrates (dextrose), and lipids (fats). Additional components of PN include electrolytes, vitamins, and trace elements. The PN formula is tailored to the individual patient's specific needs. Dextrose and lipids caloric value that the body needs to meet energy requirements. Lipids provide essential fatty acids to prevent fatty acid deficiency and support wound healing and red blood cell production. Amino acids provide protein to maintain structure and facilitate tissue repair and wound healing. Vitamins, trace minerals and electrolytes help maintain fluid and electrolyte balance, promote tissue repair/wound healing, maintain biochemical homeostasis, regulate acid–base balance, support metabolism and maintain osmotic pressure (Morton & Fontaine, 2018). Because of the high glucose concentration, usually about 25% (thus, a hypertonic solution), it is important to monitor blood glucose levels based on the patient's clinical status and the PN infusion schedule (cycled vs. continuous) (Ayers et al., 2014). Refer to Skill 37-3 on pages 1437–1440.

PN is administered using an electronic infusion device with anti–free-flow protection and alarms for occlusion, via continuous or cyclic infusion (Gorski et al., 2021). Physical incompatibility between the intravenous nutrition formula and other intravenous solutions, especially medications, is a potential problem that must be addressed. If the patient has a multilumen catheter in place, dedicate one lumen for the administration of the PN. Do not use that lumen or administration set for any other purpose, to prevent incompatibility problems. If the patient's intravenous catheter has only one lumen, attempt to obtain a peripheral intravenous access for the administration of additional solutions. Consider discussing the potential for a midline or peripherally inserted central catheter with the patient's health care team. If an additional access is not available, research the compatibility of the solutions to be administered. Little research exists on the stability and compatibility of PN solutions and most medications. Medications are not added to or coinfused with the PN before or during infusion without consultation with a pharmacist regarding compatibility and

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

stability (Gorski et al, 2021). If compatible medications or other solutions must be given through the same lumen as PN, attach the administration set as close to the catheter hub as possible to limit the amount of contact between the drug (or solution) and the PN solution. A pharmacist can add insulin to PN as part of the plan of care related to glycemic control (Murphy et al., 2020). Never add medication to PN solutions after they are dispensed from the pharmacy (Gorski et al., 2021).

PREVENTING COMPLICATIONS

PN therapy is costly, requires constant monitoring, and has the potential for causing infections as well as metabolic and mechanical complications. It should be used only when enteral intake is inadequate or contraindicated, and should be gradually discontinued as soon as possible (McClave, Taylor, et al., 2016). Prevention of potential complications associated with PN requires vigilance and careful monitoring by the nurse (Guenter et al., 2018). Potential complications include the following (Dudek, 2022; Gorski et al., 2021; Morton & Fontaine, 2018):

- Complications related to the use of central venous access devices, such as pneumothorax, thromboembolism (inflammation of a blood vessel and formation of a thrombus [blood clot]), and air embolism
- Infection and sepsis (central line–associated blood stream infections [CLABSIs])
- Metabolic alterations, such as hyperglycemia or hypoglycemia
- Fluid, electrolyte, and acid–base imbalances
- Hyperlipidemia
- Liver and gallbladder disease
- Refeeding syndrome (life-threatening complication related to overfeeding carbohydrates in nutritionally debilitated patients, characterized by metabolic and physiologic shifts of fluid, electrolytes, and minerals from the extracellular fluid to intracellular fluid) (Dudek, 2022, p. 352).

Guidelines for Nursing Care 37-2 lists nursing guidelines for monitoring administration of PN.

PARENTERAL NUTRITION IN THE HOME SETTING

Many patients require long-term PN and continue such therapy in the home. Individuals with advanced cancer, difficulty swallowing, or chronic bowel problems are candidates for this type of nutritional support. PN is often administered as a cyclic infusion in the home setting. A cyclic infusion is administered during a portion of the day, often overnight, providing periods of freedom from the infusion device and increased mobility. Nurses are involved in educating the patient and caregiver about the techniques and responsibilities associated with PN, providing technical and psychological support, and documenting the assessments that allow PN to be continued in the home. Patient education should specifically include:

- Purpose and expected duration of PN
- Proper storage of PN containers and supplies
- Infection prevention measures, including hand hygiene and maintaining sterile components of the infusion system (Gorski et al., 2021)
  - Safe environment for preparation, including clean workspace
- Signs and symptoms of infection/sepsis and prevention, recognition and management of non–infectious-related complications and/or problems (Pironi et al., 2020).
- Circumstances that require contacting the health care team
- Basic care of the venous access device used to administer
- Use and maintenance of infusion equipment
- Frequency for measuring the patient's weight, intake and output, and monitoring glucose levels

Evaluating

The effectiveness of the plan of care is evaluated as the last step in the nursing process. On an ongoing basis, the nurse accomplishes the following:

- Evaluates the patient's progress toward meeting nutritional outcomes
- Evaluates the patient's tolerance and adherence to the prescribed diet, when appropriate

▶ Guidelines for Nursing Care 37-2

Monitoring Administration of Parenteral Nutrition

- Use the same catheter lumen for administration of parenteral nutrition each time the tubing is changed.
- Use an electronic infusion device to administer infusion of parenteral nutrition.

- Infusion rate changes are made incrementally to avoid severe hyperglycemia or hypoglycemia. Taper infusion rates gradually (Ayers et al., 2014).
- Discard unused parenteral nutrition solution within 24 hours of starting its administration.
- Check vital signs every 4 hours to monitor for development of infection or sepsis.
- Monitor blood glucose levels as appropriate based on the patient's clinical status (Ayers et al., 2014; Ratliff et al., 2018).
- Use aseptic technique when changing solution, tubing, filter, or dressings according to facility policy.
- Infusion administration sets should include an in-line filter. Change infusion administration sets every 24 hours.
- Avoid blood sampling via the venous access device used for PN when feasible (Gorski et al., 2021).
- Change site dressings according to facility protocol. Transparent semipermeable dressings are changed once per week. Gauze dressings do not allow for inspection of exit site without dressing removal and should be changed every 48 hours. In addition, change dressings immediately if they become wet, soiled, or nonocclusive.
- Check that all connections are securely taped, catheter is clamped before opening the system, and insertion site is covered with sterile dressing.
- Compare the patient's daily weight to fluid intake and output. Total weight gain should not be greater than 3 lb per week. Weight gain greater than 1 lb per day indicates fluid retention.
- Assess serum protein and electrolyte levels for signs of imbalance.

Source: Adapted from Ayers, P., Adams, S., Boullata, J., Gervasio, J., Holcombe, B., Kraft, M. D., Marshall, N., Neal, A., Sacks, G., Seres, D. S., Worthington, P., & American Society for Parenteral and Enteral Nutrition. (2014). A.S.P.E.N. Parenteral nutrition safety consensus recommendations. *Journal of Parenteral and Enteral Nutrition*, *38*(3), 296–333. https://doi.org/10.1177/0148607113511992; Infusion Nurses Society (INS). (2016a). *Policies and procedures for infusion therapy* (5th ed.). https://doi.org/10.1097/NHH.0000000000000481.

- Assesses the patient's and family/caregiver's level of understanding of the diet and/or nutrition-related interventions and the need for further instruction or reinforcement
- Communicates findings to other members of the health care team
- Revises the plan of care, as needed, or terminates nursing care

REFLECTIVE PRACTICE LEADING TO PERSONAL LEARNING

Remember that the goal of reflective practice is to look at an experience, understand it, and learn from it. As you begin to develop expertise in implementing measures related to nutrition, reflect on your experiences—successes and failures—in order to improve your practice. How can you do it better next time? What did you learn today that can help you tomorrow? Begin your reflection by paying close attention to the following while performing nutrition interventions and providing nursing care:

- Did your preparation and practice related to performing interventions related to nutrition result in your feeling confident in your ability to provide care? Did your competence and confidence inspire the patient's and family's or caregivers trust?
- How did you prioritize the data you collected? What patterns in the data did you identify? What knowledge from your learning, personal experience and intuition did you use to make decisions and develop your plan of care?
- How confident are you that the nutrition data you communicated and recorded accurately communicates the health status, health problems, issues, risks, and strengths of the patient? How successfully have you communicated this information to other members of the health care team?
- Were you aware of any cultural and/or ethnic beliefs or practices that may have influenced the patient's personal nutrition practices? Were you aware of any stereotypes or prejudices that might have negatively influenced the clinical encounter? If so, how did you address these?
- Did you need to modify the plan of care as a result of ongoing assessments? Did you think of better interventions to produce the expected outcomes?
- As you concluded your care, did the patient and family/caregiver know your name, and know what to expect of you and nursing? Did the patient sense that you are respectful, caring, and competent to provide care?

Perhaps the most important questions to reflect on are: Are your patients and their families/caregivers better for having had *you* share in the critical responsibility of partnering with them to address their nutrition needs? Are your patients now receiving thoughtful, person-centered, prioritized, holistic, evidence-based treatment and care because of your efforts?

Skill 37-1 Administering a Tube Feeding (Open System)

DELEGATION CONSIDERATIONS

The administration of a tube feeding is not usually delegated to assistive personnel (AP) in the acute care setting. The administration of a tube feeding in some settings may be delegated to AP who have received appropriate training, after assessment of tube placement and patency by the registered nurse. Depending on the state's nurse practice act and the organization's policies and procedures, the administration of a tube feeding may be delegated to licensed practical/vocational nurses (LPN/LVNs). The decision to delegate must be based on careful analysis of the patient's needs and circumstances as well as the qualifications of the person to whom the task is being delegated. Refer to the Delegation Guidelines in Appendix A.

EQUIPMENT

- Prescribed tube-feeding formula at room temperature
- Feeding bag or prefilled tube-feeding set
- Stethoscope
- Nonsterile gloves
- Additional PPE, as indicated
- Alcohol preps
- Disposable pad or towel
- Large syringe (20 to 50 mL)
- Enteral feeding pump (if ordered)
- Rubber band
- Clamp (Hoffman or butterfly)
- IV pole
- Water for irrigation and hydration, as needed
- pH test strip (calibrated in units of 0.5 and approved for use with human secretions)
- Tape measure, or other measuring device

IMPLEMENTATION

ACTION	RATIONALE
1. Gather equipment. Check amount, concentration, type, and frequency of tube feeding in the patient's health record. Check the formula expiration date.	This provides for an organized approach to the task. Checking ensures that correct feeding will be administered. Outdated formula may be contaminated.
 2. Perform hand hygiene and put on PPE, if indicated.	Hand hygiene and PPE prevent the spread of microorganisms. PPE is required based on transmission precautions.
 3. Identify the patient.	Identifying the patient ensures the right patient receives the intervention and helps prevent errors.
4. Explain the procedure to the patient. Answer any questions, as needed.	Explanation facilitates patient engagement.
5. Assemble equipment on the overbed table or other surface within reach.	Organization facilitates performance of the task.
6. Close the patient's bedside curtain or door. Raise the bed to a comfortable working position, usually elbow height of the caregiver (VHACEOSH, 2016). Perform respiratory and abdominal assessments as	Closing curtains or the door provides for patient privacy. Having the bed at the proper height prevents back and muscle strain. Assessment is vital to detect changes in the patient's condition before initiating

described above.	the intervention.
7. **Position the patient as upright as possible with the head of the bed elevated at least 30 to 45 degrees or as near-normal position for eating as possible.** Patient should remain in this position during feeding and for 1 hour afterward. **Patients for whom the semi-recumbent position is contraindicated or who cannot tolerate a semi-Fowler position should be placed in a reverse- or anti-Trendelenburg position** (Boullata et al., 2017; Roveron et al., 2018).	These positions minimize possibility of reflux, aspiration, and pneumonia (McClave, Taylor, et al., 2016; Roveron et al., 2018).
8. Put on gloves. Confirm placement of the nasogastric tube in the patient's stomach using at least two methods.	Gloves prevent contact with blood and body fluids. With the exception of radiographic examination, which is usually done immediately after insertion to verify initial tube placement, the use of two or more of these techniques in conjunction with each other increases the likelihood of correct tube placement (AACN, 2020; Anderson, 2019b; Anderson, 2018a; Dias et al., 2019; Rahimi et al., 2015).
9. If assessments to check placement are inconclusive, the exposed tube length has changed, or there are any other indications that the tube may not be in place, check placement by radiograph (x-ray) of placement of tube, based on facility policy.	Radiographic confirmation is considered the most reliable method for identifying the position of the NG tube (AACN, 2020; Boullata et al., 2017).
10. If gastric residual volume (GRV) checks are part of facility policy and procedure, check GRV: After multiple steps have been taken to ensure that the feeding tube is located in the stomach or small intestine, aspirate all gastric contents with the syringe and measure to check for gastric residual—the amount of feeding remaining in the stomach. Return the residual based on facility policy. Proceed with feeding if the amount of residual does not exceed facility policy or the limit indicated in the health record. Refer to additional information in the *Special Considerations* below.	GRV has been used to monitor for tolerance of enteral nutrition; however, there is little support for this intervention as routine measurement for most patients, and it is not considered best practice and should not be used as part of routine care to monitor enteral nutrition (McClave, Taylor, et al., 2016; Ozen et al., 2018; Parker et al., 2019; Pars & Çavuşoğlu, 2019; Rysavy et al., 2020). GRV is not a suitable parameter to determine feeding intolerance (McClave, Taylor, et al., 2016; Pars & Çavuşoğlu, 2019). GRV has been shown to be a poor marker of true gastric volume; gastric emptying; and risk of aspiration, pneumonia, and poor outcomes (Hartwell et al., 2018; McClave, DiBaise, et al., 2016). The use of GRVs as a monitor for tolerance increases the risk of tube clogging and decreases attainment of nutritional goals as a result of disruption of delivery of enteral nutrition (McClave, DiBaise, et al., 2016).
 11. Flush tube with 30 to 50 mL of water for irrigation. Disconnect syringe from tubing and cap end of tubing while preparing the formula feeding equipment. Remove gloves. Perform hand hygiene.	Flushing the tube prevents occlusion (Bischoff et al., 2020; Boullata et al., 2017; Drummond Hayes & Hayes, 2018). Capping the tube deters the entry of microorganisms and prevents leakage onto the bed linens. Hand hygiene prevents transmission of microorganisms.
12. Put on gloves before preparing, assembling, and handling any part of the feeding system.	Gloves prevent contact with blood and body fluids and deter transmission of contaminants to feeding equipment and/or formula.
13. Administer feeding.	

When Using a Feeding Bag Administration System and Gravity (Bolus; Open System)

a. Label the bag and/or tubing with date and time. Hang the bag on the IV pole and adjust to about 12 inches above the stomach. Clamp tubing.	Labeling date and time of first use allows for disposal of bag and tubing within 24 hours, to deter growth of microorganisms. Proper feeding bag height reduces risk of formula being introduced too quickly.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

b. Check the expiration date of the formula. Cleanse top of feeding container with a disinfectant before opening it (Figure 1). Pour formula into the feeding bag and allow solution to run through tubing. Close the clamp.

Cleansing the container top with alcohol minimizes risk for contaminants entering feeding bag. Formula displaces air in the tubing.

c. Attach feeding administration set to the feeding tube (Figure 2), open clamp, and regulate drip according to the prescribed rate or allow feeding to run in over 30 minutes.

Introducing formula at an appropriate rate allows the stomach to accommodate to the feeding and decreases GI distress.

FIGURE 1. Cleaning top of feeding container with alcohol before opening it.

FIGURE 2. Attaching feeding administration set to NG tube.

d. **Add 30 to 60 mL (1 to 2 oz) of water for irrigation to feeding bag when feeding is almost completed** (Figure 3) and allow it to run through the tube.

Water rinses the feeding from the tube and helps to keep it patent as well as provides hydration for the patient. Feeding tubes should be flushed with at least 30 mL of water before starting and after completion of bolus feedings and every 4 to 8 hours during continuous feeding (Bischoff et al., 2020; Boullata et al., 2017; Roveron et al., 2018), based on the patient's fluid needs and restrictions (Boullata et al., 2017).

e. Clamp the tubing immediately after water has been instilled. Disconnect the feeding administration set from the feeding tube. Clamp the tube and cover the end with cap (Figure 4).

Clamping the tube prevents air from entering the stomach. Capping the tube deters entry of microorganisms and covering end of tube protects patient and linens from fluid leakage from tube.

FIGURE 3. Pouring water into feeding bag.

FIGURE 4. Capping NG tube after it is clamped.

When Using a Large Syringe (Bolus; Open System)

a. Remove the plunger from the 30- or 60-mL syringe (Figure 5).

Introducing the formula at a slow, regular rate allows the stomach to accommodate to the feeding and decreases GI distress. The higher the syringe is held, the faster the formula flows.

b. Attach the syringe to the feeding tube and pour a premeasured amount of tube-feeding formula into the syringe (Figure 6). Open the clamp on the feeding tube and allow the formula to enter the tube. Regulate the rate, fast or slow, by the height of the syringe. **Do not push the formula with the syringe plunger.**

FIGURE 5. Removing plunger from a 60-mL syringe.

FIGURE 6. Pouring formula into syringe.

c. When feeding is almost completed, **add 30 to 60 mL (1 to 2 oz) of water for irrigation to the syringe** (Figure 7) and allow it to run through the tube.

Water rinses the feeding from the tube and helps to keep it patent as well as provides hydration for the patient. Feeding tubes should be flushed with at least 30 mL of water before starting and after completion of bolus feedings (Bischoff et al., 2020; Boullata et al., 2017; Roveron et al., 2018), based on the patient's fluid needs and restrictions (Boullata et al., 2017).

FIGURE 7. Pouring water into almost-empty syringe.

d. When the syringe has emptied, hold it high, clamp the tube, and disconnect it from the tube. Cover the end of the tube with the cap.

By holding syringe high, the formula will not backflow out of tube and onto patient. Clamping the tube prevents air from entering the stomach. Capping end of tube deters entry of microorganisms and prevents fluid leakage from tube.

When Using an Enteral Feeding Pump (Open System)

a. Close the flow-regulator clamp on tubing and fill the feeding bag with prescribed formula, as described in Steps 13a and 13b. Place a label on the bag with patient's name, date, and time the feeding was hung.

Closing the clamp prevents the formula from moving through the tubing until the nurse is ready. Labeling date and time of first use allows for disposal of the bag and tubing within 24 hours, to deter growth of microorganisms.

b. Hang the feeding container on the IV pole. Open the clamp on tubing and allow the solution to

This primes the tubing, removing air in the tubing and preventing air from being forced into the stomach or

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

flow through the tubing.	intestines.
c. Connect the administration setup to the feeding pump, following the manufacturer's directions. Set the prescribed rate (Figure 8).	Feeding pumps vary. Some of the newer pumps have built-in safeguards that protect the patient from complications. Safety features include cassettes that prevent free flow of formula, automatic tube flush, safety tips that prevent accidental attachment to an IV setup, and various audible and visible alarms. The rate of infusion begins at the recommended rate, based on guidelines from the dietician or nutrition nurse specialist, and the rate is advanced in increments until the desired rate is achieved (Anderson, 2018b); feeding should be advanced to goal within 48 to 72 hours of initiation (McClave, DiBaise, et al., 2016).

FIGURE 8. Setting infusion rate on pump.

d. **Flush the tube with at least 30 mL of water at least every 4 to 8 hours during continuous feeding. Verify placement before administering flush.**	Feeding tubes should be flushed with at least 30 mL of water before starting and after completion of bolus feedings; every 4 to 8 hours during continuous feeding (Bischoff et al., 2020; Boullata et al., 2017; Roveron et al., 2018); and before and after medication administration (Drummond Hayes & Hayes, 2018) to prevent blockage, based on the patient's fluid needs and restrictions (Boullata et al., 2017).
14. Remove equipment and return the patient to a position of comfort. Remove gloves. Perform hand hygiene. Raise the side rail and lower the bed.	This promotes patient comfort and safety. Removing gloves properly reduces the risk for infection transmission and contamination of other items. Hand hygiene prevents transmission of microorganisms.
15. Put on gloves. Wash and clean equipment or replace according to facility policy. Remove gloves. Perform hand hygiene.	Gloves prevent contamination and deter spread of microorganisms. Reusable systems are cleansed with soap and water with each use and replaced every 24 hours. Refer to facility policy and manufacturer's guidelines for specifics on equipment care.
16. Monitor patient tolerance of enteral nutrition. Observe the patient's response during and after tube feeding and signs of tolerance at least daily.	Patient tolerance of the volume and type of formula must be monitored daily (Boullata et al., 2017; McClave, Taylor, et al., 2016).
17. **Have the patient remain in an upright position for at least 1 hour after feeding.** Refer to Step 7.	This minimizes possibility of reflux, aspiration, and pneumonia and should be implemented unless contraindicated (McClave, Taylor, et al., 2016; Roveron et al., 2018).

18. Remove additional PPE, if used. Perform hand hygiene.

Proper removal of PPE reduces the risk for infection transmission and contamination of other items. Hand hygiene prevents transmission of microorganisms.

DOCUMENTATION

Guidelines

Document the type of NG tube or gastrostomy/jejunostomy tube that is present. Record the criteria that were used to confirm tube placement before feeding was initiated and during administration, as indicated. Record respiratory and abdominal assessments. If GRVs are part of facility policy and procedure, record the amount of gastric residual volume that was obtained. Document the position of the patient, the type of feeding, and the method and the amount of feeding. Include any relevant patient teaching. Document results of evaluation of tolerance of enteral feeding.

Sample Documentation

Practice documenting NG tube insertion in *Lippincott DocuCare*.

10/29/25 1815 Position of NG tube was compared with initial measurement on insertion; no change in measurement. No signs of respiratory distress. Abdomen nondistended and soft; patient denies pain or nausea. HOB raised to 45 degrees. Gastric aspirate pH 3.9. 150 mL of Jevity 1.2 Cal administered over 30 minutes. Tube flushed with 60-mL water with ease. Patient instructed to call for nurse for pain or nausea or other concerns related to feeding.

—S. Essner, RN

UNEXPECTED SITUATIONS AND ASSOCIATED INTERVENTIONS

- *Nasogastric tube is identified not to be in stomach or intestine:* Tube must be in the stomach before feeding. If the tube is in misplaced, the patient is at increased risk for aspiration. Anticipate replacement of feeding tube.
- *Patient reports nausea after tube feeding:* Ensure that the head of the bed remains elevated and that suction equipment is at the bedside. Assess for other signs and symptoms of changes in tolerance to enteral feeding. Check the medication record to see if any antiemetics have been ordered for the patient. Consider collaborating with the health care team to review administration rate, volume, and type of nutritional formula. Monitor for pattern of nausea related to enteral feeding.
- *When attempting to aspirate contents, the nurse notes that tube is clogged:* Feeding tubes are prone to blockage, due to protein-rich formula solutions, the viscosity of the feeding formulas and relatively small diameter of the feeding tube lumens, the use of the tubes for medication administration, and inadequate water flushes (Bischoff et al., 2020; Drummond Hayes & Hayes, 2018). Try to remove the clog: use air bolus or attach a 30- or 60-mL piston syringe to the feeding tube and pull back the plunger to help dislodge the clog. Fill the syringe with warm water and attempt to flush. If met with resistance, use gentle back and forth motion of the plunger to help loosen the clog. If necessary, clamp the tube to allow the warm water to penetrate the clog for up to 20 minutes and then attempt to flush (Boullata et al., 2017). The tube may have to be replaced. To prevent clogs, ensure that adequate flushing is completed after each feeding and before and after medication administration (Bischoff et al., 2020; Drummond Hayes & Hayes, 2018).

DEVELOPING CLINICAL REASONING AND CLINICAL JUDGMENT

SPECIAL CONSIDERATIONS

- There is no benefit from stopping feedings during short periods of lowering of the head of the bed (such as turning the patient) (Boullata et al., 2017). If a prolonged procedure will require lowering of the head of the bed, feedings should be stopped during this period; feedings should be promptly restarted when the procedure is ended or as feasible.
- If GRV checks are part of facility policy and procedure, automatic cessation of enteral nutrition should be avoided for GRVs < 500 mL in the absence of other signs of intolerance (Boullata et al., 2017; McClave, Taylor, et al., 2016; Roveron et al., 2018).
- Volume-based feeding protocols in which 24-hour or daily volumes are targeted instead of hourly rates have been shown to increase volume of nutrition delivered (Heyland et al., 2013, as cited in McClave, Taylor, et al., 2016). This type of method empowers nurses to increase feeding rates to make up for volume lost for scheduled and unscheduled interruptions or while enteral nutrition is held and increase attainment of nutritional goals, supporting

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

optimal nutritional intake (Kinikin et al., 2020; McClave, Taylor, et al., 2016).

- Feedings into the intestine are always continuous and include initiation at a lower rate with a gradual increase in the rate until the target rate identified to meet nutritional goals is met (Bischoff et al., 2020).
- A combination of methods, such as overnight continuous feeding and bolus feeding during the day, may be used for some patients to best meet their needs and allow for autonomy and lifestyle preferences (Bischoff et al., 2020). For other patients, cyclic feeding, administering continuous feeding for a portion of the 24-hour period, may be implemented. The usual routine is to feed the patient for 12 to 16 hours, most often overnight. Cyclic feeding allows the patient to attempt eating regular meals during the day, if this is possible, making ambulation and activity easier.
- Tolerance to gastric feeding can be improved through use of a prokinetic agent, continuous infusion, and elevation of the head of the bed (McClave, DiBaise et al., 2016).
- Sterile water should be used for tube flushes in immunocompromised or critically ill patients (Allen, 2015; Boullata et al., 2017).
- If GRV checks are part of facility policy and procedure, evaluate the significance of a single high gastric residual volume in relation to other indicators of GI intolerance, including abdominal distention, abdominal discomfort, nausea, and vomiting (AACN, 2018).
- Immediately refrigerate formulas reconstituted in advance. Discard unused reconstituted and refrigerated formulas within 24 hours of preparation (Boullata et al., 2017).
- Discard unused reconstituted formulas exposed to room temperature after 4 hours (Boullata et al., 2017).
- Some feeding equipment allows for the addition of water for flushes to a second feeding container, which enters the system through a second set of tubing. The feeding pump will automatically administer the preset volume of flush at the preset frequency.

Skill 37-2 Caring for a Gastrostomy Tube

DELEGATION CONSIDERATIONS

The care of a gastrostomy tube, in the postoperative period, is not delegated to assistive personnel (AP) in the acute care setting. The care of a healed gastrostomy tube site in some settings may be delegated to AP who have received appropriate training, after assessment of the tube by the registered nurse. Depending on the state's nurse practice act and the organization's policies and procedures, the care of a gastrostomy tube may be delegated to licensed practical/vocational nurses (LPN/LVNs). The decision to delegate must be based on careful analysis of the patient's needs and circumstances as well as the qualifications of the person to whom the task is being delegated. Refer to the Delegation Guidelines in Appendix A.

EQUIPMENT

- Nonsterile gloves
- Additional PPE, as indicated
- Washcloth, towel, and skin cleanser or cotton-tipped applicators and sterile saline solution (depending on patient circumstances)
- Gauze (if needed)

IMPLEMENTATION

ACTION	RATIONALE
1. Gather equipment. Verify the prescribed interventions or facility policy and procedure regarding site care.	Assembling equipment provides for an organized approach to the task. Verification ensures the patient receives the correct intervention.
 2. Perform hand hygiene and put on PPE, if indicated.	Hand hygiene and PPE prevent the spread of microorganisms. PPE is required based on transmission precautions.
	Identifying the patient ensures the right patient receives the intervention and helps prevent errors.

	3. Identify the patient.	
4.	Explain the procedure to the patient. Answer any questions, as needed.	Explanation facilitates patient engagement.
5.	Assess for presence of pain at the tube-insertion site. If pain is present, offer the patient analgesic medication per the prescribed interventions and wait for the medication to take effect before beginning insertion-site care.	Feeding tubes can be uncomfortable, especially in the first few days after insertion. Analgesic medication may permit the patient to tolerate the insertion site care more easily. After the first few days, pain at the site should diminish (Roveron et al., 2018).
6.	Pull the patient's bedside curtain. Assemble equipment on the bedside table, within reach. Raise the bed to a comfortable working position (VHACEOSH, 2016).	This provides for privacy. Assembling equipment provides for organized approach to the task. An appropriate working height facilitates comfort and proper body mechanics for the nurse.
7.	Put on gloves. Assess the gastrostomy site, as described above.	Gloves prevent contact with blood and body fluids. Assessment is vital to detect changes in the patient's condition before initiating the intervention.
8.	Measure the length of the exposed tube, comparing it with the initial measurement after insertion. Alternatively, examine the mark on the tube at the skin; the mark should be at skin level at the insertion site.	Tube length should be checked and compared with the initial measurement or marking daily (Roveron et al, 2018). A change in the length of the exposed tube may indicate displacement.
9.	Beginning 24 hours after placement of the tube and for the first week, cleanse the stoma and peristomal skin with sterile saline to remove any discharge or material around the tube (Bischoff et al., 2020; Roveron et al., 2018) (Figure 1). Pat the skin around the insertion site dry. If necessary, cover the stoma with sterile gauze to absorb exudate or other fluids (Roveron et al., 2018).	Cleaning the new site with sterile saline solution prevents the introduction of microorganisms into the wound (Roveron et al., 2018). Crust and drainage can harbor bacteria and lead to skin breakdown. Drying the skin thoroughly prevents skin breakdown. Gauze absorbs drainage.
10.	After the first week to 10 days, wet a washcloth and apply a small amount of skin cleanser onto the washcloth. Gently cleanse around the insertion, removing any crust or drainage (Bischoff et al., 2020; Roveron et al., 2018) (Figure 2). Rinse the site, removing all cleanser. Pat the skin around the insertion site dry. If necessary, based on facility policy and patient situation, place a gauze dressing above the external fixation device. Alternatively, if the exterior fixation device is 5 mm above the skin, the dressing may be placed under the exterior fixation device, if the dressing is not too thick (Roveron et al., 2018).	Crust and drainage can harbor bacteria and lead to skin breakdown. Removing the cleanser helps to prevent skin irritation. If able, the patient may shower and cleanse the site with soap and water. Drying the skin thoroughly prevents skin breakdown. Placing the dressing above the external fixation device avoids excessive tension (Roveron et al., 2018). Gauze absorbs drainage.

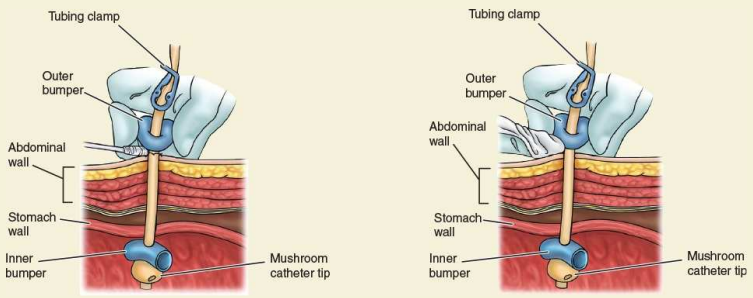

FIGURE 1. Wiping gastric tube site with cotton-tipped applicator and sterile saline.

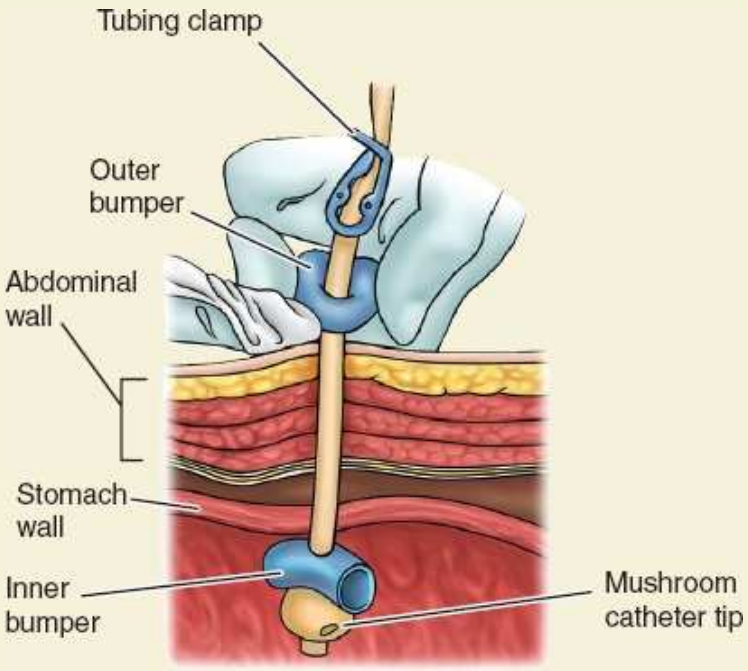

FIGURE 2. Cleaning site with skin cleanser, water, and washcloth.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

11. After the first 24 hours, gently rotate the position of the gastrostomy tube 360 degrees. **Rotation of the tube should be done at least once a week and no more than once a day** (Roveron et al., 2018).	Rotation of the tube prevents adherence to the tract and adhesion (Roveron et al., 2018).
12. After the first 7 to 10 days, loosen the exterior fixation device and gently push the tube into the stomach 2 to 3 cm, then gently pull it back until it reaches the area of minimal resistance (the gastric wall). **Push/pull of the tube should be done at least once a week and no more than once a day** (Bischoff et al., 2020; Roveron et al., 2018). Assess that the guard or external bumper is not digging into the surrounding skin. The external fixation device should be 0.5 to 1 cm above the skin (Bischoff et al., 2020; Roveron et al., 2018). **Avoid placing any tension on the tube.**	The gastrocutaneous tract heals in 7 to 10 days (Roveron et al., 2018). This maneuver reduces the risk for buried bumper syndrome (Bischoff et al., 2020; Roveron et al., 2018). Proper placement prevents/avoids excessive tube movement and enlargement of the stoma (Roveron et al., 2018). The external fixation device should be 0.5 to 1 cm above the skin to avoid excessive tension between the interior and exterior fixation devices and to reduce the risk of ischemia, necrosis, infection, and buried bumper syndrome (Bischoff et al., 2020; Roveron et al., 2018). Excessive distance between the external fixation device and the skin could lead to fixation of the gastric wall to the abdominal wall and formation of a gastrocutaneous fistula (Roveron et al., 2018). Excessive traction may contribute to enlargement of the stoma and the development of leakage around the tube (Roveron et al., 2018).
13. For most patients, the site can be left open to air unless there is drainage. Avoid the use of creams or powders around the stoma (Roveron et al., 2018).	Dressing is not necessary in the absence of drainage (Bischoff et al., 2020; Roveron et al., 2018). Avoiding use of creams or powders around the stoma prevents growth of pathogens (Roveron et al., 2018).
14. If the tube is not in use, check that the cap is securely in place.	The cap should remain closed when the tube is not in use to deter entry of microorganisms and prevent leakage from the tube.
15. Secure the gastrostomy tube to the patient's abdomen in a way that stabilizes the tube and avoids excessive traction (Boullata et al., 2017; Pars & Çavuşoğlu, 2019; Roveron et al., 2018). Assess the integrity of the tape or device used to secure the tube to the stomach.	Excessive friction may result in development of peristomal hypergranulation tissue (Bischoff et al., 2020; Roveron et al., 2018). Excessive traction may contribute to enlargement of the stoma and the development of leakage around the tube (Roveron et al., 2018).
 16. Remove gloves. Perform hand hygiene. Lower the bed and assist the patient to a position of comfort, as needed.	Removing gloves reduces the risk for infection transmission and contamination of other items. Hand hygiene prevents transmission of microorganisms. Lowering the bed and assisting the patient ensure patient safety and comfort.
 17. Remove additional PPE, if used. Perform hand hygiene.	Proper removal of PPE reduces the risk for infection transmission and contamination of other items. Hand hygiene prevents transmission of microorganisms.

DOCUMENTATION

Guidelines

Document the site care that was provided, including the substance used to cleanse the tube site. Record the assessment of the site, including the surrounding skin and measurement of length of external tube and comparison to length on insertion. Note the presence of any drainage, recording the amount and color, and pressure injury, erythema, inflammation, erosion, or hypergranulation tissue. Note the rotation and/or push/pull of the tube. Note the external fixator position. Comment on the patient's response to the care, if the patient experienced any pain, and if an analgesic was administered. Record any patient instruction that was provided.

Sample Documentation

10/10/25 1145 Gastrostomy tube site cleansed with skin cleanser and water. No change in measurement of tube length from initial measurement. Tube rotated without difficulty. Site is of consistent tone with surrounding skin, without any signs of skin breakdown. Small amount of clear crust noted on tube. Patient tolerated site care without incident. Wife at bedside, actively participating in tube care.

—S. Essner, RN

DEVELOPING CLINICAL REASONING AND CLINICAL JUDGMENT

UNEXPECTED SITUATIONS AND ASSOCIATED INTERVENTIONS

- *Gastrostomy tube is leaking large amount of drainage:* Check tension of tube. If there is a large amount of slack between the internal guard and the external bumper, drainage can leak out of site. Apply gentle pressure to the tube while pressing the external bumper closer to the skin (0.5 to 1 cm from skin [Bischoff et al., 2020; Roveron et al., 2018]). If the tube has an internal balloon holding it in place (similar to a urinary catheter balloon), check to make sure that the balloon is inflated properly.
- *Skin irritation is noted around insertion site:* Investigate the cause of the irritation. Address the cause of the leakage; apply skin barrier or zinc oxide–based skin protectant (Bischoff et al., 2020). If the skin is erythematous and appears to be broken down, gastric fluids may be leaking from the site. Gastric fluids have a low pH and are very acidic. Address the leakage. If the skin has a patchy, red rash, the cause could be candidiasis (yeast). Consult with the health care team regarding the use of an antifungal powder. Ensure that the site is kept dry.
- *Site appears erythematous and patient reports pain at site:* Consult with the health care team; the patient could be developing an infection at the site.
- *Patient reports severe pain that does not respond to routine analgesics when the tube is used for feeding/hydration or when site care is provided during the first 72 hours after placement of the tube*: Discontinue any type of administration through the tube and notify the health care team (Roveron et al., 2018).

SPECIAL CONSIDERATIONS

General Considerations

- Feeding tubes should be flushed with at least 30 mL of water before starting and after completion of bolus feedings, every 4 to 8 hours during continuous feeding, and before and after medication administration (Bischoff et al., 2020; Boullata et al., 2017; Pars & Çavuşoğlu, 2019; Roveron et al., 2018), based on the patient's fluid needs and restrictions (Boullata et al., 2017).
- Avoid occlusive dressings at gastrostomy site; occlusive dressings promote a moist wound environment and can lead to skin maceration (Bischoff et al., 2020).
- Glycerin hydrogel or glycogel dressings may be used as an alternative to gauze dressings (Bischoff et al., 2020). Use of this type of dressing removes the need for daily dressing changes (Bischoff et al., 2020).
- Do not place a dressing between the skin and external fixation device unless drainage is present. Change the dressing immediately when soiled, to prevent skin complications.
- If the length of the exposed tube has changed or marking on tube is not visible, do not use the tube. Consult with the health care team regarding the finding.
- If the patient experiences pain during nutritional infusion, prolonged pain after the procedure, passage of nutritional formula or medications through the stoma, or bleeding from the site, stop the enteral nutrition feeding immediately and consult with the health care team (Roveron et al., 2018, p. 331).

Community-Based Care Considerations

- Advise patients and caregivers to stop the enteral nutrition feeding immediately and contact their health care provider if the patient experiences pain during nutritional infusion, prolonged pain after the procedure, passage of nutritional formula or medications through the stoma, or bleeding from the site (Roveron et al., 2018, p. 331).
- For patients with a well-healed exit site, showering, bathing, and swimming (it is advisable to cover the site with a waterproof dressing when swimming in public pools) is possible after a few weeks (Bischoff et al., 2020).
- All information related to home enteral nutrition should be provided to patients and family members/caregivers verbally and in writing and/or pictures (Bischoff et al., 2020).

Skill 37-3 Obtaining a Capillary Blood Sample for Glucose Testing

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

DELEGATION CONSIDERATIONS

Obtaining a capillary blood sample for glucose testing may be delegated to assistive personnel (AP) as well as to licensed practical/vocational nurses (LPN/LVNs). The decision to delegate must be based on careful analysis of the patient's needs and circumstances as well as the qualifications of the person to whom the task is being delegated. Refer to the Delegation Guidelines in Appendix A.

EQUIPMENT

- Blood glucose meter
- Sterile lancet
- Cotton balls or gauze squares
- Testing strips for meter
- Nonsterile gloves
- Additional PPE, as indicated
- Skin cleanser and water or alcohol swab

Implementation

ACTION	RATIONALE
1. Check the patient's health record or plan of care for monitoring schedule. Additional testing may be indicated based on nursing judgment and the patient's condition.	This confirms scheduled times for checking blood glucose. Independent nursing judgment may lead to the decision to test more frequently, based on the patient's condition.
2. Gather equipment. Check the expiration date on blood test strips.	This provides an organized approach to the task. Blood test strips that are past expiration date could cause inaccurate results and should not be used.
 3. Perform hand hygiene and put on PPE, if indicated.	Hand hygiene and PPE prevent the transmission of microorganisms. PPE is required based on transmission precautions.
 4. Identify the patient. Explain the procedure to the patient and instruct the patient about the need for monitoring blood glucose.	Identifying the patient ensures the right patient receives the intervention and helps prevent errors. Explanation helps to alleviate anxiety and facilitate engagement.
5. Close curtains around the bed and close the door to the room, if possible.	Closing the curtain or door provides for patient privacy.
6. Turn on the monitor.	The monitor must be on for use.
7. Enter the patient's identification number or scan their identification bracelet, if required, according to facility policy.	Use of identification number allows for electronic storage and accurate identification of patient data.
8. Put on gloves.	Gloves protect the nurse from exposure to blood or body fluids.
9. Prepare the lancet using aseptic technique.	Aseptic technique maintains sterility.
10. Remove test strip from the vial. **Recap container immediately.** Test strips also come individually wrapped. **Check that the code number for the strip matches the code number on the monitor screen.**	Immediate recapping protects strips from exposure to humidity, light, and discoloration. Matching code numbers on the strip and glucose monitor ensures that the machine is calibrated correctly.
11. Insert the strip into the meter according to directions for that specific device. Alternatively, strip may be placed in meter after collection of sample on test strip, depending on meter in use.	Correctly inserted strip allows meter to read blood glucose level accurately.
12. **Have the patient wash their hands with skin**	Washing with skin cleanser and water or alcohol

cleanser and warm water and dry thoroughly. Alternatively, cleanse the skin with an alcohol swab. Allow skin to dry completely.	cleanses the puncture site. Warm water also helps to cause vasodilation. Alcohol can interfere with accuracy of results if not completely dried.
13. Choose a skin site that is intact, warm, and free of calluses and edema (Van Leeuwen & Bladh, 2017).	Areas with lesions are not suitable for capillary sampling. Calluses, edema, and vasoconstriction (cool to palpation) interfere with the ability to obtain a blood sample.
14. Hold the lancet perpendicular to the skin and pierce the skin with the lancet (Figure 1).	Holding the lancet in the proper position facilitates proper skin penetration.

FIGURE 1. Piercing patient's finger with lancet.

15. Encourage bleeding by lowering the hand, making use of gravity. Lightly stroke the finger, if necessary, until a sufficient amount of blood has formed to cover the sample area on the strip, based on monitor requirements (check instructions for monitor). If necessary, squeeze from the base of the finger (CDC, 2021d). Take care not to squeeze at the puncture site and not to touch the puncture site or blood.	An appropriate-sized droplet facilitates accurate test results. Squeezing can cause injury to the patient and alter the test.
16. Gently touch a drop of blood to the test strip without smearing it (Figure 2). Depending on the meter in use, insert the strip into the meter after collection of the sample on the test strip.	Smearing blood on the strip may result in inaccurate test results.

FIGURE 2. Applying blood to test strip.

17. Apply pressure to puncture site with a cotton ball or dry gauze. **Do not use alcohol wipe.**	Pressure causes hemostasis. Alcohol stings and may dry the skin.
18. Read blood glucose results and document the results in the EHR or other designated location, based on	Timing depends on type of meter.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

facility policy. Inform the patient of the test result.	
19. Turn off the meter, remove the test strip, and dispose of supplies appropriately. Place the lancet in a sharps container.	Proper disposal prevents exposure to blood and accidental needlestick.
 20. Remove gloves and any other PPE, if used. Perform hand hygiene.	Proper removal of PPE reduces the risk for infection transmission and contamination of other items. Hand hygiene reduces the transmission of microorganisms.

DOCUMENTATION

Guidelines

Document blood glucose level in the patient's health record, according to facility policy. Document pertinent patient assessments, any intervention related to glucose level, and any patient teaching. Communicate abnormal results and/or significant assessments to the health care team.

Sample Documentation

Practice documenting blood glucose testing in *Lippincott DocuCare*.

11/1/25 0800 Patient performed own fingerstick blood glucose test with minimal guidance. Verbalized rationale for fasting measurement and able to state symptoms of hypoglycemia. Patient's fingerstick blood glucose level 168. Four units regular Humulin insulin given per sliding scale, in addition to 10 units NPH Humulin insulin scheduled for 0800. Patient encouraged to review written guidelines for subcutaneous insulin administration; will review procedure and plan to have patient administer insulin at dinnertime. Patient verbalized an understanding.

—B. Clapp, RN

Developing Clinical Reasoning and Clinical Judgment

UNEXPECTED SITUATIONS AND ASSOCIATED INTERVENTIONS

- *Extremity is pale and cool to the touch:* Begin by warming the extremity. Have adult patients warm their hands by rubbing them together or washing with warm water. Warm, moist compresses may also be used.
- *Blood glucose level results are above- or below-normal parameters:* Assess the patient for signs of hyperglycemia or hypoglycemia, respectively. Check patient's health record for prescribed interventions, such as insulin dosage or glucose-containing carbohydrate administration (ADA, 2021). Notify health care team of results, assessment data, and interventions.

SPECIAL CONSIDERATIONS

General Considerations

- If the selected site feels cool or appears pale, warm compresses can be applied for 3 to 5 minutes to dilate the capillaries.
- Sampling of blood from an alternative site other than fingertips may have limitations. Blood in the fingertips shows changes in glucose levels more quickly than blood in other parts of the body. This means that alternative site test results may differ from fingertip test results when glucose levels are changing rapidly (e.g., after a meal, taking insulin, or during or after exercise) because the results may be inaccurate. Caution patients to use a fingertip sample if it is less than 2 hours after eating, less than 2 hours after injecting rapid-acting insulin, during exercise or within 2 hours of exercise, when sick or under stress, when having symptoms of hypoglycemia, if unable to recognize symptoms of hypoglycemia, or if site results do not agree with the way the patient feels (U.S. FDA, 2019).
- Meters require calibration at least monthly or according to the manufacturer's recommendation, and when a new bottle of test strips is opened. Manufacturer's directions for calibration should be followed. After calibration, the meter is checked for accuracy by testing a control solution containing a known amount of glucose.
- Alternative testing sites, other than fingertips, should not be used to calibrate a continuous glucose monitor or for insulin dosing calculations (U.S. FDA, 2019).
- Inadequate sampling can cause errors in the results. It is very important to be aware of requirements for the specific monitor used.

- Continuous glucose monitoring (CGM) systems use sensors placed just below the skin to check glucose levels in tissue fluid. A transmitter sends information about glucose levels from the sensor to a wireless monitor. These devices provide real-time measurements of glucose levels every few minutes (NIDDK, 2017). These systems provide a way to see glucose trends, and track patterns (NIDDK, 2017).
- Most models of CGMs require confirmation of a CGM reading with a fingerstick blood glucose test before taking insulin or treating hypoglycemia (NIDDK, 2017).

Infant and Child Considerations

- Heel sticks, using the outer aspect of the heel, may be used for infants. Warming the heel for 5 to 10 minutes before the sample is taken dilates the blood vessels in the area and aids in sampling (KarabiyikOğurlu et al., 2020; Vedder, 2021). This technique is not without controversy, as it is painful and can lead to scarring and infection, including infection of bone and cartilage, due to excessive depth of the puncture (Gorski et al., 2021; Vedder, 2021). Venipuncture by a skilled phlebotomist is suggested instead of heel lance methods due to the increased pain from heel lance (Gorski et al., 2021). Automatic lancing devices are preferred over manual devices to control the depth of puncture and to reduce the risk of bone or cartilage infection (Gorski et al., 2021).

Older Adult Considerations

- Blood glucose meters are available with large digital readouts or audio components for patients with visual impairments (Williams, n.d.).

Community-Based Care Considerations

- Patients monitor blood glucose levels routinely at home. Provide education focusing on important elements of diabetes education to assist patients in managing their diabetes, including the signs, symptoms, and management of hypoglycemia and hyperglycemia; correct administration of oral hypoglycemic agents and/or insulin; fingerstick blood glucose monitoring; and the accurate use of fingerstick blood glucose monitoring equipment.
- Many different types of monitors are available. Assist patients to identify desirable features for individual use.

EVOLVING CASE STUDY 37-1

Scenario: Susan Oakland, a 21-year-old student, is pregnant with her first child. She was seen at the prenatal clinical for her first visit at 5 weeks of gestation. On her next visit, 4 weeks later, she reports persistent nausea, vomiting, and fatigue, contributing to a loss of appetite.

QUESTION r/t CUES: Which assessment data are of highest priority for the nurse to collect to provide additional information to address Susan's decreased nutritional intake?

A. Calculate the patient's BMI; measure the patient's waist circumference
B. The patient's plans for childcare
C. Patient's baseline and current weight
D. The patient's decision to breast/chest or bottle feed

Scenario: The patient confides that "Eating food has become pretty unappealing." The patient relays that she is very weight conscious; she appears pale and somewhat withdrawn. The patient and her husband are first-semester graduate students; their source of income is graduate assistantships. She has lost 3 lb since her first visit at 5 weeks of gestation.

QUESTION r/t ANALYZING CUES: What other information (assessment data or evidence) should the nurse obtain related to this issue? Select all that apply.

A. Patient's use of vitamin supplements
B. The patient's living situation
C. The food budget the patient and her husband have established
D. A 24-hour food recall
E. An in-depth psychiatric assessment

Scenario: The patient's 24-hour recall revealed an inadequate intake from the milk food group and marginal intake from grain and meat groups. She skips breakfast because of a "hurried schedule," which is now complicated by nausea. The patient shares that she dislikes red meat and eats it only once or twice a month. She also dislikes milk and substitutes sugar-free soft drinks and water.

QUESTION r/t PRIORITIZING HYPOTHESIS: Based on the assessments of this patient, which priority problem should the nurse identify to guide the plan of care?

A. Anxiety

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

B. Impaired nutritional intake
C. Risk for impaired skin integrity
D. Fatigue

Scenario: The nurse decides to focus on ways to manage nausea and vomiting and achieve and maintain adequate nutritional intake.

QUESTION r/t GENERATING SOLUTIONS: Which intervention will be most effective to help the patient achieve and maintain improved nutrition?

A. Reinforce the need to consume large amounts of nutrient-dense foods to support the developing fetus
B. Encourage the patient to consume small, frequent meals that include nutrient-dense foods
C. Provide a list of foods that must be eaten during pregnancy, regardless of the patient's preferences
D. Explain that a rigid, fixed schedule of meals is necessary to ensure adequate nutrition

Scenario: Susan's pregnancy continues to progress, but her weight loss persists into week 10 of the pregnancy, and she has lost an additional 4 lb. She has kept a food diary of her intake and has also trended her feelings of nausea and episodes of vomiting. The midwife is concerned and appreciates the need for further intervention.

QUESTION r/t TAKING ACTION: The nurse is preparing teaching materials for the patient. Which materials should the nurse prepare to use for the teaching session with this patient and her husband?

A. Percutaneous endoscopic gastrostomy (PEG) insertion and associated formula administration
B. Megadoses of nutritional supplements including calcium, folic acid, and calcium
C. Prescription for ondansetron, an antinausea agent that blocks the triggers of nausea and vomiting
D. Information on eating disorders such as anorexia nervosa, bulimia, and laxative/diuretic use disorders

Scenario: Susan comes back for her well check-up at 15 weeks and reports that the nausea and vomiting resolved with the use of the medication, but that she has not taken any doses for 2 weeks.

QUESTION r/t EVALUATING OUTCOMES: Although the patient reports feeling better, which of the following objective measures would the nurse use to evaluate the success of the nursing interventions and resolution of the health problem for this particular patient? Select all that apply.

A. The patient is maintaining approximately an extra 340 calories per day in her diet
B. The patient is no longer vomiting after taking her prescribed prenatal supplements
C. The patient reports being able to tolerate a nightly beer with the evening meal
D. The patient divulges the use of nightly suppositories to stimulate a bowel movement
E. The patient's weight is steadily increasing at a rate commensurate with gestational age

DEVELOPING CLINICAL REASONING AND CLINICAL JUDGMENT

. Work through the Evolving Case Study 37-1 on page 1441 to help develop your clinical reasoning and clinical judgment skills.
. Prepare a diet for an economically disadvantaged family consisting of a single working mother and her three children, ages 3 to 14 years, taking into consideration the family's culture (specify a minority culture in your locale) and yearly income (below poverty level).
. Prepare a 1-day menu that meets the recommended daily allowance of essential nutrients for the following patients:

- An obese teenager
- A child vegetarian
- An executive with high blood pressure who dines out frequently with patients
- A woman running a minimum of 12 miles daily as she trains for a marathon

PRACTICING FOR NCLEX

. A nurse at a health fair calculates the body mass index (BMI) of a person who weighs 68 kg and is 165 cm (1.65 m) tall. How will the nurse document the BMI?

a. 25 kg/m^2
b. 46 kg/m^2
c. 68 kg/m^2
d. 165 kg/m^2

. After administering an enteral feeding, a nurse evaluates the patient's tolerance of the feeding. Which findings suggesting intolerance require collaboration with the dietician and health care provider? Select all that apply.

a. Nausea and/or vomiting

b. Weight gain
c. Bowel sounds 20/min
d. 200-mL gastric residual
e. Absence of diarrhea and constipation
f. Slight abdominal pain and distention

. A nurse is feeding an older adult patient with dementia. What intervention will best promote nutritional intake?
a. Stroke the underside of the patient's chin to promote swallowing.
b. Serve meals in different places and at different times.
c. Offer a whole tray of various foods to choose from.
d. Avoid between-meal snacks to ensure hunger at mealtime.

. A patient with COPD is experiencing anorexia and weight loss. Which intervention would be most helpful in stimulating appetite in this patient?
a. Administering pain medication after meals.
b. Encouraging the patient's family to bring food from home when possible.
c. Scheduling respiratory therapy nebulizer treatments before each meal.
d. Reinforcing the importance of eating what is delivered to them.

. A nurse is feeding a patient who is experiencing dysphagia. Which nursing intervention will best prevent aspiration?
a. Feed the patient solids first and liquids last.
b. Place the bed in the semi-Fowler position during feeding.
c. Provide a 30-minute rest period prior to mealtime.
d. Provide a straw for the patient's beverages and soups.

. During interprofessional rounds, the charge nurse and health care provider evaluate patients to determine their need for parenteral nutrition (PN). Which patients will be identified as candidates for this type of nutritional support? Select all that apply.
a. Patient with irritable bowel syndrome and intractable diarrhea
b. Patient with celiac disease not absorbing nutrients from the GI tract
c. Patient who is underweight and needs short-term nutritional support
d. Patient who is comatose and needs long-term nutritional support
e. Patient who has anorexia and refuses to take foods via the oral route
f. Patient with burns who has not been able to eat adequately for 5 days

. A nurse is feeding a patient who reports feeling nauseated and unable to eat what is being offered. What would be the most appropriate initial action of the nurse in this situation?
a. Remove the tray from the room.
b. Administer an antiemetic and encourage the patient to take small amounts.
c. Explore why the patient does not want to eat the food.
d. Offer high-calorie snacks such as pudding and ice cream.

. A nurse is receiving report on a patient with alcoholism who will be transferred to the medical-surgical unit. Due to long-term alcohol exposure, the nurse plans for administration of which nutrient?
a. B vitamins
b. Lipids
c. Fluids
d. C vitamins

. A nursing student is caring for a patient who had a gastrostomy tube placement 12 hours ago. Which action by the student is correct?
a. Using a cotton-tipped applicator dipped into sterile saline solution and gently cleaning around the insertion site
b. Washing the area surrounding the tube with a wet washcloth and with soap and water.
c. Adjusting the external disk every 3 hours to avoid crusting around the tube.
d. Taping a gauze dressing over the site after cleansing it.
e. Assessing the gastric residual every 4 hours.
f. Discontinuing feedings when gastric residual volume is 120 mL.

. A nurse is assessing a patient who has been NPO (nothing by mouth) prior to abdominal surgery. The patient is ordered a clear liquid diet for breakfast, to advance to a house diet as tolerated. Which assessments would indicate to the nurse that the patient's diet should not be advanced?

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

a. The patient consumed 75% of the liquids on the breakfast tray.
b. The patient tells you they are hungry.
c. The patient's abdomen is soft, nondistended, with bowel sounds.
d. The patient reports fullness and diarrhea after breakfast.

. A patient hospitalized for a stroke has a prescription for continuous tube feedings through a small-bore nasogastric tube. Following tube placement, which action by the nurse best confirms correct tube placement?
a. Auscultating the bowel sounds
b. Measuring the pH of gastric aspirate
c. Measuring the amount of residual in the stomach
d. Ensuring validation of tube placement by x-ray

. A nurse specializing in care of older adults speaks to a group of nursing students about that population's challenge with obtaining sufficient nutrition. Which points will the nurse include in the discussion? Select all that apply.
a. An increase in BMR and physical activity require additional calories.
b. Tooth loss and periodontal disease may make chewing more difficult.
c. Decreased peristalsis can result in constipation, requiring additional fiber and fluid.
d. Loss of taste between sweet and salty occurs with a preference for sweets.
e. Older adults express an increase thirst sensation.
f. Caloric needs decrease, and the need for nutrients increases, especially protein.

. A nurse in the intensive care unit is reviewing diagnostic studies to evaluate a patient's nutritional status. What findings consistent with inadequate nutrition require follow-up by the nurse? Select all that apply.
a. Decreased hemoglobin
b. Low prealbumin level
c. Increased transferrin
d. Anemia
e. Elevated lymphocytes

. A nurse plans to administer a bolus tube feeding for a patient but is unable to aspirate gastric contents due to a clogged tube. What action will the nurse take next?
a. Use warm water or air, applying gentle pressure to remove the clog.
b. Use the tube's stylet to unclog the tubes.
c. Administer a cola beverage to remove the clog.
d. Replace the tube with a new one.

. A nurse performs presurgical assessments of patients in an ambulatory care center. Which patient assessment requires collaboration with the surgeon, as the procedure could need to be postponed?
a. 19-year-old patient who is a vegan
b. Older adult patient who takes daily nutritional drinks
c. 43-year-old patient who takes ginkgo biloba and an aspirin daily
d. Infant who is breastfeeding

. A nurse is caring for a patient with ill-fitting dentures. What modification to their diet will the nurse suggest?
a. Clear liquid
b. Full liquid
c. Mechanically altered
d. Honeylike liquids

ANSWERS WITH RATIONALES

. **a.** Example: Weight = 68 kg, height = 165 cm (1.65 m), Calculation: $68 \div (1.65)^2 = 24.98$

. **a, c, e.** Criteria to consider when evaluating patient feeding tolerance include absence of nausea, vomiting, minimal or no gastric residual, absence of diarrhea and constipation, absence of abdominal pain and distention, presence of bowel sounds within normal limits.

. **a.** To feed a patient with dementia, the nurse should stroke the underside of the patient's chin to promote swallowing, serve meals in the same place and at the same time, provide one food item at a time since a whole tray may be overwhelming, and provide between-meal snacks that are easy to consume using the hands.

. **b.** Food from home that the patient enjoys may stimulate them to eat. Pain medication should be given before meals, respiratory therapy should be scheduled after meals, and telling the patient what they must eat is no guarantee that they will comply.

- **c.** The nurse should provide a 30-minute rest period prior to mealtime to promote better swallowing. The nurse alternates solids and liquids when feeding the patient; sits the patient upright or, if on bedrest, elevates the head of the bed at a 90-degree angle; and initiates a nutrition consult for diet modification and food size and/or consistency. Straws are avoided in patients with dysphagia. Assessing breath sounds will help detect aspiration but not prevent it.
- **a, b, f.** Assessment criteria used to determine the need for PN include an inability to achieve or maintain enteral access, motility disorders, intractable diarrhea, impaired absorption of nutrients from the GI tract, and when oral intake has been or is expected to be inadequate over a 7- to 14-day period. PN promotes tissue healing and is a good choice for a patient with burns who has an inadequate diet with an increased need for calories and nutrients. Oral intake is the best method of feeding; the second-best method is via the enteral route. For short-term use (less than 4 weeks), a nasogastric or nasointestinal route is usually selected. A gastrostomy (enteral feeding) is the preferred route to deliver enteral nutrition in the patient who is comatose because the gastroesophageal sphincter remains intact, making regurgitation and aspiration less likely than with NG tube feedings. Patients who refuse to take food should not be force fed nutrients against their will.
- **a.** The first action of the nurse when a patient has nausea is to remove the tray, which may have noxious odor, from the room. The nurse may then offer small amounts of foods and liquids such as crackers or ginger ale. The nurse may also administer a prescribed antiemetic and try small amounts of food when it takes effect.
- **a.** The need for B vitamins is increased in alcoholism because these nutrients are used to metabolize alcohol, thus depleting their supply. Obesity, dehydration, and vitamin C deficiency may be present, but these are not directly related to the effect of alcohol on the GI tract.
- **a.** When caring for a new gastrostomy tube, the nurse would use a cotton-tipped applicator dipped in sterile saline to gently cleanse the area, removing any crust or drainage. The nurse would not use a washcloth with soap and water on a new gastrostomy tube but may use this method if the site is healed. Also, once the sutures are removed, the nurse should rotate the external bumper 90 degrees once a day. The nurse should leave the site open to air. If drainage is present, one thickness of precut gauze should be placed under the external bumper and changed as needed to keep the area dry.
- **d.** Tolerance to a diet can be assessed by the following: absence of nausea, vomiting, and diarrhea; absence of feelings of fullness; absence of abdominal pain and distention; feelings of hunger; and the ability to consume at least 50% to 75% of the food on the meal tray.
- **d.** Radiographic examination is the most accurate method to validate tube placement in the stomach. In addition, the length of the exposed tube is measured after insertion and documented. Tube length should be checked and compared with this initial measurement, in conjunction with the previous two methods for checking tube placement. Other methods that can be used are aspiration of gastric contents and measurement of the pH of the aspirate. Visual assessment of aspirated gastric contents is also suggested as a tool to check placement. The auscultatory method is considered inaccurate and unreliable. Measurement of residual volume amount does not confirm placement.
- **b, c, d, f.** Due to age-related changes, caloric needs of the body decrease; however, the need for nutrients, including protein, calcium, vitamin B_{12}, and vitamin D increase. If tooth loss and periodontal disease occur, adequate nutritional intake may become more difficult. An increase in fiber and fluid intake can relieve constipation related to decreased peristalsis. Older adults are also prone to dehydration related to loss of thirst sensation. Loss of taste between sweet and salty occurs with a preference for sweets. Dietary restrictions related to chronic illness, limited income, isolation, and age-related physiologic changes place persons in this age group at risk for malnutrition.
- **a, b, d, e**. Test results for hemoglobin (normal = 12 to 18 g/dL): decrease indicates anemia. Results for hematocrit (normal = 40% to 50%): decrease indicates anemia; increase indicates dehydration. Serum albumin and prealbumin tests for malnutrition and malabsorption will be decreased, as will transferrin and blood urea nitrogen. Elevated lymphocytes may indicate infection.
- **a.** To remove a clog in a feeding tube, the nurse should try using warm water or air and gentle pressure to unclog it. The stylet should never be used to unclog a tube, and cola and meat tenderizers have not been shown effective in removing clogs. The nurse should first attempt to remove the clog, and, if unsuccessful, the tube should be replaced.
- **c.** Patients taking gingko biloba (an herbal), aspirin, and vitamin E (dietary supplement) may have increased risk for excessive bleeding and may requiring surgery to be postponed. Being a vegan should not affect surgery unless the patient has serious nutritional deficiencies. Drinking nutritional drinks and breastfeeding do not adversely affect the outcomes of surgery.
- **c.** Mechanically altered diets provide adequate in calories and nutrients and contain chopped, ground, or soft foods. Liquid diets are generally used as transitional diets when eating resumes after acute illness, surgery, or parenteral nutrition. Clear-liquid diets are inadequate in calories, protein, and most nutrients; progression to more nutritious alternatives is recommended as soon as possible. Full-liquid diets include clear liquids plus milk and milk drinks, puddings, custards, plain frozen desserts, pasteurized eggs, cereal gruels, vegetable juices, and milk and egg substitutes in addition to clear liquids. A high-calorie, high-protein supplement is recommended if a full-liquid diet is used for more than 3 days.

Urinary Elimination

Elana Jaspers

Elana Jaspers, age 83, is experiencing a decreased ability to perform activities of daily living (ADLs) related to arthritis. After being hospitalized for pneumonia, Mrs. Jaspers moved into an extended-care facility. A short time after arrival in their new home, Mrs. Jaspers began having difficulty with urinary incontinence.

Anna Galinski

Anna Galinski, age 85, is frail and has numerous medical problems. She lives in a long-term care facility and, like many of the residents, was on a toileting regimen. Not long after a new charge nurse arrived, Anna, and the other residents who used to be on toileting regimens, had indwelling catheters inserted.

Midori Morita

Midori Morita, age 69, is taking care of her 70-year-old husband at home. Mrs. Morita asks, “Should I talk with my husband’s doctor about getting a urinary catheter? Ever since he came home from the hospital this last time, he seems unable to use the urinal. He dribbles urine constantly, and I can’t keep up with

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

the laundry. He had a catheter in the hospital."

Learning Outcomes

After completing the chapter, you will be able to accomplish the following:

. Describe the anatomy and physiology of the urinary system.
. Identify variables that influence urination.
. Assess urinary elimination, using appropriate interview questions and physical assessment skills.
. Perform the following assessment techniques: measure urine output, collect urine specimens, determine the presence of select abnormal urine constituents, determine urine specific gravity, and assist with diagnostic tests and procedures.
. Diagnose actual and potential health problems and needs related to urinary elimination that may be addressed through nursing intervention.
. Demonstrate interventions promote normal urination; facilitate use of the toilet, bedpan, urinal, and commode; perform catheterizations; and assist with urinary diversions.
. Describe nursing interventions that can be used to manage urinary incontinence effectively.
. Describe nursing interventions that can prevent the development of urinary tract infections.
. Plan, implement, and evaluate nursing care related to diagnoses/patient problems involving alterations in and related to nutrition.

voiding

Elimination from the urinary tract helps to rid the body of waste products and materials that exceed bodily needs. This chapter describes the anatomy and physiology of the urinary system and factors that affect **urination**, the process of emptying the bladder. A practical guide for assessing urinary elimination is included, along with detailed information on specific assessment measures, such as monitoring fluid intake, collecting urine specimens, testing urine, and assisting with other diagnostic procedures. Potential and actual health problems and needs related to urinary elimination are provided, and patient outcomes related to optimal urinary function are identified. This chapter presents nursing strategies to address these patient outcomes. The concluding care plan illustrates the use of specific nursing interventions to assist patients with urinary elimination problems and needs. Refer also to the accompanying Reflective Practice box (on page 1450).

ANATOMY AND PHYSIOLOGY

Kidneys and Ureters

The kidneys are located on either side of the vertebral column behind the peritoneum, in the upper abdominal cavity. One of the more significant functions of the kidneys is to help maintain the composition and volume of body fluids. About once every 30 minutes, the body's total blood volume passes through the kidneys for waste removal. The kidneys filter and excrete blood constituents that are not needed and retain those that are. Despite varying kinds and amounts of food and fluids ingested, body fluids remain relatively stable if the kidneys are functioning properly. **Urine**, the waste product excreted by the kidneys, contains organic, inorganic, and liquid wastes.

The nephron is the basic structural and functional unit of the kidneys. There are about 1 million nephrons in each kidney. Each nephron consists of a complicated system of arterioles, capillaries, and tubules. Nephrons remove the end products of metabolism, such as urea, creatinine, and uric acid from the blood plasma and form urine. The nephrons maintain and regulate fluid balance through the mechanisms of selective reabsorption and secretion of water, electrolytes, and other substances.

Once formed, urine from the nephrons empties into the pelvis of each kidney. From each kidney, urine is transported by rhythmic peristalsis through the ureters to the urinary bladder. The ureters enter the bladder obliquely. A fold of membrane in the bladder closes the entrance to the ureters so that urine is not forced up the ureters to the kidneys when pressure exists in the bladder. Figure 38-1 (on page 1451) shows the urinary systems for patients with male and female genitalia and the position of the kidneys and ureters in the abdomen.

Bladder

The urinary bladder is a smooth muscle sac that serves as a temporary reservoir for urine. It is composed of three layers of muscle tissue: the inner longitudinal layer, the middle circular layer, and the outer longitudinal layer. These three layers are called the detrusor muscle. At the base of the bladder, the middle circular layer of muscle tissue forms the internal, or involuntary, sphincter, which guards the opening between the urinary bladder and the urethra. The urethra conveys urine from the bladder to the exterior of the body.

The urinary bladder muscle is innervated by the autonomic nervous system. The sympathetic system carries inhibitory impulses to the bladder and motor impulses to the internal sphincter. These impulses cause the detrusor muscle to relax and the internal sphincter to constrict, retaining urine in the bladder. The parasympathetic system carries motor impulses to the bladder and inhibitory impulses to the internal sphincter. These impulses cause the detrusor muscle to contract and the sphincter to relax. The urinary bladder is shown in Figure 38-2 on page 1451.

QSEN Reflective Practice: Cultivating QSEN Competencies

CHALLENGE TO ETHICAL SKILLS

We had a strange experience during our rotation in a community long-term care facility. I was assigned to care for Anna Galinski, an 85-year-old frail adult with numerous medical problems. Like many of the residents, Mrs. Galinski was on a toileting regimen. Interventions to enhance resident safety and reduce health care–associated infections (HAIs) in long-term care facilities are an important focus and include reducing indwelling catheter use and catheter-associated urinary tract infection (CAUTI). In the middle of our 7-week experience, a new charge nurse started working on our unit. All of a sudden, Anna and the other residents who used to be on toileting regimens were given indwelling catheters. Knowing the greatly increased risk of infections with indwelling catheters, we suspected that the decision to rely on indwelling catheters was more a matter of convenience for the staff than what was in the best interests of the residents. How do you advocate for the patients and challenge the actions of a charge nurse?

Thinking Outside the Box: Possible Courses of Action

- Don’t rock the boat! In 3 weeks, we’d be out of there. Keep our mouths shut and don’t challenge authority.
- Ask for a meeting with the new charge nurse to explain our concerns, bringing our instructor for support. Be willing to go higher if the charge nurse cannot justify their decision and refuses to respond to our concerns.
- Work around the problem and try to get the residents’ families to raise the issue.

Evaluating a Good Outcome: How Do I Define Success?

- Decisions are made about indwelling catheters that benefit and do not harm residents.
- I am faithful to my advocacy responsibilities within the current scope of my practice as a third-year student.
- I learn how to make the health care system work for patients/residents.
- I learn how to constructively challenge a health care provider or colleague.

Personal Learning: Here’s to the Future!

This turned into a painful experience that made me realize just how difficult it can be to be an effective advocate for patients and residents. I am also newly aware of just how vulnerable long-term care facility residents are. A group of four students and myself asked to meet with the charge nurse. When we told them our concerns, they tried to justify their decision, but we still couldn’t see any proof that the decision was made to benefit residents. Regrettably, they didn’t respond to our concerns about infections at all. Because they were adamant about keeping the catheters, we told them that we would take the matter higher. Ultimately, we had to go all the way to the medical director, after thoroughly researching our concerns and getting lots of support for the argument we were making. In the process, the charge nurse made horrible accusations about us, threatening to ensure that students from our school would never work in the facility again. Eventually, all was well that ended well. The charge nurse was “relieved of their administrative responsibilities” and our good names were restored. However, the process that we went through was difficult.

QSEN SELF-REFLECTION ON QUALITY AND SAFETY COMPETENCIES DEVELOPING KNOWLEDGE, SKILLS, AND ATTITUDES FOR CONTINUOUS IMPROVEMENT

How do you think you would respond in a similar situation? Why? What does this tell you about yourself and about the adequacy of your skills for professional practice? Do you agree with the criteria that the nursing student used to evaluate a successful outcome? Are there any other criteria that would be appropriate to use? Did the nursing student meet the criteria? Why or why not? What *knowledge, skills,* and *attitudes* do you need to develop to continuously improve the quality and safety of care for patients like Anna Galinski?

Patient-Centered Care: What resources could you or the nurses use as a basis to provide compassionate and appropriate care based on respect for the patient’s needs? How did the nursing student act as a patient advocate? Was the human dignity of the patient maintained?

Did the nursing students act appropriately? Legally? Ethically? Why or why not?

Teamwork and Collaboration/Quality Improvement: What communication skills do you need to improve

to ensure that you function as a member of the patient-care team? What skills do you need to implement effective strategies for communicating and resolving conflict? What skills do you need to assert your own position/perspective in discussions about patient care? What other services or resources might be available to aid in this type of decision-making process?

Safety/Evidence-Based Practice: What skills do you need to improve to ensure that patients in your care receive the best nursing care possible? What evidence for practice provides guidance for decision making regarding care of this patient? What issues or factors might have played a role in the charge nurse's response? The students' responses? Do you think that the charge nurse would have responded differently if the students had included their instructor in the meeting?

Informatics: Can you identify the essential information that must be available in Mrs. Galinski's electronic health record to support safe patient care and coordination of care? Can you think of other ways to respond to or approach the situation?

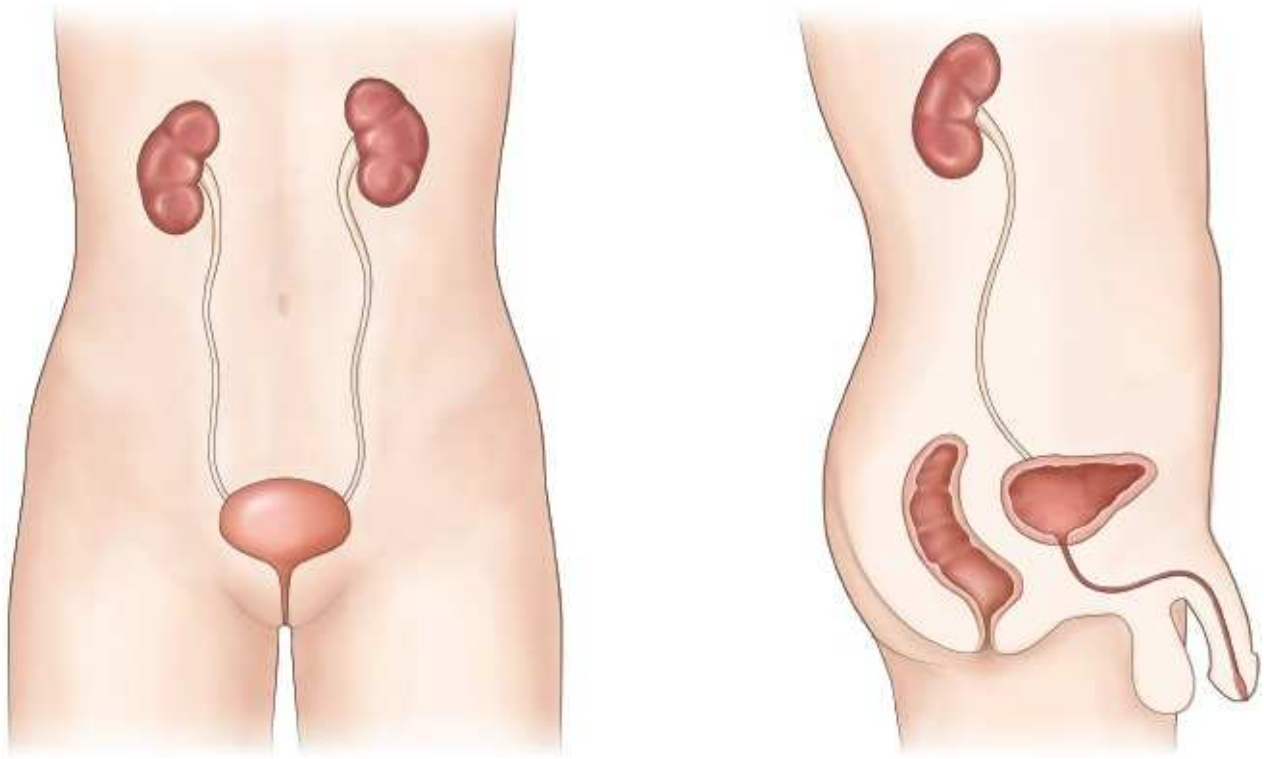

FIGURE 38-1. Frontal view of the female urinary tract **(left)** and lateral view of the male urinary tract **(right)**

The bladder normally contains urine under very little pressure. As the volume of urine increases, the pressure increases only slightly. The bladder wall is able to adapt to this pressure because of the muscle tissue in the bladder. This makes it possible for urine to continue to enter the bladder from the ureters against low pressure. When the pressure becomes sufficient to stimulate nerves in the bladder wall (stretch receptors), the person feels a desire to empty the bladder.

Urethra

The urethra's function is to transport urine from the bladder to the exterior of the body. The anatomy of the urethra differs in patients with male and female genitalia. The male urethra functions in the excretory system and the reproductive system. It is about 8 inches (20 cm) long and consists of three parts: the prostatic, the membranous, and the cavernous portions (Fig. 38-3). The external urethral sphincter consists of striated muscle and is located just beyond the prostatic portion of the urethra. The external sphincter is under voluntary control. The female urethra is about 1.6 inches (4 cm) long (Norris, 2020). The external, or voluntary, sphincter is located in the middle of the urethra (see Fig. 38-2). No portion of the female urethra is external to the body, as in the male.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

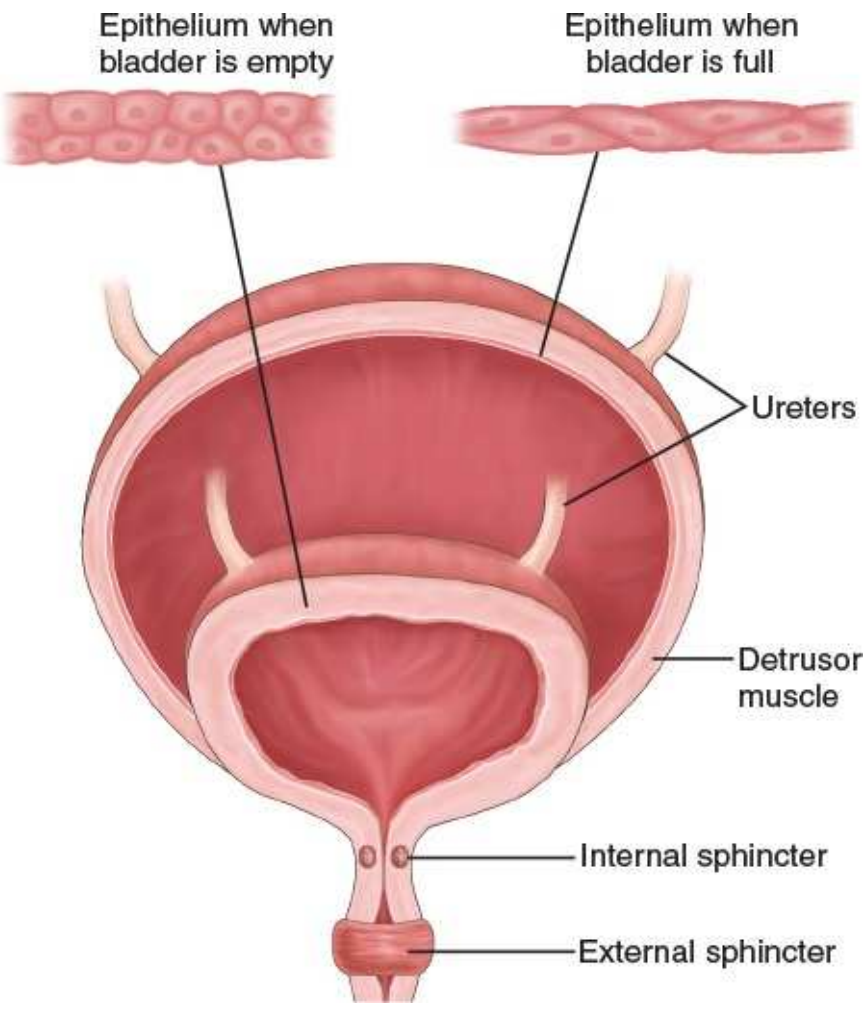

FIGURE 38-2. The urinary bladder.

Act of Urination

The process of emptying the bladder is known as urination, **micturition**, or **voiding** (void). The nerve centers for urination are situated in the brain and the spinal cord. Urinating, or voiding, is largely an involuntary reflex act, but its control can be learned. The voluntary control of urination develops as the higher nerve centers develop after infancy. Until that time, voiding is purely a reflex action. People whose bladders are no longer controlled by the brain because of injury or disease also void by reflex only. This is called **autonomic bladder**.

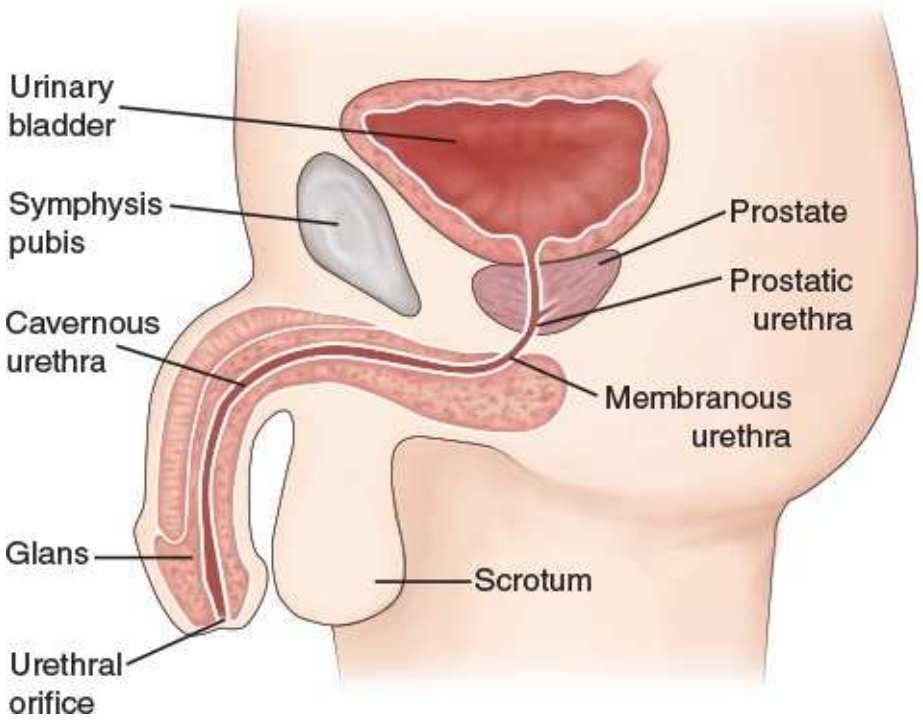

FIGURE 38-3. Parts of the male urethra.

Stretch receptors in the bladder are stimulated as the urine collects. The person feels a desire to void, usually when the bladder fills to about 150 to 250 mL in an adult. The pressure within the bladder is many times greater during urination than it is during the time the bladder is filling. When urination is initiated, the detrusor muscle contracts, the internal sphincter relaxes, and urine enters the posterior urethra. The muscles of the perineum and the external sphincter relax, the muscle of the abdominal wall contracts slightly, the diaphragm lowers, and urination occurs.

The act of urination is normally painless. The voluntary control of voiding is limited to initiating, restraining, and interrupting the act. Restraint of voiding is thought to occur subconsciously when the volume of urine in the bladder is small. If voiding is delayed, however, the bladder continues to fill. Discomfort may then be felt when undue distention occurs, and the urgency to void becomes paramount.

Sometimes, increased abdominal pressure—such as occurs during coughing and sneezing—forces an involuntary escape of urine. This is a particular problem for some people with female genitalia because the urethra is shorter. Any involuntary loss of urine that causes such a problem is referred to as **urinary incontinence**. Urinary incontinence is

discussed in detail later in the chapter. Strong psychological factors, such as marked fear, may also result in involuntary urination. Alternatively, in certain conditions, it may be difficult for a person to relax the restraining muscles sufficiently to void, such as when a shy or embarrassed person needs to give a urine specimen.

Frequency of Urination

The frequency of urination depends on the amount of urine being produced. The more urine produced, the more often voiding is necessary. Except when fluid intake is very large, most healthy people do not void during normal sleeping hours. The first voided urine of the day is usually more concentrated than other urine excreted during the day. Because the first urine of the day is not fresh, but rather an accumulation of a number of hours of kidney output, this urine may or may not be used as a specimen for certain tests.

Some people normally void small amounts at frequent intervals because they habitually respond to the first early urge to void. This habit usually is meaningless and is not necessarily an indication of disease. On the other hand, if this pattern occurs as a change in urination routine, it may indicate illness. Other people have habits of infrequent voiding. For example, some people go 8 to 12 waking hours or longer without urinating. A habitual low fluid intake or a decrease in the sensation of thirst associated with aging may be one reason. The inaccessibility of toilet facilities owing to travel, work circumstances, or illness, as well as limitations in mobility, can also lead to infrequent urination. People who habitually urinate infrequently develop more urinary tract infections (UTIs) and kidney disorders than those who urinate at least every 3 to 4 hours. The reason for this is believed to be stagnation of urine in the bladder, which serves as a good medium for bacterial growth. Newly occurring infrequent voiding can also indicate a decreased production of urine caused by a kidney or circulatory disorder. **Urinary retention** occurs when urine is produced normally but is not excreted completely from the bladder. Factors associated with urinary retention include medications, an enlarged prostate, or vaginal prolapse.

FACTORS AFFECTING URINATION

Numerous factors affect the amount and quality of urine produced by the body and the manner in which it is excreted.

Developmental Considerations

Infants are born without voluntary control of urination and with little ability to concentrate urine. An infant's urine is usually very light in' color and without odor. At about age 6 weeks, the infant's nephrons are able to control reabsorption of fluids in the tubules and effectively concentrate urine. As a child grows, the bladder gradually enlarges, with an increase in capacity. Most children develop urinary control between ages 2 and 5 years. Daytime control precedes nighttime control, and girls generally develop control earlier than boys. Older children and adults control urination voluntarily. They seldom wake to void at night because their kidneys are able to concentrate urine and produce less urine at night as a result of decreased renal blood flow.

Toilet Training

Voluntary control of the urethral sphincters occurs between ages 18 and 24 months. However, many other factors are required to achieve conscious control of bladder function. Toilet training usually begins at about age 2 to 3 years.

Assessment of a child's readiness for toilet training includes (American Academy of Pediatrics [AAP], n.d.; Kyle & Carman, 2021):

- Ability to indicate wants and needs verbally
- Motor skills to sit on and rise from the potty chair
- Showing an interest in the potty
- Ability to hold urine for a period of time (as indicated by diapers not always being wet)
- Willingness to follow instructions

The child's desire to gain control is also important. Wanting to be like a parent or older sibling often provides adequate motivation. Lifelong attitudes toward urination, the body, and cleanliness may develop during the time of toilet training.

Cultures approach toilet training differently. In some cultures, toilet training begins before the child is 1 year old; in other cultures, it may not be considered until the child is near 5 years old. It is important to recognize cultural influences on this parenting responsibility while promoting flexibility. Reassure parents that any regression of toileting skills that occurs during a child's illness or hospitalization is to be expected and is usually short-lived.

Occasional daytime incontinence of urine in a child is usually not a cause for concern. Continued incontinence of urine past the age of toilet training is termed **enuresis**. Nocturnal enuresis (nighttime bedwetting) usually subsides by age 6 years (Kyle & Carman, 2021).

Effects of Aging

Physiologic changes that accompany normal aging may affect urination in older adults. These changes include the following:

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

- The diminished ability of the kidneys to concentrate urine may result in **nocturia** (the need to wake up at night in order to urinate [Weiss, 2020]).
- Decreased bladder muscle tone may reduce the capacity of the bladder to hold urine, resulting in increased frequency of urination.
- Decreased bladder contractility may lead to urine retention and stasis, which increases the likelihood of UTI.
- Neuromuscular problems, degenerative joint problems, alterations in thought processes, and weakness may interfere with voluntary control and the ability to reach a toilet in time.

Medications prescribed for other health problems in the older adult may interfere with bladder function. For example, diuretics cause increased urine production, resulting in the need for increased urination and possibly **urge incontinence** (the involuntary loss of urine that occurs soon after feeling an urgent need to void). Sedatives and tranquilizers may diminish awareness of the need to void.

Consider **Midori Morita's** 70-year-old husband who has been experiencing urinary problems since their last hospitalization. The nurse would need to keep in mind age-related changes during assessment of Mr. Morita in order to determine if they are experiencing urinary problems related to these changes or if they are due to another cause.

Food and Fluid Intake

When the body is functioning well, the kidneys help the body maintain a careful balance of fluid intake and output, which should be about equal. When the body is dehydrated, the kidneys reabsorb fluid. The urine produced is more concentrated and is decreased in amount. Conversely, with fluid overload, the kidneys excrete a large quantity of dilute urine.

Alcohol produces a diuretic effect by inhibiting the release of antidiuretic hormone, increasing urine production. Foods high in water may increase urine production. Foods and beverages with high sodium content cause sodium and water reabsorption and retention, thereby decreasing urine formation. Certain foods may affect the odor of the urine (asparagus, onions) or its color (beets).

Psychological Variables

Many individual, family, and sociocultural variables influence a person's usual voiding habits. For some people, voiding is a personal and private act—something one does not talk about. Needing assistance with a bedpan or urinal may provoke great embarrassment and anxiety, especially when the bedpan is offered by a nurse of the opposite sex assigned at birth. For others, voiding is a natural act that does not cause embarrassment; these people readily excuse themselves to void whenever the urge presents.

Some people who experience stress void smaller amounts of urine at more frequent intervals. Stress can also interfere with the ability to relax the perineal muscles and the external urethral sphincter. When this happens, the person may feel an urge to void, but emptying the bladder completely becomes difficult or impossible.

Activity and Muscle Tone

Among the many benefits of regular exercise are increased metabolism and optimal urine production and elimination. During prolonged periods of immobility, decreased bladder and sphincter tone can result in poor urinary control and urinary stasis. People with indwelling urinary catheters lose bladder tone because the bladder muscle is not being stretched by the bladder filling with urine. Other causes of decreased muscle tone include childbearing, muscle atrophy due to decreased estrogen levels as seen with menopause, and damage to muscles from trauma.

Pathologic Conditions

Certain renal or urologic problems can affect both the quantity and the quality of urine produced. Diseases associated with renal problems include congenital urinary tract abnormalities, polycystic kidney disease, **urinary tract infection (UTI)**, urinary calculi (kidney stones), hypertension, diabetes, gout, and certain connective tissue disorders. Renal failure is a condition in which the kidneys fail to remove metabolic end products from the blood and are unable to regulate fluid, electrolyte, and pH balance. Acute kidney injury (AKI) is a sudden decline in kidney function (over hours or within a day [Norris, 2020]), and may be caused by conditions such as severe dehydration, anaphylactic shock, sepsis,

and ureteral obstruction. AKI is potentially reversible if recognized early, the precipitating factors can be corrected or removed, and it is treated appropriately before permanent kidney damage has occurred (Norris, 2020). Chronic kidney disease (CKD) is the slow loss of kidney function over months or years as a result of irreparable damage to the kidneys. CKD is caused by conditions such as diabetes, hypertension, and glomerulonephritis. Progression of CKD will eventually lead to the final stage of CKD, known as kidney (renal) failure or end-stage renal disease (ESRD). In kidney failure, kidney function drops below 15%, and the kidneys are unable to adequately excrete metabolic waste and regulate fluid and electrolyte balance (NIDDK, 2018a).

Diseases that reduce physical activity or lead to generalized weakness, such as arthritis, Parkinson's disease, and degenerative joint disease, may interfere with toileting. Cognitive deficits and certain psychiatric problems can interfere with a person's ability or desire to control urination voluntarily. Fever and diaphoresis (profuse perspiration) result in body fluid conservation by the kidneys, in which urine production is decreased, and the urine is highly concentrated. Other pathologic conditions, such as heart failure, may lead to fluid retention and decreased urine output. High blood glucose levels, such as with diabetes, may lead to an increase in urine output secondary to an osmotic diuretic effect.

Medications

Medications have numerous effects on urine production and elimination. Of gravest concern are the many prescription and nonprescription drugs known to be **nephrotoxic** (capable of causing kidney damage). Abuse of analgesics, such as aspirin or ibuprofen, can cause nephrotoxicity. Some antibiotics, such as gentamicin, can be nephrotoxic as well.

Diuretics, which commonly are used in the treatment of hypertension and other disorders, prevent the reabsorption of water and certain electrolytes in the tubules. Depending on the dose of the drug, diuretics cause moderate to severe increases in production and excretion of dilute urine. Cholinergic medications stimulate contraction of the detrusor muscle and produce urination. Some analgesics and tranquilizers suppress the central nervous system, interfering with urination by diminishing the effectiveness of the neural reflex.

Certain drugs cause urine to change color, including the following:

- Anticoagulants may cause **hematuria** (blood in the urine), leading to a pink or red color.
- Diuretics can lighten the color of urine to pale yellow.
- Phenazopyridine, a urinary tract analgesic, can cause orange or orange-red urine.
- The antidepressant amitriptyline or B-complex vitamins can turn urine green or blue-green.
- Levodopa (L-dopa), an antiparkinson drug, and injectable iron compounds can lead to brown or black urine.

NURSING PROCESS FOR URINARY ELIMINATION

Assessing

A comprehensive nursing assessment of the functioning of a patient's urinary system includes the following:

- Collection of data about the patient's voiding patterns, habits, and difficulties and a history of current or past urinary problems
- Assessment of the bladder, if indicated, and urethral meatus; assessment of skin integrity and hydration; and examination of the urine
- Correlation of these findings with the results of diagnostic tests and procedures for examining the urine and the urinary tract

Recall **Anna Galinski**, the 85-year-old frail individual living in a long-term care facility. Initially, Ms. Galinski was placed on a toileting regimen, but now they and other patients on the unit have indwelling catheters. In determining how to respond to the situation, it would be helpful for the nurse to perform a comprehensive assessment of the patient. Doing so would provide information to substantiate whether or not catheter insertion was indicated or still appropriate.

Nursing History

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

A nursing history should include questions for the patient (or caregiver) about usual voiding habits and any current or past voiding difficulties. Box 38-1 lists some additional terms that can be used to describe several urinary problems. When interacting with patients, use terminology that the patient and/or the caregiver understands. The accompanying Focused Assessment Guide 38-1 lists elements of a urinary elimination history that should be incorporated into the initial nursing assessment.

When caring for infants, assess the number of wet diapers per day that the infant produces. Newborns should have six to eight wet diapers per day (Kyle & Carman, 2021). With young children, assess whether the child has achieved bladder control during both day and nighttime. Be sure to indicate on the nursing history and care plan the words that the child uses to indicate the need to void.

Decreased bladder tone may be a problem for older adults. Explore any problems, how the person normally handles these problems, and your judgment of the adequacy of the solution while obtaining the nursing history.

Box 38-1 Additional Terms Used to Describe Urinary Problems

Anuria: 24-hour urine output is less than 50 mL
Dysuria: Painful or difficult urination
Frequency: Increased incidence of voiding
Glycosuria: Presence of glucose in the urine
Nocturia: Awakening at night to urinate
Oliguria: 24-hour urine output is less than 400 mL
Polyuria: Excessive output of urine (diuresis)
Proteinuria: Protein in the urine
Pyuria: Pus in the urine
Urgency: Strong desire to void
Urinary incontinence: Involuntary loss of urine

Patients with urinary diversions may have established individualized personal care routines. A **urinary diversion** involves the surgical creation of an alternate route for excretion of urine and is discussed later in the chapter. Assess the procedures and equipment used by patients to make sure they follow accepted guidelines and do not predispose themselves to infection or other risk. Record in both the history and the care plan any special routine, equipment, or supplies the patient uses for urinary elimination.

Focused Assessment Guide 38-1

URINARY ELIMINATION

Factors to Assess	Questions and Approaches
Usual patterns of urinary elimination	How often do you urinate (pass your water) during the day? Do you awaken at night to empty your bladder? How would you describe your urine?
Recent changes in urinary elimination	Have you noticed any changes in your usual urinary patterns (frequency, amount, force of stream, difficulty, comfort)? Do you ever leak urine (e.g., on your way to the bathroom or when you sneeze or cough)? Do you ever notice that your undergarments are wet or damp?
Aids to elimination	Is there anything you do that helps you to urinate?
Present or past occurrence of voiding difficulties (nature of problem, onset, frequency, causes, severity, symptoms, intervention attempted, results)	Tell me about any problems you are having now when you urinate (urgency, pain or burning, difficulty starting or stopping stream, dribbling, incontinence). If there is a problem, describe what you feel like before you urinate and while you are urinating. Have you had any urinary problems in the past (any history of urinary tract infections, kidney or bladder disease or problems)? Do you use any type of absorbent pad or product to protect your clothes?
Presence of urinary diversion (normal routine, history of problems)	Tell me about your usual routine with your ileal conduit.

When a patient (or caregiver) reports a problem with voiding, explore its duration, severity, and precipitating factors. Also, note the patient's perception of the problem and the adequacy of the patient's self-care behaviors.

Remember **Midori Morita**, the wife of the 70-year-old individual experiencing problems with "dribbling." The nurse would need to question Mr. and Mrs. Morita about the problem, obtaining specific information such as when it started, how often it occurs, how much the patient is voiding, events of the previous hospitalization, and any factors associated with it such as use of medications, increased fluid intake, or changes in mobility.

Physical Assessment

The physical assessment of urinary functioning includes an examination of the urinary bladder, if indicated, urethral meatus, skin, and urine. The kidneys are normally well protected by considerable fat and connective tissue, making palpation difficult. Palpation of the kidneys is usually performed as part of a more detailed assessment. This technique requires deep palpation and is generally assessed by advanced health care professionals, such as an advanced practice nurse or health care provider.

BLADDER

Assessment of the bladder may be indicated when patients experience difficulty voiding or other alterations in elimination. The bladder is normally positioned below the symphysis pubis and cannot be palpated or percussed when empty. When the bladder is distended, it rises above the symphysis pubis and may reach to just below the umbilicus (Fig. 38-4). Before palpating the bladder, always inquire as to when the patient last voided. Observe the lower abdominal wall, noting any swelling, and palpate this area for tenderness. If distended, note the height of the edge of the bladder above the symphysis pubis.

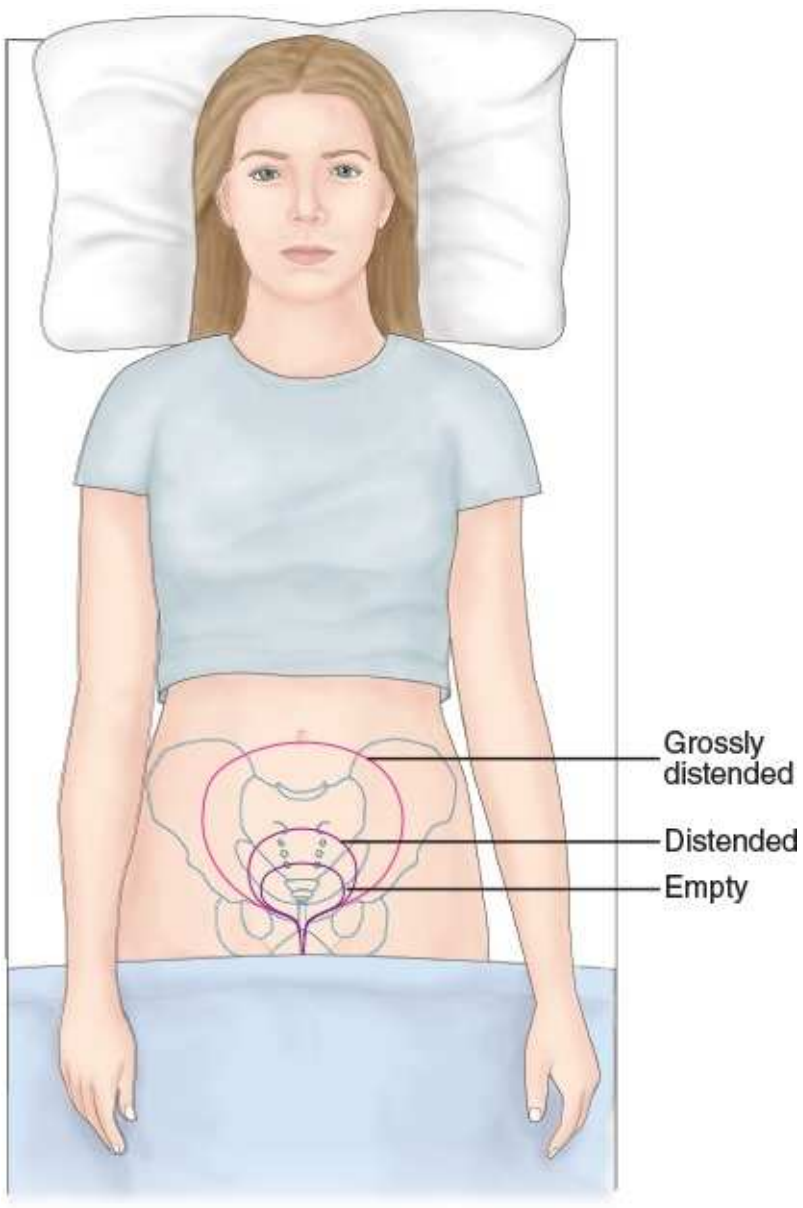

FIGURE 38-4. Position of bladder when empty and distended.

A bedside scanner is another commonly used method to assess the fullness of the bladder. These portable bladder ultrasound devices create an image of the patient's bladder and calculate urine volume present in the bladder. This

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

method is noninvasive and painless. A bladder scan can be performed at the bedside, poses little risk for infection, and is a safer alternative to catheterization to determine bladder urine volume (Widdall, 2015). Results are most accurate when the patient is in the supine position during the scanning. Skill 38-1 outlines the procedure for assessing bladder volume using an ultrasound bladder scanner.

URETHRAL ORIFICE

Inspect the urethral orifice for any signs of inflammation, discharge, or foul odor. In patients with female genitalia, the urethral meatus is a slit-like opening below the clitoris and above the vaginal orifice. Place patients with female genitalia in the dorsal recumbent position with the inner labia retracted for good visualization of the meatus. In patients with male genitalia, the meatus is at the tip of the penis. If the patient with male genitalia is uncircumcised, retract the foreskin to visualize the meatus.

SKIN INTEGRITY AND HYDRATION

Because problems with urinary functioning may result in disturbances in hydration and excretion of body wastes, assess the skin carefully for color, texture, and turgor. Assess the integrity of the skin in the perineal area. Problems with incontinence may result in severe excoriation (abrasion of the epidermis). Additional information related to assessment of the skin is discussed in Chapters 27 and 33.

Recall **Elana Jaspers**, the older person who is experiencing urinary incontinence and a decreased ability to perform ADLs. Inspecting the perineal area would be extremely important when assessing Mrs. Jaspers, whose problems with urinary incontinence and decreased mobility place them at increased risk for changes in skin integrity.

Urine Characteristics

Assess the patient's urine for color, odor, clarity, and the presence of any sediment. Note any abnormalities. In select patients, monitor the pH and **specific gravity** of the urine (which is a measure of the density of urine compared with the density of water) and check the urine for abnormal constituents such as protein, blood, glucose, ketone bodies, and bacteria (see the section entitled Point-of-Care Urine Testing). The normal characteristics of urine are detailed in Table 38-1.

Additional Assessment Techniques

In addition to the nursing history and physical examination, the nurse gathers data about urinary elimination through the following assessment measures: measuring urine output, collecting urine specimens, performing point-of-care urine testing, and assisting with diagnostic procedures. These are discussed in the following sections.

MEASURING URINE OUTPUT

Measuring the patient's fluid intake and output is an important nursing responsibility. Accuracy of the total fluid intake and output from all sources aids in identifying potential alterations in fluid balance and is essential for planning the patient's nursing care, as well as medical care. The measurement of fluid intake and output is described further in Chapter 41. Gloves are required when handling urine to prevent exposure to pathogenic microorganisms or blood that may be present in the urine. Goggles also are worn whenever there is a concern of urine splashing. The measurement of fluid intake and output may be delegated to assistive personnel. However, the nurse is responsible for ensuring that staff members understand the required procedures, and the nurse must validate the accuracy of the measurements.

Measuring Urine Output in Patients Who Are Continent

Patients who have self-control over urination are **continent** of urine. Several devices used to collect or measure urine are shown in Figures 38-5A, B. The procedure for measuring the urine output of a patient who is continent is outlined in Box 38-2. To ensure that all voided urine is measured, be sure to tell patients when their urine output is to be measured and recorded. A specimen hat is a valuable device that can be placed under the toilet seat to collect and measure voided urine for patients who use the bathroom (see Fig. 38-5B). Patients who are willing and able can be

taught to measure and record their own output. The procedure for measuring the urine output of a patient who is continent is outlined in Box 38-2 on page 1458.

Measuring Urine Output in Patients Who Are Incontinent

Urinary incontinence is the involuntary or uncontrolled loss of urine from the bladder. Patients who experience involuntary or uncontrolled loss of urine are **incontinent**. It is difficult to accurately measure urinary output for incontinent patients. Note the number of times the patient is incontinent and any notable urine characteristics, such as color and odor. Additional nursing interventions are required to collect urine for measurement. Use of scheduled toileting (assisting the patient to the toilet to attempt to void on a regular basis, such as every 2 hours) can assist in obtaining urine for measurement and for required laboratory specimens and in preventing incontinence. External collecting devices are useful in managing urinary incontinence and provide a mechanism to measure urinary output (Vasavada et al., 2019a). An innovative alternative technique has been suggested in the evidence for practice. Measurement of urinary output via weighing of absorbent pads has been used successfully to monitor urinary output in patients who are incontinent, as well as to reduce use of indwelling urinary catheters (Beuscher, 2014). This initiative is similar to the commonly used practice of weighing diapers to obtain accurate urinary output in nontoilet-trained pediatric settings. The dry pad weight is subtracted from the wet pad weight. The resulting difference in gram weight is then converted to milliliters (1 g = 1 mL) (Beuscher, 2014).

Table 38-1 Characteristics of Urine

CHARACTERISTIC	NORMAL FINDINGS	SPECIAL CONSIDERATIONS
Color	A freshly voided specimen is pale yellow, straw-colored, or amber, depending on its concentration.	Urine is darker than normal when it is concentrated. Urine is lighter than normal when it is diluted. Certain drugs, such as cascara, L-dopa, and sulfonamides, alter the color of urine. Some foods can alter the color; for example, beets can cause urine to appear red.
Odor	Normal urine smell is aromatic. As urine stands, it often develops an ammonia odor because of bacterial action.	Some foods cause urine to have a characteristic odor; for example, asparagus causes urine to have a strong, musty odor. Urine high in glucose content has a sweet odor. Urine that is heavily infected has a fetid odor.
Turbidity	Fresh urine should be clear or translucent; as urine stands and cools, it becomes cloudy.	Cloudiness observed in freshly voided urine is abnormal and may be due to the presence of red blood cells, white blood cells, bacteria, vaginal discharge, sperm, or prostatic fluid.
pH	The normal pH is 5–6, with a range of 4.5–8. Urine becomes alkaline on standing when carbon dioxide diffuses into the air. Urine alkalinity or acidity may be promoted through diet to inhibit bacterial growth or urinary stone development or to facilitate the therapeutic activity of certain medications.	A high-protein diet causes urine to become excessively acidic. Certain foods tend to produce alkaline urine, such as citrus fruits, dairy products, and vegetables, especially legumes. Certain foods such as meats tend to produce acidic urine. Certain drugs influence the acidity or alkalinity of urine; for example, ammonium chloride produces acidic urine, and potassium citrate and sodium bicarbonate produce alkaline urine.
Specific gravity	This is a measure of the density of the	Concentrated urine will have a higher-

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

	chemicals and particles in the urine and is a measure of the ability of the kidneys to concentrate urine. The normal range is 1.015–1.025.	than-normal specific gravity; diluted urine will have a lower-than-normal specific gravity. In the absence of kidney disease, a high specific gravity usually indicates dehydration, and a low specific gravity indicates overhydration.
Constituents	*Organic* constituents of urine include urea, uric acid, creatinine, hippuric acid, indican, urene pigments, and undetermined nitrogen. *Inorganic* constituents are ammonia, sodium, chloride, traces of iron, phosphorus, sulfur, potassium, and calcium.	*Abnormal constituents* of urine include blood, pus, albumin, glucose, ketone bodies, casts, gross bacteria, and bile.

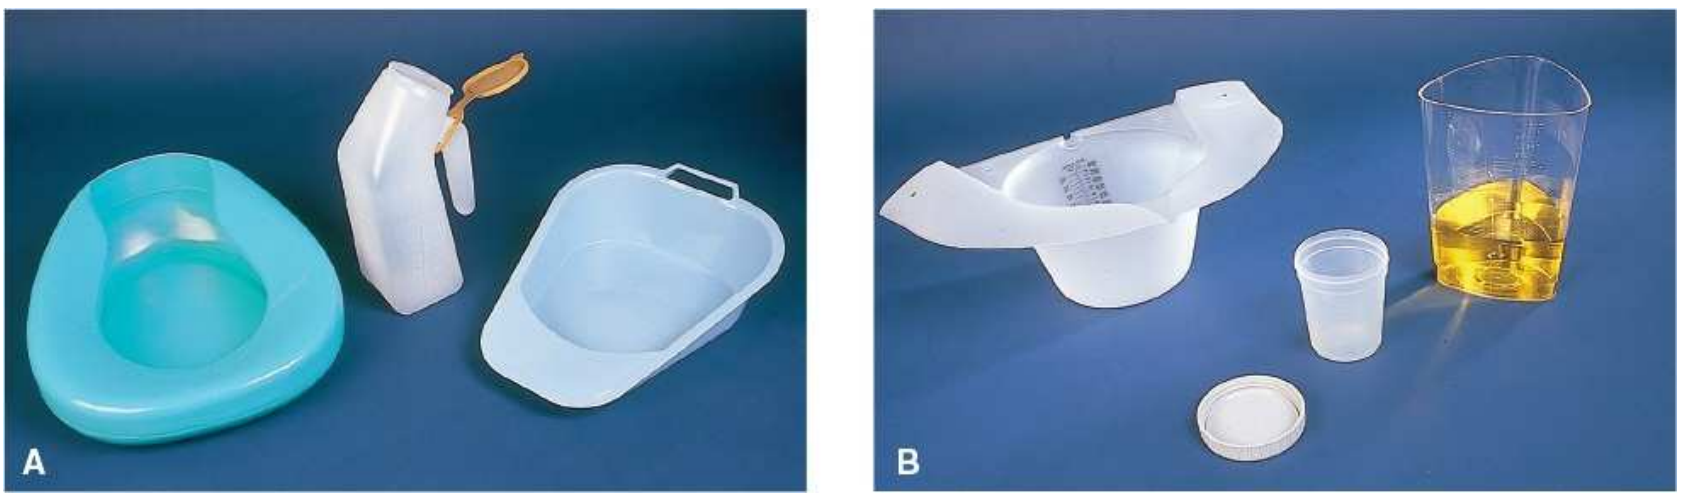

FIGURE 38-5. Devices for collecting and measuring urine. **A.** (**left** to **right**) Bedpan, urinal, and fracture pan. **B.** (**left** to **right**) Specimen hat: container that is placed anteriorly on the toilet, underneath the seat to collect urine; specimen cup: container that holds urine; calibrated measuring device: container to accurately measure urine output.

Urinary incontinence and associated nursing care interventions are discussed in more detail later in the chapter.

Box 38-2 **Measuring Urine Output in Continent Patients**

1. Ask the patient to void into a bedpan, urinal, or specimen hat (container), either in bed or in the bathroom. Urinary devices used to collect or measure urine are shown in Figure 38-5.
2. Put on gloves. Pour the urine from the collection device into the appropriate measuring device provided by the facility (examples are provided in Figure 38-5B). The devices are calibrated in milliliters. Collection devices may be calibrated for measurement, eliminating the need for an additional measuring device.
3. Place the calibrated container on a flat surface, such as a shelf, for an accurate reading. Reading at eye level, note the amount of urine voided and record it in the patient's electronic record. Record the total amount voided during each shift. The total for the 24-hour period is usually calculated by the electronic documentation software.
4. Discard the urine in the toilet unless a specimen is required. If a specimen is required, pour the urine into an appropriate specimen container.

Measuring Urine Output in Patients With an Indwelling Catheter

Indwelling urethral catheters are connected to a drainage and collection system (see Fig. 38-6), and the urine collected in the drainage bag is measured to calculate urine output. The procedure for measuring the urine output of a patient with an indwelling catheter is outlined in Box 38-3. Catheterized patients who are acutely ill may require hourly or even more frequent measurements of urine. This is facilitated by using a special collection bag that has a built-in calibrated measuring chamber called a urimeter (see Fig. 38-6A). After assessing and recording the amount of urine produced hourly, tilt the measuring chamber on the urimeter so that this urine flows into the general collection bag. This empties the measuring chamber, making it ready to collect the next hour's urine.

Box 38-3 **Measuring Urine Output in Patients With an Indwelling Urinary Catheter**

1. Put on gloves.
2. Place a calibrated measuring device (Fig. 38-5) beneath the urine collection bag (Fig. 38-6). To prevent the spread of infection, patients should have their own calibrated measuring device.
3. Place the drainage spout from the collection bag above, but not touching, the calibrated measuring device, and open the clamp.
4. Allow the urine to flow from the collection bag into the measuring device.
5. Reclamp the drainage tube, wipe the spout of the tube with an alcohol pad, and replace the tube into the slot on the drainage bag. Proceed with measurement of urine as described earlier.

COLLECTING URINE SPECIMENS

Various techniques are used for collecting urine specimens. The nurse needs to understand the rationale for the specific test ordered, as well as the correct collection procedure associated with the required test in order to ensure obtaining the appropriate urine sample.

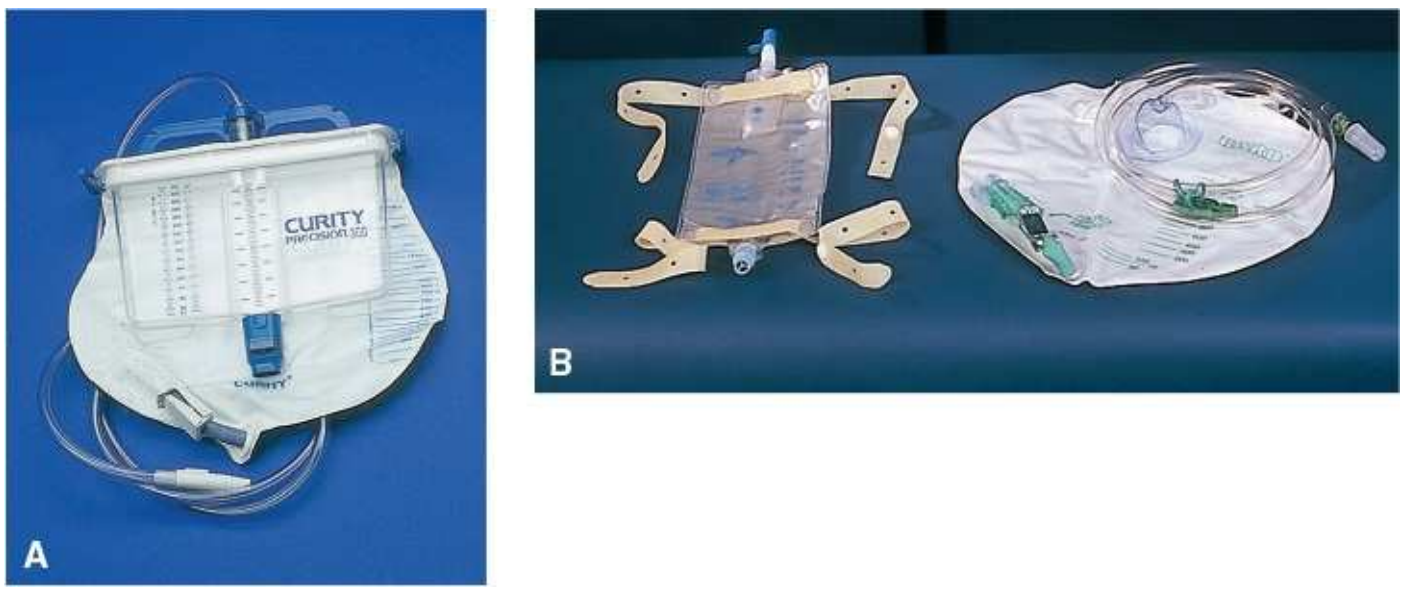

FIGURE 38-6. Urine collection bags. **A.** Large urine collection bag with urimeter. **B.** Small (leg bag) and large urine collection bags.

Routine Urinalysis

A sterile urine specimen is not required for a routine urinalysis. Collect urine by having the patient void into a clean bedpan, urinal, or receptacle (e.g., a specimen hat in the toilet bowl). Take care to avoid contamination with feces. If a patient with female genitalia is menstruating when a urine sample is obtained, note this on the laboratory slip because red blood cells may appear in the urine. When patients are voiding into a bedpan or collection device on the toilet, instruct them not to place toilet tissue into the urine. Using aseptic technique, pour the urine into an appropriate container; label it with the patient's name, date, and time of collection; package it appropriately based on facility policy and place it in a sealable biohazard bag; and send it to the laboratory for examination. Do not leave urine standing at room temperature for a long period; transport the specimen to the laboratory. If unable to take the specimen to the laboratory immediately, refrigerate it (Fischbach et al., 2022).

Guidelines for Nursing Care 38-1

Obtaining A Clean-Catch or Midstream Urine Specimen

Patients With Female Genitalia

- Perform hand hygiene and put on PPE, if indicated.

- Identify the patient.
- Explain to the patient what you are going to do and why.
- Put on unsterile gloves.
- Separate the labia. Clean the area at the meatus with soap and water, or according to policy.
- Have the patient void about 30 mL into the toilet or bedpan and discard this urine.
- Position the sterile specimen container near, but not touching, the meatus, and collect at least 3 to 5 mL of urine in the container. If the specimen is being collected while the patient is lying down, ask them to void forcibly to prevent urine from dribbling across the perineum.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

- Stop collecting urine before the patient empties their bladder. Allow the patient to continue voiding into a bedpan or the commode and discard this urine.

- Remove gloves and other PPE if used. Perform hand hygiene.
- Label the specimen container, package it appropriately, and send it to the laboratory.

Patients With Male Genitalia

- Perform hand hygiene and put on PPE, if indicated.

- Identify the patient.
- Explain to the patient what you are going to do and why.
- Put on unsterile gloves
- Retract the foreskin to expose the glans penis in the uncircumcised patient with male genitalia.
- Clean the area of the external meatus with soap and water.
- Have the patient void about 30 mL into the toilet or urinal and discard this urine.
- Have the patient void directly into the sterile container and collect at least 3 to 5 mL of urine in the container.
- Stop collecting urine before the patient empties their bladder. Allow the patient to void the remaining urine into the toilet or urinal and discard it.
- Return the foreskin to its normal position in an uncircumcised patient to prevent swelling and irritation of the glans penis.

- Remove gloves and other PPE if used. Perform hand hygiene.
- Label the specimen container appropriately and send the specimen to the laboratory.

Clean-Catch or Midstream Specimen

A clean-catch specimen of urine is required in some situations. A clean-catch urine specimen is collected during midstream voiding and minimizes bacterial contamination from adjacent anatomic areas (Fischbach et al., 2022). The patient voids a small amount and then collects the urine specimen. Initial voiding of a small amount of urine helps to flush away any organisms near the meatus and minimizes the risk of inaccurate findings if these organisms were to enter the specimen. In addition, it is generally thought that urine voided at midstream is most characteristic of the urine the body is producing. Do not leave urine standing at room temperature for a long period; transport the specimen to the laboratory. If unable to take the specimen to the laboratory immediately, refrigerate it (Fischbach et al., 2022). A patient who can carry out the technique properly may collect their own clean-catch midstream urine specimen and often prefers to do so. The nurse provides the appropriate equipment and instructions for the procedure. Refer to Guidelines for Nursing Care 38-1.

Sterile Specimen

Sterile urine specimens may be obtained by catheterizing the patient's bladder or by taking the specimen from an indwelling catheter already in place. Refer to the Catheterizing the Patient's Bladder discussion and Skill 38-2 on pages 1489–1493 and Skill 38-3 on pages 1493–1499.

When it is necessary to collect a urine specimen from a patient with an indwelling catheter, the specimen should be obtained from the catheter itself using the special port for specimens (see Guidelines for Nursing Care 38-2 on page 1460). Do not collect the specimen from the collecting receptacle; a specimen from the collecting receptacle (drainage bag) may not be fresh urine and could result in an inaccurate analysis. Always observe sterile technique while collecting a urine specimen from an indwelling catheter. Guidelines for Nursing Care 38-2 outlines the procedure to collect a urine specimen from an indwelling urinary catheter.

▶ Guidelines for Nursing Care 38-2

Obtaining a Urine Specimen From an Indwelling Urinary Catheter

- Gather equipment, including a syringe, an antiseptic swab, a sterile specimen container, nonsterile gloves, and possibly a clamp. The size of the syringe for the specimen depends on the specific laboratory test. A urine culture requires about 3 mL, whereas routine urinalysis requires at least 10 mL of urine.

- Perform hand hygiene and put on PPE, if indicated.

- Identify the patient.
- Explain to the patient what you are going to do and why.
- If urine is not present in the tube, clamp the tube below the access port briefly (not to exceed 30 minutes) to allow urine to accumulate.
- Put on unsterile gloves.
- Clean the access port with an antiseptic swab (Figure A), and carefully attach the syringe to the port.
- Aspirate urine into the syringe (Figure B).
- Remove the syringe. Release the clamp if one was used.
- Transfer the specimen to the appropriate container.

- Remove gloves and other PPE if used. Perform hand hygiene.
- Label the specimen with the patient's name, date, and time of collection
- Package based on facility policy, and place in a sealable biohazard bag. Transport the specimen to the lab according to facility policy.

A. Using an antiseptic swab to clean the access port. **B.** Aspirating urine into the syringe. (*Source:* Used with permission from Shutterstock. *Photos by B. Proud.*)

Urine Specimens From a Urinary Diversion

Urine specimens can be obtained from urinary diversions via several methods. Clean urine specimens can be obtained from a urinary diversion appliance into a clean container for a routine urinalysis (Williams, 2012). Specimens for culture should never be obtained directly from an existing urostomy pouch or drainage bag (Mahoney et al., 2013; Wound Ostomy and Continence Nurses Society [WOCN], 2018). If a urine sample is needed for culture and sensitivity, most sources suggest that it should be obtained by sterile catheterization or clean-catch drip collection (Mahoney et al., 2013; Williams, 2012; WOCN, 2018). However, results of at least one study suggest that collection from a clean urostomy pouch is also acceptable (Vaarala, 2018).

In order to collect a specimen using sterile catheterization, remove the stoma appliance and clean the **stoma** (a surgically created opening on the body surface) site with solution, based on facility policy (Mahoney et al., 2013; WOCN, 2018). Using sterile technique, insert the urinary catheter no more than 2 to 3 inches into the stoma site. If there is resistance, rotate the catheter gently until it slides forward. If there is continued resistance, do not force the catheter any further (Mahoney et al., 2013; Williams, 2012; WOCN, 2018). After collection of a sufficient amount of urine, remove the catheter and reapply the stoma appliance.

If a urinary catheter is not available, a specimen may still be obtained (Mahoney et al., 2013; WOCN, 2018)). Remove the stoma appliance and clean the stoma site with solution, based on facility policy (Mahoney et al., 2013; WOCN, 2018). Discard the first few drops of urine by allowing urine to drip onto sterile gauze (Mahoney et al., 2013; WOCN, 2018). Hold a sterile specimen cup under the stoma to collect urine. After collection of a sufficient amount of urine, reapply the stoma appliance.

24-Hour Urine Specimens

For some laboratory studies, 24-hour specimen collection is required. The patient and the entire nursing team must understand the importance of collecting all the urine voided in a 24-hour period. Post a sign on the patient's bathroom door as a helpful reminder not to discard urine. Initiate a collection at a specific time (which is recorded) by asking the

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

patient to empty the bladder. Discard this urine and then collect all urine voided for the next 24 hours. At the end of the 24 hours, ask the patient to void. Add this urine to the previously collected urine, and then send the entire specimen to the laboratory (Fischbach et al., 2022).

Depending on the type of examination, the urine from each voiding may be kept in a separately marked container and the time of each voiding recorded, or all urine voided may be collected in a common receptacle. The laboratory usually specifies whether a preservative is used to retard decomposition and whether the specimen is to be refrigerated or kept on ice. In some situations, the patient may be required to collect the specimen at home. It is very important for the patient and the patient's caregivers to understand the specific collection, storage, timing, and transportation instructions for the prescribed test.

Specimens From Infants and Children

Midstream collection can be accomplished with children older than age 2 years, provided the child is able to follow direction and engage in their care and with the nurse. Try having the child sit facing the back of the toilet, straddling the toilet seat. The nurse or parent can position themselves behind the child, holding the sterile container for urine collection.

The most reliable method to obtain a urine specimen for culture (associated with lower contamination rates) in neonates and young infants is to perform a suprapubic aspiration or transurethral catheterization (American Academy of Pediatrics [AAP], 2016; Cheek et al., 2015). Suprapubic aspiration is not within the scope of practice of registered nurses (May, 2018) and is painful. Pain management during the procedure is important—topical anesthetic cream should be used when time permits as well as age-appropriate distraction techniques (Cheek et al., 2015). Sampling options should be discussed with the health care team and the patient's parents/caregivers.

POINT-OF-CARE URINE TESTING

In some situations, the nurse may perform tests to detect abnormal constituents in urine specimens at the bedside or in the office setting. This is especially true when urine specimens are being tested repeatedly for known abnormalities, when screening tests are being used, or when laboratory facilities are not readily available. For example, a nurse may test urine for the presence of glucose, protein, bilirubin, bacteria, and blood. The results of the test are recorded on the patient's record. Many commercially prepared diagnostic kits are available for such tests and can be used in the home or the health care facility. Although these tests are economical and fast, laboratory analysis is recommended when precise results are needed.

Most commercially prepared diagnostic kits contain all needed equipment and the appropriate reagent (a substance used in a chemical reaction to detect another substance). Reagents are available as tablets, fluids, impregnated paper, and plastic strips with a special coating. When the urine comes in contact with the reagent, a chemical reaction occurs, causing a color change. This color is then compared with an accompanying chart that describes the significance of the color. The precise directions for the amount of the specimen, the time allowed for the chemical reaction, and the interpretation of the color vary with the manufacturer. Therefore, always follow the directions accompanying the diagnostic kit exactly.

The nurse may also determine the specific gravity of urine, which is a measure of the density of urine compared with the density of water (refer to Table 38-1). The higher the number, the more concentrated the urine is, unless there are abnormal components, such as glucose or protein, in the urine. Specific gravity can be determined with manufactured plastic reagent strips, as described previously.

PROVIDING SUPPORT FOR DIAGNOSTIC PROCEDURES

Various diagnostic procedures, which can be performed in a hospital or outpatient facility, are used to study the urinary system. Common diagnostic procedures related to the urinary system include urodynamic studies, cystoscopy, intravenous pyelogram, retrograde pyelogram, computed tomography (CT) scans, renal biopsy, and ultrasound examination. Nurses are responsible for preparing the patient for the procedure and giving appropriate aftercare and providing related patient education. Explaining the procedure helps reduce the patient's anxieties. The preparation and aftercare of the patient for each of these procedures are described in Box 38-4 on page 1462.

Diagnosing Actual or Potential Health Problems and Needs

An assessment of a patient's urinary status may lead to the identification of one or more actual or potential health problems and needs related to urinary elimination. Following the formulation of the actual or potential health problems and needs, the nurse communicates findings to other nursing and health care professionals through the use of the written and spoken word. The written actual or potential health problem or need becomes a permanent part of the patient's health record. Examples of health problems and needs with related etiology and signs and symptoms can be found in the Examples of Actual or Potential Health Problems and Needs: Urinary Elimination on page 1463.

Outcome Identification and Planning

Expected outcomes are derived from the actual or potential urinary elimination problems identified. The goal is to

maintain or restore optimum function related to urinary elimination, alleviate symptoms or side effects of disease or treatment, and prevent complications. General patient outcomes are listed here. Actual patient outcomes should list specific behaviors and criteria individualized for the patient situation. The patient will:

Box 38-4 Common Diagnostic Procedures Used to Study the Urinary Tract

Urodynamic Studies

Urodynamic studies are a group of tests that measure how urine flows, is stored, and is eliminated in the lower urinary tract. They are used to identify abnormal voiding patterns in people with incontinence or the inability to void normally.

Preparation

- Usually, no fluid or food restrictions are necessary before the test.
- Bladder should be full before the test.
- Inform the patient that a catheter will be inserted during the test.

Aftercare

- Instruct the patient to drink 8 to 10 8-oz glasses of water in the 24 hours after the test.
- Teach the patient the signs and symptoms of a urinary tract infection and to report any symptoms immediately.

Cystoscopy

Cystoscopy is the direct visual examination of the bladder, ureteral orifices, and urethra with a cystoscope. It is used to view, diagnose, and treat disorders of the lower urinary tract, interior bladder, urethra, male prostatic urethra, and ureteral orifices.

Preparation

- The patient is allowed liquids on the morning of the examination.
- Sedation and analgesics are usually prescribed before the procedure.
- Verify documentation of informed consent (required for the procedure).
- Explain to the patient that the procedure is ordinarily painless.

Aftercare

- Know that tissue swelling, dysuria, and hematuria may occur because of trauma from the procedure.
- Encourage a generous fluid intake and observe and measure urine output for at least 24 hours.
- Observe the patient for urinary retention and for signs of infection; procedure-related infection after a cystoscopy may occur.

Intravenous Pyelogram (Excretory or Intravenous Urography)

Intravenous pyelogram is the radiographic examination of the kidney and ureter after a contrast material is injected intravenously. It is used to diagnose renal disease and urinary tract dysfunction.

Preparation

- Withhold fluids or foods for 12 hours before testing. Obtain patient's allergy history, focusing on prior allergic reaction to contrast substances and sensitivity to iodine, shellfish, or seafood (contrast may contain iodine).
- This test is contraindicated for patients with elevated BUN and creatinine levels and pregnant patients. Some facilities require a recent creatinine level for all patients over 40 years of age prior to performing the procedure (Fischbach et al., 2022).
- Older, debilitated, or young patients may not tolerate this dehydration; compromises may need to be made for those patients.
- Give a laxative the evening before the examination and an enema the morning of the examination so that stool and gas do not interfere with visualization.
- Verify documentation of informed consent (required for the procedure).
- Instruct the patient to void before the examination.

Aftercare

- Offer fluids and food immediately after the examination.
- Provide sufficient fluids to replace those lost during the pretest period and/or encourage a generous

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

fluid intake.

- Observe the patient for and provide patient teaching related to signs of a reaction to the contrast material, such as a rash, nausea, and hives. Contrast may initiate acute renal failure. Monitor intake and output.

Retrograde Pyelogram

Retrograde pyelogram is the radiographic and endoscopic examination of the kidneys and ureters, with placement of ureteral catheter up to the level of the renal pelvis as part of the endoscopic examination. Contrast material is then injected into the renal pelvis through the ureteral catheter, followed by radiographic images.

Preparation

- Do not give fluids or food after midnight before the examination.
- This test is contraindicated for pregnant patients and those with an iodine allergy.
- This test is contraindicated for patients with elevated BUN and creatinine levels and pregnant patients. Some facilities require a recent creatinine level for all patients over 40 years of age prior to performing the procedure (Fischbach et al., 2022).
- Give a laxative the evening before the examination and an enema the morning of the examination so that stool and gas do not interfere with visualization.
- Instruct the patient to void before the examination.
- Verify documentation of informed consent (required for the procedure).

Aftercare

- Offer foods and fluids immediately if no anesthesia has been used. If anesthesia has been used, delay offering foods and fluids for several hours.
- Check the vital signs regularly if anesthesia has been used.
- Observe the patient for signs of a reaction to the contrast material, such as a rash, nausea, and hives.
- Monitor urine output and appearance for at least 24 hours. Hematuria and dysuria can occur.
- Be aware that ureteral catheters may be in place and should be connected to drainage receptacles so that the amount and character of drainage from each catheter can be noted.

Renal Ultrasound

A renal ultrasound is a noninvasive procedure that involves the use of ultrasound to visualize the renal parenchyma and renal blood vessels. It is used to characterize renal masses and infections, visualize large calculi; detect malformed kidneys; provide guidance during other procedures, such as biopsy; and monitor the status of renal transplants and kidney development in children with congenital processes.

Preparation

- Verify documentation of informed consent (required).
- Food and fluid restriction are usually not necessary but may be required in certain facilities (Fischbach et al., 2022).
- Explain to the patient that the procedure is painless.

Aftercare

- No special care is required after this procedure.

Computed Tomography (CT Scanning)

CT scanning is a noninvasive radiographic procedure whereby a body part can be scanned from different angles with an x-ray beam and a computer that calculates varying tissue densities and records a cross-sectional image.

Preparation

- Verify documentation of informed consent (required).
- The patient is usually NPO for 8 hours before the test if a contrast dye is used.
- Obtain patient's history of any allergic reaction or hypersensitivity to shellfish, iodine, or any contrast dyes (contrast may contain iodine).
- Remove all metal objects from the patient before the test.
- Medications may usually be taken until 2 hours before the test.
- Some patients may receive sedation and/or analgesics to help control feelings of claustrophobia during the procedure.

Aftercare

- Observe for a delayed reaction to the contrast dye (skin rash, urticaria, headache, vomiting). An oral antihistamine may be given for some reactions.
- Instruct the patient to resume usual diet and activity unless otherwise indicated.

- Produce urine output about equal to fluid intake
- Maintain fluid and electrolyte balance
- Empty the bladder completely at regular intervals
- Report ease of voiding
- Maintain skin integrity
- Demonstrate appropriate self-care behaviors

Implementing

Nursing interventions focus on maintaining and promoting normal urinary patterns, improving or controlling urinary incontinence, preventing potential problems associated with bladder catheterization, and assisting with care of urinary diversions. Nurses can assist the patient and family/caregivers to achieve desirable outcomes for their urination needs.

Examples of Actual or Potential Health Problems and Needs

URINARY ELIMINATION

Actual or Potential Health Problems and Needs	Possible Etiologic Factors	Potential Signs and Symptoms
Urinary Retention	• Sensory motor impairment • Enlarged prostate • Medications, such as antidepressants, antihistamines, calcium-channel blockers, anticholinergics • Anatomic obstruction	• Postvoid residual of 450 mL via bladder scanner • *"It takes a while for the urine to come and sometimes I have to go every hour!"* • *"I have to get up frequently at night to urinate."*
Stress Incontinence of Urine	• Weak pelvic muscles and structural supports	• Patient reports involuntary leakage of urine with sudden movement, coughing, sneezing, and laughing.
Risk for Urge Incontinence of Urine	• Alcohol and caffeine consumption, fecal impaction, urinary tract infection, ineffective toileting habits	—

Source: International Council of Nurses (ICN). (2019). Nursing diagnosis and outcome statements. https://www.icn.ch/sites/default/files/inline-files/ICNP2019-DC.pdf; Wolters Kluwer. (2022). Problem-based care plans. In Lippincott Advisor. Wolters Kluwer. https://advisor.lww.com/lna/home.do

Think back to **Anna Galinski**, the frail person in a long-term care facility. The toileting program focused on maintaining and promoting the patient's normal urinary patterns. However, now that the patient has an indwelling catheter, the nurse needs to focus on preventing problems associated with catheterization. Weighing the risks and benefits of catheterization for this patient would be crucial

Promoting Health 38-1

URINE ELIMINATION

Use the assessment checklist to determine how well you are meeting your needs related to urinary elimination. Then develop a prescription for self-care by choosing appropriate behaviors from the list of suggestions.

Assessment Checklist

☐ almost always ☐ sometimes ☐ almost never

☐	☐	☐	1. I urinate at regular intervals throughout the day.
☐	☐	☐	2. I have an adequate fluid intake.
☐	☐	☐	3. I limit my sodium intake.
☐	☐	☐	4. My urine volume remains relatively constant.

Self-Care Behaviors

1. Maintain a normal voiding pattern and volume.
2. Respond as soon as possible to the urge to void.
3. Drink six to eight 8-oz glasses of water daily.
4. Avoid foods that contain excess sodium.
5. Monitor use of caffeine, alcohol, or medication schedules that promote voiding and may interfere with sleep.
6. Seek medical assistance for any change in the characteristics of urine or presence of pain on urination.

Information to promote effective urinary elimination—such as information about elimination problems, urinary incontinence, and renal and bladder diseases—is available online.

Promoting Urinary Elimination

Nursing care to promote urinary elimination includes interventions to support voiding habits, fluid intake, strengthening of muscle tone, stimulating urination and resolving urinary retention, and assisting with toileting. Nurses working with patients to promote appropriate behaviors related to urine elimination should examine their own behaviors as factors in the success of the plan. Nurses who role model good health behaviors are more effective teachers. Use the display, Promoting Health 37-1, for yourself before using it with others.

MAINTAINING REGULAR VOIDING HABITS

If the patient's voiding habits are adequate, provide care or teach the patient to maintain these habits to ensure comfort and satisfactory urine output. Attention to the following variables is helpful:

- *Schedule:* Some patients report urinating on demand in no apparent pattern. Others have inflexible patterns that have developed over the years and become anxious if these are interrupted. Some patients need assistance to urinate and may experience urgency. Nursing actions should support the patient's usual urinating pattern as much as possible.
- *Urge to void:* Assist the patient to void when the patient first feels the urge to void. Routinely delaying urination may result in difficulty initiating a stream and/or urinary stasis. Urinary stasis can contribute to the development of UTIs.
- *Privacy:* Many adults and children cannot urinate in the presence of another person. Unless the patient is extremely weak and requires assistance, provide privacy in the health care facility and in the home.
- *Position:* Helping patients assume their usual voiding position may be all that is necessary to resolve an inability to urinate. Some patients with male genitalia cannot use a urinal while lying down or sitting; encourage them to void while standing at the bedside unless this is contraindicated. Similarly, some patients with female genitalia cannot void easily on a bedpan but respond favorably with a bedside commode.
- *Hygiene:* Patients who are confined to bed find it difficult to perform their usual genital hygiene. Careful cleansing of the perineal and genital areas is needed for patient comfort and to prevent infection. This is easily accomplished for patients on bedrest by using warmed, moistened disposable washcloths and skin cleanser or by pouring warm, soapy water over the perineal area while the patient is still on the bedpan, followed by clear water.

Because people customarily wash their hands after toileting and hand hygiene prevents transmission of microorganisms, offer patients confined to bed a moistened towelette or soap and water to wipe their hands after

removing the bedpan or urinal. Nursing strategies to address age-related changes affecting urinary elimination are identified in the accompanying Focus on the Older Adult box.

Recall **Anna Galinski**, the frail older person in the long-term care facility. Strategies to promote normal urinary elimination should have been attempted to determine their effectiveness in promoting urinary elimination prior to use of a urinary catheter. In addition, when advocating for the patient, the nurse would strongly urge incorporating strategies to promote normal urinary elimination into the patient's care plan to determine their effectiveness, ultimately substantiating that catheterization was not necessary.

PROMOTING FLUID INTAKE

Many people routinely drink less fluid than is optimal to promote healthy urinary functioning. Adults with no disease-related fluid restrictions should drink an average of six to eight 8-oz glasses of liquid daily (NIDDK, 2017). A common misperception is that drinking this much fluid causes water retention and contributes to weight gain. If a good proportion of the daily fluid intake is water, the kidneys and urinary structures are well flushed, and waste products, including potentially harmful bacteria, are removed. Monitor fluid intake for excessive amounts of caffeine-containing beverages, high-sodium beverages, and high-sugar beverages.

Focus on the Older Adult

NURSING STRATEGIES TO ADDRESS AGE-RELATED CHANGES AFFECTING URINARY ELIMINATION

Age-Related Change	Nursing Strategies
Nocturia, frequency, and urgency	• Ensure easy access to the bathroom or commode. • Discourage fluid intake at bedtime. • Discourage alcohol use before bedtime. • Evaluate medication regimen and schedule, particularly diuretics and drugs that produce sedation or confusion. • Use a night light. • Use clothing that is easily removed for voiding. • Keep assistive ambulatory devices (walkers, canes, and the like) readily available. • Evaluate gait and ability to ambulate safely. • Assess for urinary tract infection.
Incontinence	• Maintain a fluid intake (Davis et al., 2020). • Discourage use of alcohol, artificial sweeteners, and caffeine. • Provide easy access to the bathroom. • Assess factors that influence voiding. • Use assistive devices when necessary (raised toilet seat, grab bars, walker). • Use collection devices when necessary (urinal or bedpan). • Ensure safety when ambulating (e.g., skid-proof slippers). • Encourage use of whole, unprocessed, coarse wheat bran to prevent constipation and fecal impaction. • Perform pelvic floor muscle training (PFMT) exercises several times daily. • Encourage participation in a bladder retraining program.
Urinary tract infections	• Maintain a liberal fluid intake (Dudek, 2022; Wu et al., 2020). • Encourage shower instead of tub bath to decrease opportunity for

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

bacteria in bath water to enter urethra.
- Encourage appropriate perineal care and frequent changing of incontinence briefs.
- Void at frequent intervals; every 2 hours if possible.
- Void immediately after sexual intercourse.
- Females should avoid use of potentially irritating feminine products, such as deodorant sprays, douches, and powders in the genital area.

Provide fresh water, juices, and fluids of preference to patients with alterations in mobility. Remind children and patients who are confused to drink. Fluid restrictions may be ordered for patients with certain health problems. For others, an above-average intake of fluids is prescribed. Incorporate this information in the care plan and provide patient education.

STRENGTHENING MUSCLE TONE

Weakening of the pelvic floor muscles is a common cause of urinary continence problems (Cera & Twiss, 2018; Shin et al., 2016). Pelvic floor muscle training (PFMT) can improve voluntary control of urination and significantly reduce or eliminate problems with **stress incontinence** (involuntary loss of urine related to an increase in intra-abdominal pressure) by strengthening perineal and abdominal muscle tone (Pair & Somerall, 2018; Peate, 2019). PFMT, often referred to as Kegel exercises (Pair & Somerall, 2018), targets the inner muscles that lie under and support the bladder. These muscles can be toned, strengthened, and actually made larger by a regular routine of tightening and relaxing. Often patients have difficulty determining which muscles to exercise. These are the same muscles that the patient contracts to stop urinating in midstream or to control defecation. Instruct patients to contract the pelvic floor muscles for 5 to 10 seconds and to relax them for 10 seconds. Encourage the patient to perform PFMT exercises without involving the muscles in the abdomen, inner thigh, and buttocks. When the patient is familiar with these sensations, these exercises should be performed multiple times a day for at least 3 months, and possibly longer, depending on the response. The exercises can be done anywhere. Assist patients to incorporate them into their daily activities. See the accompanying PICOT in Practice box on page 1466. Urinary incontinence and associated nursing interventions is discussed in more detail later in the chapter.

ASSISTING WITH TOILETING

The amount of assistance provided to a patient in relation to toileting varies, depending on the patient's abilities and health status.

PICOT in Practice

ASKING CLINICAL QUESTIONS: PELVIC FLOOR MUSCLE TRAINING

Scenario: You and your next-door-neighbor Sarah exercise every day after work. Sarah has cancelled several days in a row. They gave birth recently, and you attribute the cancellation to being busy with the infant. Sarah confided with extreme embarrassment that they have been leaking urine when they run or cough over the past few months after childbirth. Sarah has discussed the problem with their OB/GYN, who indicated that Sarah has urinary incontinence. Sarah has seen commercials about drugs available for overactive bladder and hopes that something can help. You remember from class that pelvic floor muscle training (PFMT), or Kegel exercises, were recommended for females after childbirth and wonder if drugs or similar exercises are most appropriate for Sarah.

- **Population:** Adult females with urinary incontinence
- **Intervention:** Drugs used for overactive bladder
- **Comparison:** PFMT
- **Outcome:** Improvement of urinary incontinence
- **Time:** 3 months

PICOT Question: Among postnatal people, are PFMT exercises more effective than drugs used to treat urinary incontinence within 3 months of treatment?

Finding:

Woodley, S. J., Lawrenson, P., Boyle, R., Cody, J.D., Mørkved, S., Kernohan, A., & Hay-Smith, E. J. C. (2020). Pelvic floor muscle training for preventing and treating urinary and faecal incontinence in antenatal and postnatal women. *Cochrane Database of Systematic Reviews, 5*(5), CD007471. https://doi.org/10.1002/14651858.CD007471.pub4

The review included 46 trials involving 10,832 females from 21 countries. The studies included pregnant females and females who had delivered their baby within the last 3 months, and who reported leakage of urine, feces, both urine or feces, or no leakage. They were allocated randomly to receive PFMT, either to try to prevent incontinence

or as a treatment for incontinence, or not, and the effects were compared. This review provides evidence that early structured PFMT in early pregnancy for continent females probably prevents the onset of urinary incontinence in late pregnancy and reduces the risk of urinary incontinence slightly postnatally.

Dumoulin, C., Cacciari, L. P., & HaySmith, E. J. C. (2018). Pelvic floor muscle training versus no treatment, or inactive control treatments, for urinary incontinence in women. *Cochrane Database of Systematic Reviews, 10*(10), CD005654. https://doi.org/10.1002/14651858.CD005654.pub4

The 31 included trials involved 1,817 females from 14 countries. The studies included females with stress, urgency, or mixed urinary incontinence. They were allocated randomly to either receive or not receive PFMT, and the effects were compared for whether the condition was "cured," or "cured or improved." The review also looked at symptoms, the effect on quality of life, and the frequency and amount of urine lost. Based on the data available, PFMT is better than no treatment, placebo, or inactive control treatments for females with stress urinary incontinence or urinary incontinence (all types). The review reported confidence that PFMT can cure or improve symptoms and may reduce the number of leakage episodes in all types of urinary incontinence.
Level of Evidence I: Systematic review.
Recommendations: You assure Sarah that urinary incontinence is common in females, and the incidence increases with age. You tell Sarah about different types of urinary incontinence with different treatment recommendations and that there is strong evidence that PFMT, also known as Kegel exercises, are effective as a first treatment for females with stress or urinary incontinence (all types). You provide Sarah with information from the U.S. National Library of Medicine, Pelvic Floor Muscle Training Exercises (https://medlineplus.gov/ency/article/003975.htm) and suggest they consistently perform the exercises (10 repetitions three to five times a day) for 3 months.

Toilet

Even when the patient can use the bathroom toilet, the nurse may be responsible for noting any abnormalities of urinary elimination. In some instances, patients may be taught to report abnormalities to the nurse and instructed not to flush the toilet until the nurse checks the urine. In other instances, when the urine volume is to be calculated, the patient may need to urinate in a urinal or a specimen hat placed in the toilet so that the urine can be measured before it is discarded (see Fig. 38-5 on page 1457). Although many patients can easily be taught to measure their urine output, the nurse should assess urine characteristics at least once during a shift in acute care and more frequently if warranted.

Assist weakened patients to the bathroom. If there is any danger of the patient falling, remain in attendance. Never lock the bathroom door. Ensure that a signal bell is within easy reach so that the patient can summon help easily if feeling weak and needing assistance. A handrail near the toilet also is helpful.

Commode

Commodes are chairs—straight-back chairs or wheelchairs with open seats and a shelf or a holder underneath that holds a bucket (Fig. 38-7). Commodes can be used for patients who can get out of bed but cannot use the bathroom toilet. The commode can be placed adjacent to the bed, and the patient can be assisted to it with minimal exertion. If the patient has a roommate, any visitors may be asked to exit the room while the patient uses the commode. Remember to pull the curtain in the room and close the door to provide for patient privacy.

Bedpan and Urinal

In situations in which mobility is compromised or limited, patients with male genitalia usually prefer to use the urinal for voiding and the bedpan for defecation; patients with female genitalia usually prefer to use the bedpan for both (see Fig. 38-5 on page 1457). Many patients find it embarrassing and difficult to use the bedpan and/or the urinal. When a patient uses a bedpan or urinal, maintain the patient's privacy.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

FIGURE 38-7. Bedside commode.

A fracture bedpan is frequently used by people with fractures of the femur or lower spine. Smaller and flatter than the ordinary bedpan, it is helpful for patients who cannot easily raise themselves onto the regular bedpan. Very thin patients or older adults often find it easier and more comfortable to use the fracture bedpan.

Caring for Patients With Urinary Tract Infections

UTIs are among the most common health care–associated infections and are a common cause of systemic infections in older adults (Clarke et al., 2020; Sepsis Alliance, 2020; Touhy & Jett, 2018). Bladder and urethra infections are the most common type of UTI, but any part of the urinary tract can become infected (Mayo Foundation for Medical Education and Research [MFMER], 2020; National Institute of Diabetes and Digestive and Kidney Diseases [NIDDK], 2017). People with female genitalia are especially vulnerable to UTIs because the urethra is shorter and in closer proximity to the vagina and rectum (NIDDK, 2017). UTIs can affect both the upper urinary tract, involving the kidneys and ureters (pyelonephritis) and lower urinary tract, involving the bladder and urethra (cystitis). *Escherichia coli,* bacteria commonly found in the gastrointestinal tract, are the most common causal organism of infection of the bladder (MFMER, 2020; NIDDK, 2017).

RISK FACTORS

Those at greatest risk for a UTI include the following:

- *Sexually active people with female genitalia:* During intercourse, perineal bacteria can migrate into the urethra and bladder (NIDDK, 2017; National Kidney Foundation [NKF], 2016).
- *People who use diaphragms for contraception:* The spermicide used with a diaphragm decreases the amount of normally protective vaginal flora (NIDDK, 2017).
- *Postmenopausal people:* Urinary stasis, which is common at this age, provides an optimal environment for bacteria to multiply; in addition, decreased estrogen contributes to loss of protective vaginal flora (NIDDK, 2017).
- *People with an indwelling urinary catheter in place:* Bacteria travel through or around the catheter and into the bladder. UTIs are the most common type of health care–associated infection (HAI) reported to the National Healthcare Safety Network, and approximately 75% of these UTIs are associated with a urinary catheter (Centers for Disease Control and Prevention [CDC], 2015). A catheter-associated urinary tract infection (CAUTI) increases health care costs and is associated with increased morbidity and mortality. CAUTIs are considered by the Centers for Medicare and Medicaid Services to represent a reasonably preventable complication of hospitalization. As such, no additional payment is provided to hospitals for CAUTI treatment-related costs (CMS, 2020). Although a break in sterile technique during placement can lead to an infection, most pathogens are introduced via handling of the catheter and drainage device after placement.
- *People with diabetes:* Changes in the body's defense system related to diabetes may increase the risk for UTIs (NKF, 2016).
- *Older adults:* The physiologic changes associated with aging (listed earlier in the chapter) predispose older people to the development of UTIs and other infections (Sepsis Alliance, 2020). In addition, enlargement of the prostate as a person ages can contribute to the development of UTIs (NKF, 2016).

Consider **Anna Galinski**, the frail older adult in the long-term care facility. Their risk for developing a UTI is increased due to their age. This risk now is further increased because of the catheter insertion.

DIAGNOSTIC EVALUATION

In addition to the nursing history and physical examination, laboratory findings can identify the presence of a UTI. A urine sample for urinalysis may be collected and tested for bacteria and white blood cells. A urinalysis suggests the presence of an infection if bacteria and white blood cells are present in the sample (NIDDK, 2017). A urine sample from a clean-catch or sterile specimen may be sent to the laboratory for a culture and sensitivity (C&S) test. A bacterial count of >100,000 colony-forming units (CFU)/mL indicates infection (Fischbach et al., 2022). Lower counts may be considered clinically significant if the patient has signs and symptoms of a UTI (Fischbach et al., 2022). The

presence of bacteria in a clean-catch midstream or sterile urine specimen, accompanied by symptoms (e.g., dysuria, urinary frequency or urgency, or cloudy urine with a foul odor), indicates a UTI. Red blood cells and nitrates also may be present in the urine.

TREATMENT AND PATIENT EDUCATION

Various protocols are used to treat UTIs. A short-course antibiotic regimen (one large dose vs. 3 or 7 days of smaller doses) usually eradicates infections of the lower urinary tract; longer antimicrobial therapy is required for upper UTIs (Cleveland Clinic, 2019).

Patient education can help prevent UTIs. Teaching the patient about measures that promote health is an important nursing responsibility. Instruct the patient to:

- Drink six to eight 8-oz glasses of liquid daily (NIDDK, 2017).
- Do not postpone going to the bathroom; urinate when you feel the urge (NKF, 2016). Take enough time to fully empty the bladder when urinating (NIDDK, 2017).
- If you have female genitalia, dry the perineal area after urination or defecation from the front to the back (from the urethra toward the rectum) (MFMER, 2020; NIDDK, 2017).
- Void before and after sex (intercourse) (MFMER, 2020; NIDDK, 2017; NKF, 2016).
- If you have repeat bladder infections and use a diaphragm, unlubricated condoms, or spermicide, talk with your health care professional about switching birth control methods; these methods can increase the chances of developing a bladder infection (NIDDK, 2017).
- Wear underwear with a cotton crotch and avoid clothing that is tight and restrictive on the lower half of the body (MFMER, 2020; NIDDK, 2017).

Nursing interventions to prevent UTIs for a patient with an indwelling catheter are discussed later in the chapter.

Caring for an Incontinent Patient

Urinary incontinence (loss of bladder control with involuntary leakage of urine) is widely underreported and underdiagnosed (Touhy & Jett, 2018; Vasavada et al., 2019b). It is one of the most common chronic health problems. However, it is not an inevitable result of growing old or bearing children (Touhy & Jett, 2018; Yates, 2019). Many people self-manage this life-altering condition for many years before seeking assistance from a health care provider.

Urinary incontinence is more prevalent in females and increases with age (Davis et al., 2020; Vasavada et al., 2019b). It is a special problem for older adults who may experience decreasing control over urination and who may find it more difficult to reach a toilet in time to void because of mobility problems or dexterity problems in undressing. The discomfort, odor, and embarrassment of urine-soaked clothing can greatly diminish a person's self-concept, causing the person to feel like a social outcast.

Age-related changes do affect urinary function, but urinary incontinence can be treated, and individualized interventions can help the patient lead a normal life. Incontinence is a symptom, is treatable, and is often curable (Society of Urologic Nurses and Associates [SUNA], 2019). Specific treatment is based on the specific type on incontinence and its cause (Vasavada et al., 2019b).

Review the scenario at the beginning of the chapter describing **Midori Morita** and their husband. The nurse should assess the feelings of Midori and her husband related to the problems associated with Mr. Morita's urinary dribbling and incontinence. Mrs. Morita may be feeling overwhelmed and possibly upset or angry. Her husband most likely would be feeling embarrassed and possibly disgusted. Helping them resolve these feelings is essential for effective care.

TYPES OF URINARY INCONTINENCE

There are numerous types of urinary incontinence. **Transient incontinence** appears suddenly and is usually caused by an illness or temporary problem that is short-lived or treatable (Hall, 2018). It is usually caused by treatable factors, such as confusion secondary to acute illness or infection or as a result of medical treatment, such as the use of diuretics or intravenous fluid administration. When the underlying problem is resolved, the patient should regain continence (Hall, 2018). **Stress incontinence** (discussed earlier in the chapter) occurs because of weak pelvic floor

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

muscles and/or a deficient urethral sphincter, causing an involuntary loss of urine related to an increase in intra-abdominal pressure (National Association for Continence [NAFC], n.d.a). This commonly occurs during coughing, sneezing, laughing, lifting, changing position, or exercising (SUNA, 2019). Childbirth, menopause, obesity, or straining from chronic constipation can also result in urine loss (Hooper, 2019; International Continence Society [ICS], 2015). The leakage usually does not occur when the person is supine. Urge incontinence is the involuntary loss of urine that occurs soon after feeling an urgent need to void (urgency). Urge incontinence may be associated with overactive bladder syndrome (ICS, 2015). These patients experience a loss of urine before getting to the toilet and an inability to suppress the need to urinate. **Mixed incontinence** is a combination of stress incontinence and urgency incontinence and is marked by involuntary leakage associated with urgency as well as with exertion, effort, sneezing, and coughing (National Association for Continence [NAFC], n.d.a; SUNA, 2019; Vasavada et al., 2019b). **Overflow incontinence**, or chronic retention of urine, is the involuntary loss of urine associated with overdistention and overflow of the bladder (SUNA, 2019). The signal to empty the bladder may be underactive or absent, the bladder fills, and dribbling occurs. It may be due to a secondary effect of some medications, neurologic conditions, diabetes, and obstruction or injury (SUNA, 2019). **Functional incontinence** is urine loss caused by the inability to reach the toilet because of environmental barriers, physical limitations, loss of memory, or disorientation (National Institute on Aging, 2017; Vasavada et al., 2019b).

Patients with **reflex incontinence** experience emptying of the bladder without the sensation of the need to void from damage to the nerves that normally signal the brain that the bladder is filling (Harvard Health Publishing, 2014). Spinal cord injuries, multiple sclerosis or damage from surgery or radiation treatment may lead to this type of incontinence (Harvard Health Publishing, 2014). **Total (continuous) incontinence** is a continuous and unpredictable loss of urine, resulting from surgery, trauma, or physical malformation such as a urogenital fistula (Vasavada et al., 2019c). Urination cannot be controlled.

Urinary incontinence is treatable (SUNA, 2019). Appropriate interventions can significantly reduce the symptoms of urinary incontinence and even prevent its occurrence. Successful treatment of urinary incontinence is tailored to the specific type of incontinence and its cause (National Institute on Aging, 2017; Vasavada et al., 2019b).

ASSESSMENT

Through careful assessment and planned interventions (see upcoming discussion), continence may be restored. A detailed patient history is an important part of the assessment. Refer to the previous discussion regarding nursing assessment on pages 1454–1461. Carefully assess environmental factors for their potential impact on urinary incontinence. Equipment that gives the person better access to toileting facilities, such as a walker, cane, wheelchair, and Velcro closings on clothing, may be necessary. Dietary habits, such as caffeine, artificial sweeteners, or insufficient fluid intake, both of which can irritate the bladder and contribute to incontinence, indicate the need for teaching about nutrition (National Association for Continence, n.d.b).

A voiding record or diary provides information about the frequency, timing, and amount of voiding. By noting any patterns to voiding, either continent or incontinent, the nurse may find correlations with medications, fluid intake, or other causes of incontinence and may be able to prevent any further incontinent episodes. Voiding diaries can also be used to evaluate the effectiveness of interventions.

Physical examination and specific diagnostic tests also aid in identifying urinary incontinence. Palpate the patient's abdomen for a distended bladder, any masses, or tenderness. The **postvoid residual (PVR)** urine (the amount of urine remaining in the bladder immediately after voiding) can be measured by the use of a portable ultrasound device that scans the bladder. Bladder ultrasound poses no risk for infection and is considered a safer alternative to catheterization. A PVR of less than 50 mL indicates adequate bladder emptying. A PVR of greater than 100 mL is an indication the bladder is not emptying correctly (Bauldoff et al., 2020). This measurement can also be obtained by catheterizing the patient. Catheterization, however, involves the increased risk for introduction of microorganisms into the bladder and resulting UTI. Refer to Skill 38-1 (on pages 1489–1493) for the procedure for assessing bladder volume using an ultrasound bladder scanner. Urine specimens are used to screen for UTI, a frequent cause of urinary incontinence (Davis et al., 2020; Hooper, 2019).

Think back to **Midori Morita**, the person caring for her husband, who is experiencing urinary problems at home. The nurse would need to carefully assess all aspects of Mr. Morita's current status, including the

environment, and develop a patient-specific teaching plan for Mr., and Mrs. Morita.

TREATMENT

Noninvasive, low-risk behavioral interventions are the first line of therapy for urinary incontinence (Newman, 2019a; Pair & Somerall, 2018; Peate, 2019). Community settings are ideally suited for using many of these interventions. Nurses are able to identify patients who are incontinent and use these interventions to help patients manage incontinence. Nurses may also refer a patient to an advanced practice continence nurse or other health care provider expert in the community. All nurses caring for older adults need to be familiar with education about urinary incontinence. Many possible treatment interventions for urinary incontinence fall within the nurse's scope of practice. Many patients incorrectly believe that surgery is the only treatment option for urinary incontinence. Surgical intervention is considered only if behavioral and pharmacologic measures prove ineffective (Davis et al., 2020; Peate, 2019). Indwelling urinary catheters are not recommended because of the associated risk of developing a UTI (Davis et al., 2020; Gould et al., 2019; Payne, 2020). Refer to Box 38-5 on page 1470 for a summary of behavioral and other treatment interventions and to the previous discussion related to strengthening muscle tone on page 1465.

Absorbent products can provide protection for skin and clothing but should not be used in place of definitive interventions to decrease or eliminate urinary incontinence (Vasavada et al., 2019a). These products absorb or contain urine leakage. Many types of disposable and reusable products are available, including perineal pads or liners, protective underwear, pads for furniture and beds, guards and drip collection pouches, and adult briefs (continence pads) (National Institute on Aging, 2017; Vasavada et al., 2019a). When used improperly, such products may cause incontinence-associated dermatitis or skin breakdown and place the patient at risk for a UTI (Nazarko, 2015; Vasavada et al., 2019a). Refer to the following Incontinence-Associated Dermatitis section for more information. Long-term use of these products is not recommended until the following factors have been considered and discussed with a health care provider:

- Functional disability of the patient
- Type and severity of incontinence
- Availability of caregivers
- Failure of previous treatment programs
- Patient preference

Advertisements for adult disposable briefs (undergarments) have increased public awareness about urinary incontinence, but they fail to mention possible treatment strategies. Refer to the accompanying Focused Critical Thinking Guide 38-1 on page 1471. External collecting devices may be useful in managing urinary incontinence (NIDDK, 2018b; Vasavada et al., 2019a). Refer to the External Urine Collection Devices on page 1472.

INCONTINENCE-ASSOCIATED DERMATITIS

Excessive contact of the skin with urine or feces leads to a form of moisture-associated skin damage known as **incontinence-associated dermatitis (IAD)**, inflammation of the skin (Lim & Carville, 2019; Mitchell & Hill, 2020; Voegeli, 2018). Excessive moisture can lead to overhydration (maceration) and disruption to the structure of the outer layers of the skin (Voegeli, 2018). Bacteria on the skin act to break down urea in urine to form highly alkaline ammonia, resulting in a shift of the pH of the skin away from normally slightly acidic, thus increasing the disruption to the protective barrier of the skin (Voegeli, 2018). Penetration by bacteria through damaged skin compounds the inflammatory response (Voegeli, 2018). Incontinence and resulting excessive moisture also contribute to pressure injury formation (Gray & Guiliano, 2018; Jacobson & Wright, 2015; Lachenbruch et al., 2016). Symptoms of IAD include erythema with poorly defined edges located in patches on the skin or continuously over large areas, and the skin may feel warmer and firmer than the surrounding unaffected skin (Beeckman et al., 2015; Francis, 2018). In patients with darker skin tones, skin may appear paler, darker, purple, dark red, or yellow when compared with the surrounding area (Beeckman et al., 2015). Lesions may be present, including vesicles, bullae, papules, or pustules. The epidermis may be damaged to varying depths with patients reporting discomfort, pain, burning, itching, or tingling (Beeckman et al., 2015; Francis, 2018; Jacobson & Wright, 2015). In addition to discomfort and pain, patients may experience loss of independence, alterations in activities and sleep, reduced quality of life, and secondary skin infections (bacterial and fungal) (Beeckman et al., 2015; Voegeli, 2018; Yates, 2018b).

Box 38-5 **Treatment Options for Urinary Incontinence**

Behavioral Techniques

- *Pelvic floor muscle training exercises:* Pelvic floor muscle training (PFMT) exercises (Kegel exercises) can be used to strengthen pelvic floor muscles and sphincter muscles. PFMT exercises can be done alone or with biofeedback.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

- *Biofeedback:* Measuring devices are used to help the patient become aware of when pelvic floor muscles are contracting.
- *Electrical stimulation:* Electrodes are placed in the vagina or rectum that then stimulate nearby muscles to contract.
- *Scheduled voiding* (*Timed voiding) Prompted voiding or Bladder training:* May be used with biofeedback. Patient keeps track of when voiding and leaking occur to enable oneself to plan when to void, with increasing length of voiding intervals. Bladder training involves biofeedback and muscle training. Urgency control is addressed using distraction and relaxation techniques. Prompting from a caregiver (reminding the individual to use the toilet and encouraging maintenance of bladder control between voiding) maybe included for individuals who have impaired cognitive function.

Weight Loss

- Obesity is a risk factor for incontinence because of increasing intra-abdominal pressure and pelvic floor weakness. Weight loss should be considered as a lifestyle change to improve incontinence in overweight patients.

Pharmacologic Treatment

- Treatment is dependent on the type of incontinence. Some medications inhibit contractions of the bladder, others may relax muscles, and some tighten muscles at the bladder neck and urethra.
- Collagen may be injected into the tissue around the urethra to add bulk and help close the urethral opening.

Mechanical Treatment

- *Pessaries*: A stiff ring that is inserted into the vagina, where it helps to reposition the urethra. The pessary may be placed by the patient or by a nurse.
- *External barriers*: Adhere to the urethral opening to stop urine leakage. The barrier is a small foam pad placed over the urethral opening. It seals against the body to keep urine from leaking. It is removed and discarded before the patient voids.
- *Urethral insert*: Small device, like a plug, that fits into the urethra. Removed to void, the insert is replaced until the patient needs to void again.
- *Surgical intervention*: Used as a last resort. Type of surgery depends on cause of incontinence.

(2018b, June). Urologic diseases. Bladder control problems (Urinary incontinence). https://www.niddk.nih.gov/health-information/urologic-diseases/bladder-control-problems?dkrd=/health-information/urologic-diseases/bladder-control-problems-women; Pair, L. S., & Somerall, W. E. (2018). Urinary incontinence: Pelvic floor muscle and behavioral training for women. *The Nurse Practitioner*, *43*(1), 21–25.

Prevention of incontinence is essential to prevent and treat IAD (Yates, 2018b). Skin care and use of containment products for incontinence are also critical pieces of evidence-based nursing care (Beeckman et al., 2015; Jacobson & Wright, 2015; Voegeli, 2018; Yates, 2018a). Appropriate skin care involves a structured skin care regimen that includes regular skin assessment, skin cleansing, moisturizers or emollients to replenish and restore lipids in the skin, and the use of skin barrier protectants to proactively protect the skin from urine-associated irritation, maceration (overhydration), and breakdown (Southgate & Bradbury, 2016; Yates, 2018a).

Cleansing of the skin should be provided daily and after each episode of incontinence. Prompt attention to incontinence events is necessary to prevent IAD (Phipps et al., 2019). Skin cleansers that are specially designed for at-risk or compromised skin and are pH-balanced should be used; many are no-rinse (Beeckman et al., 2015; Southgate & Bradbury, 2016; Voegeli, 2018; Yates, 2018a). Do not use soap and hot water as soap can irritate or dry the skin, or alter the skin's pH (Yates, 2018b). Avoid rubbing, excessive friction, or scrubbing, as this can damage the skin (Jacobson & Wright, 2015; Southgate & Bradbury, 2016; Yates, 2018a). Limit the use of disposable briefs; incontinence products that wick moisture away from the skin may be used as necessary (Jacobson & Wright, 2015). A skin barrier/protectant should be applied to all skin that comes into contact or may potentially come into contact with urine after cleansing to prevent direct contact with urine and to promote resolution of IAD if present (Beeckman et al., 2015; Yates, 2018b). Products are available that are "all-in-one," ensuring all steps of skin care are implemented and include a disposable soft cloth that contains cleanser, moisturizer, and barrier, for example (Francis, 2018). Patients

with complicated IAD that does not respond to treatment with 2 weeks should be referred to an advanced practice wound specialist, such as a wound ostomy continence nurse or dermatologist (Francis, 2018).

38-1 Focused Critical Thinking Guide

Urinary Incontinence

You have been assigned to care for an 80-year-old patient, Mrs. Bartowski, who was admitted with a recurrent leg ulcer and is due to be discharged the following day. Their nursing notes indicate that they have had two or three episodes of urinary incontinence every day while in the hospital and their care plan states, "use adult incontinence briefs." You go into the room to answer Mrs. Bartowski's call bell and help them into the bathroom. They are wearing adult disposable briefs (undergarments), and a half-used package is on the chair. After voiding 150 mL of urine, Mrs. Bartowski tearfully begs, "Please don't put that diaper back on me; I'm not a child." According to their chart, Mrs. Bartowski is mentally alert, lives at home with their daughter who has visited Mrs. Bartowski in the hospital frequently and appears able to identify their need to urinate. You are aware that there are effective alternative therapies to resolve or minimize urinary incontinence rather than relying on absorbent products. However, the nurses have obviously made a decision to use disposable undergarments in this situation. You prefer to leave the disposable undergarments off, try some other measures, and possibly discuss this with the patient's daughter, but as a student nurse, you are here for only 2 days. You want to be a patient advocate and do the right thing. What should you do?

1. Identify goal of thinking

Determine whether it is more important to replace the adult briefs against the patient's wishes or leave it off and discuss the possibility of using behavioral strategies with the staff.

2. Assess adequacy of knowledge

Pertinent circumstances: Mrs. Bartowski is alert and oriented and obviously upset that disposable briefs are being used. They have used the call bell when they feel the urge to urinate, but incontinent episodes have also been documented. The nursing staff has decided that disposable briefs are appropriate for this patient. Mrs. Bartowski's daughter, with whom Mrs. Bartowski lives, appears supportive and attentive. Discharge is scheduled for tomorrow.

Prerequisite knowledge: Before you decide what to do in this situation, you need to discuss your options with your instructor. Of primary importance is whether the patient and their daughter are interested in pursuing alternatives. They can also provide invaluable information about their elimination pattern at home. The health care team must be consulted to determine the etiology of the incontinence and validate that their urinary tract is intact and functioning adequately. You will also need to review the various treatment options for incontinence because these will have to be communicated to the patient and their daughter before discharge.

Room for error/time constraints: Absorbent products can provide a sense of security and are widely used for incontinence. There is, however, the possibility that continence can be restored once incontinence is assessed, recognized, and addressed. Early dependence on absorbent products can remove the motivation to seek treatment and promote acceptance of the condition. The treatment options should be discussed with Mrs. Bartowski and their daughter before discharge tomorrow.

3. Address potential problems

Continuing to use absorbent products offers a temporary solution to the problem. They may protect the patient from embarrassment and provide a sense of security, although they do nothing to prevent incontinent episodes. Explore the patient's feelings regarding the use of these products. The use of these products can communicate expectations of an acceptance of incontinence as an inevitable part of aging, which is not true. Absorbent products can also interfere with the patient's ability to use the toilet independently. Using behavioral techniques to control incontinence will require health teaching before discharge and a long-term commitment to follow-up in the home.

4. Consult helpful resources

The patient's motivation to restore continence is your most valuable resource. The primary nurse or case manager, the primary care provider, and your instructor can also help you sort through your priorities in this situation. The latest research recommends use of behavioral techniques first to treat incontinence.

5. Critique judgment/decision

If you decide to reapply disposable briefs against the patient's wishes, you may, in fact, be supporting the myth that incontinence is inevitable and untreatable and are not providing thoughtful person-centered care. Long-term use of absorbent products can place the patient at risk for skin breakdown and a urinary tract infection if used

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

improperly. You decide to leave the disposable briefs off and establish regular intervals for voiding for the 2 days you will be caring for Mrs. Bartowski. In this short time, you hope to demonstrate to the patient, their daughter, and the staff that it is possible for Mrs. Bartowski to maintain a pattern of continence. Because Mrs.Bartowski will most likely be discharged tomorrow, you also discuss the possibility of referral to community-based care or a continence expert who will instruct, support, and follow through with the necessary components of care. When you discuss your situation at postconference, your clinical group supports your decision.

External collecting devices may be useful in managing urinary incontinence and therefore minimizing and/or preventing IAD (NIDDK, 2018a; Vasavada et al., 2019a). Refer to the following discussion related to External Urine Collection Devices. Additional information and discussion related to incontinence and skin care can be found in Chapters 32 and 33.

External Urine Collection Devices

External urine collection devices adhere to the external genitalia or pubic area and collect urinary output (Gray et al., 2016; Newman, 2020b). There are single-use disposable devices, intended for use for 1 to 2 days, and some that are reusable for multiple times (Newman, 2020a).

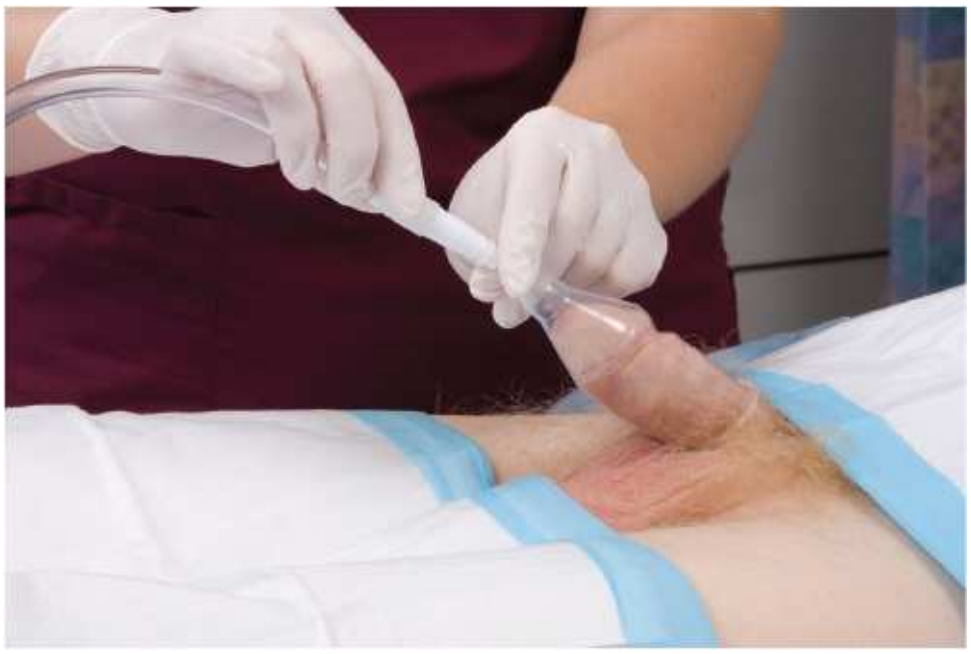

FIGURE 38-8. Urinary sheath applied externally to collect urine.

EXTERNAL URINARY SHEATH

When voluntary control of urination is difficult or not possible for patients with a penis, an alternative to an indwelling catheter is the condom-type **urinary sheath**, one type of external urine collection device for use on the penis (Newman, 2020a; Panchisin, 2016; Smart, 2014). This soft, pliable sheath made of silicone or latex material is applied externally to the penis and directs urine away from the body (Fig. 38-8). Most devices are self-adhesive. The external urinary catheter is connected to drainage tubing and a collection bag and can be used with a leg bag (refer to Fig. 38-6 [on page 1458] and the Patient Education discussion later in the chapter).

Think back to **Midori Morita**, the person described at the beginning of the chapter who is caring for her husband at home. The nurse might suggest using a urinary sheath for Mr. Morita as a possible intervention to manage his incontinence.

Nursing care of a patient with a urinary sheath includes vigilant skin care to prevent excoriation. Remove the condom daily and wash the penis with soap and water, dry it carefully, and inspect the skin for irritation. In hot and humid weather, more frequent changing may be required. Always follow the manufacturer's instructions for applying the sheath because there are several variations. In all cases, care must be taken to fasten the sheath securely enough to prevent leakage, yet not so tightly as to constrict the blood vessels in the area. When using sheath-type devices, the tip of the tubing should be kept 1 to 2 inches (2.5 to 5 cm) beyond the tip of the penis to prevent irritation to the sensitive

glans area. Maintaining free urinary drainage is another nursing priority. Institute measures to prevent the tubing from becoming kinked and urine from backing up in the tubing. Urine can lead to excoriation of the glans; position the tubing that collects the urine from the sheath to draw urine away from the penis.

For some people, the urinary sheath may not be an option because of penis retraction or inadequate length of the penile shaft (Newman, 2020a). For these patients, a non-sheath, glans-adherent device may be appropriate. This external urinary collection device has a hydrocolloid wafer faceplate that attaches to the glans around the meatus to form a seal around the meatus, reducing urine contact with the skin of the penile shaft (Newman, 2020a). An integrated tube attaches to a drainage bag to collect the urine (Newman, 2020a). A male urinary pouch is another option. This is an ostomy-like pouch that holds the penis and has an adhesive skin barrier that secures the device to the pubis (Newman, 2020a). The pouch can then be connected to a drainage bag.

EXTERNAL URINE COLLECTION SYSTEM

When voluntary control of urination is difficult or not possible for patients with female genitalia, an alternative to an indwelling catheter is a female external urine collection device (Beeson & Davis, 2018; Dublynn & Episcopia, 2019; Gentile et al., 2020; Newman, 2020a). Use of this device minimizes the risk for skin injury associated with incontinence and infection associated with an indwelling urinary catheter (Beeson & Davis, 2018; Dublynn & Episcopia, 2019; Gentile et al., 2020). The device consists of a "wick" that conforms to the perineal area between the labia against the urethra (Fig. 38-9B), collection tubing, and a collection canister attached to a pump (Fig. 38-9A). It is connected to low continuous suction providing a sump mechanism to collect and measure urine output. The device also delivers continuous air flow to promote a microclimate environment to the female perineal region (Beeson & Davis, 2018). Patients have reported a sense of cleanliness, increased comfort from remaining dry, and reduced pain and discomfort as a result of less frequent linen changes (Beeson & Davis, 2018). A female urinary pouch is another option. This is an ostomy-like pouch in which an adhesive skin barrier is cut to fit the vulvar opening and adheres to the labia to secure the pouch in place (Newman, 2020a). The pouch can then be connected to a drainage bag.

(2018). Urinary management with an external female collection device. *Journal of Wound, Ostomy and Continence Nursing*, *45*(2), 187–189. Doi: 10.1097/WON.0000000000000417

Catheterizing the Patient's Bladder

Urinary catheterization is the introduction of a catheter (tube) through the urethra into the bladder for the purpose of withdrawing urine. CAUTIs remain one of the most common causes of health care–associated infections in the United States (Knill et al., 2018). The best way to prevent a CAUTI is to use urinary catheters only when absolutely necessary (American Nurses Association [ANA], n.d.; Panchisin, 2016). The CDC provides parameters to guide the decision to insert an indwelling urinary catheter (Gould et al., 2019). When use of a urinary catheter is deemed necessary, it should be performed using strict aseptic technique, left in place only as long as needed, and removed as soon as possible (ANA, 2014; Gould et al., 2019; Gyesi-Appiah et al., 2020; SUNA, 2015).

APPROPRIATE USE OF URINARY CATHETERIZATION

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

Appropriate reasons for urinary catheterization include (ANA, 2014; Gould et al., 2019; Meddings et al., 2015):

- Relieving acute urinary retention. Retention is often temporary and is common after surgery involving the lower abdomen, pelvis, bladder, or urethra, especially if ambulation is delayed, fluid intake is minimal, or epidural analgesia is used for pain control. Bladder outlet obstruction, including mechanical obstruction such as swelling at the meatus (which can occur after childbirth), or an enlarged prostate in males may cause retention.
- Some patients who are unable to use any other bladder management method, such as those with neurogenic bladder dysfunction related to a disability (e.g., spinal cord injury) or intractable urinary retention, require long-term use of an indwelling catheter.
- Obtaining a sterile urine specimen when the patient is unable to voluntarily void.
- Accurate measurement of urinary output in critically ill patients.
- Assist in healing open sacral or perineal wounds in incontinent patients.
- Emptying the bladder before, during, or after select surgical procedures and before certain diagnostic examinations.
- Provide improved comfort for end-of-life care.
- Prolonged patient immobilization (potentially unstable thoracic or lumbar spine, multiple traumatic injuries).

Numerous algorithms and decision trees are available to assist nurses in use of best practices and to guide implementation of alternative interventions to an indwelling urinary catheter. Many facilities have adopted plans for standardizing care that outline alternatives to placing a catheter, based on indications for use, allowing nurses to use critical-thinking skills to improve patient safety and outcomes (ANA, 2014; Knill et al., 2018).

RELEVANT CONSIDERATIONS ABOUT THE LOWER URINARY TRACT

When catheterization is planned, consider the following about the lower urinary tract:

- The bladder is normally a sterile cavity.
- The external opening to the urethra can never be sterilized.
- The bladder has defense mechanisms. It empties itself of urine regularly and maintains an acidic environment, which has antibacterial advantages. These help to maintain a sterile bladder under normal circumstances and also help in clearing an infection if it occurs.
- Pathogens introduced into the bladder can ascend the ureters and cause bladder and kidney infections.
- A healthy bladder is not as susceptible to infection as an injured one. A state of lowered resistance, present in many health conditions and stressful situations, predisposes the patient to urinary infection.

TYPES OF CATHETERS

Urinary catheters are available in several different types of materials, with varying advantages and disadvantages. The use of antimicrobial coatings, such as silver alloy, on the catheter to reduce bacterial attachment, colonization, and migration, and antiseptic-impregnated catheters may contribute to decreased CAUTIs in some patient populations (Gould et al., 2019; Newman, 2013; Yates, 2016).

Intermittent urethral catheters, or straight catheters, are used to drain the bladder for short periods. Intermittent catheterization should be considered as an alternative to short-term or long-term indwelling urethral catheterization to reduce CAUTIs (Hooton et al., 2010). Intermittent catheterization is the preferred bladder management method for patients with urinary retention and bladder-emptying dysfunctions and following surgical interventions (Beauchemin et al., 2018; Gould et al., 2019). Certain advantages to intermittent catheterization, including the lower risks of CAUTI and complications, may make it a more desirable and safer option than indwelling catheterization (Panchisin, 2016; Wilson, 2015a). The Research in Nursing display provides insight into patients' experiences of and perspectives on ISC.

Research in Nursing

Bridging the Gap to Evidence-Based Practice

Self-Intermittent Catheterization

Intermittent self-catheterization (ISC) is taught to patients to help reduce complications of incomplete bladder emptying and voiding dysfunction and provides an alternative to the problems associated with indwelling catheterization (Collins, 2019; Lake, 2018). Learning ISC may be challenging, embarrassing, and fear-inducing for a patient and requires lifestyle adjustment and coping mechanisms (Collins, 2019; Logan, 2020). Nurses who have insight into the patient experiences are better equipped to meet patients' needs. What are the experiences of patients using ISC?

Related Research

Goldstine, J., Leece, R., Samas, S., & Zonderland, R. (2019). In their own words. Adults' lived experiences with intermittent catheterization. *Journal of*

Wound, Ostomy, and Continence Nursing, *46*(6), 513–518. https://doi.org/10.1097/WON.0000000000000591

This qualitative study explored the lived experiences of individuals using ISC to identify themes related to barriers and facilitators to integration of ICS in their daily lives. The sample of 25 adults from five countries had used ISC for at least 1 year and had used at least two different ISC products. Semistructured telephone interviews were conducted to gather information related to participants' reasons for using ISC, details of products in use or used in the past, and problems and/or challenges encountered with ISC products. Participants were also prompted to discuss the frequency and severity of urinary tract infection and ISC-related experiences that had influenced relationships with friends and family, mood and emotions, employment, activities, and other facets of life quality. Interviews were translated and transcribed and then analyzed for themes and subthemes. The researchers derived themes based on information from the transcribed interviews and triangulated selected themes with clinician experts in urology and previously published evidence for practice describing challenges, experiences, and health-related quality of life for ISC users. Analysis revealed nine main themes concerning individuals' lived experiences of ISC: initial fear, urinary tract infection, pain/discomfort, independence, choice, community, life quality, resilience, and acceptance. The researchers concluded that initial resistance to ISC is common, and practical challenges must be overcome. The researchers also concluded that ISC is perceived as a burden by some, but not all, users. The researchers suggested the challenge, and opportunity, for clinicians is to learn more about factors that enhance or hinder successful adaptation to ISC. The researchers suggested clinicians must develop interventions based on these insights as to what has gone right for those who have adapted to enable individuals to integrate ISC into their daily lives.

Relevance to Nursing Practice

The results of this study provide insight into the experiences of patients who use ISC to manage voiding dysfunction. Nurses play an important role in assisting patients with management of ISC. Nurses are in strategic positions to plan interventions to help address the challenges and barriers these patients encounter and to facilitate ISC to assist patients and support their desired quality of life.

Intermittent catheterization, performed by the patient or a caregiver in the home, may be necessary for patients with spinal cord injuries or other neurologic conditions. Although the risk for UTI is always present, research and practice guidelines support the use of clean, rather than sterile, technique in the home environment (Bardsley, 2015a; Beauchemin et al., 2018; Gould et al., 2019; Wilson, 2015a). Single-use catheters and no-touch catheters are options for use for ISC in the home setting (Beauchemin et al., 2018). No-touch catheterization makes use of a pre-lubricated catheter and packaging that includes a "no-touch sleeve" that allows handling of the catheter without directly touching the surface of the catheter (Fig. 38-10) (Gajewski et al., 2017). Due to this construction, no-touch catheterization reduces the risk of external contamination of the catheter, decreasing both the risk for infection and the time required to perform the procedure. The past practice of catheter reuse in community settings, instructing patients to wash and reuse the same catheter for multiple catheterizations, is not recommended; no evidence-based guidelines on cleaning or disposing of a reused catheter are available (Beauchemin et al., 2018; Newman, 2019b).

FIGURE 38-10. "No-touch" intermittent urinary catheter. (Courtesy and © Becton, Dickinson and Company)

Patients and/or caregivers should be taught to insert and remove intermittent catheters using a clean, nonsterile technique (Collins, 2019; Leach, 2018). The procedure for self-intermittent catheterization is essentially the same as

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

that used by the nurse to catheterize a patient. Initially, a patient with female genitalia may use a mirror to locate the meatus, but eventually they can learn to insert the catheter using just touch. Self-catheterization is recommended at regular intervals to allow the bladder to fill normally before being emptied again and prevent overdistention of the bladder and compromised blood supply to the bladder wall (Beaucheimin et al., 2018). Box 38-6 outlines important information related to ISC.

If a catheter is to remain in place for continuous drainage, an **indwelling urethral catheter** is used. Indwelling catheters are also called retention or Foley catheters. The indwelling urethral catheter is designed so that it does not slip out of the bladder. A balloon is inflated to ensure that the catheter remains in the bladder once it is inserted. Indwelling catheters are used for the gradual decompression of an overdistended bladder, for bladder drainage, and for continuous bladder drainage and irrigation. Several types of indwelling catheters are available, but the principles on which they operate are similar.

Box 38-6 Patient Intermittent Self-Catheterization

- Explain the reason for self-catheterization and corresponding health issues related to the need for catheterization.
- Explain the benefits of self-catheterization, including reducing high postvoid residual volumes, reduced risk of urinary tract infection compared to an indwelling urinary catheterization, and improved quality of life.
- Explain potential complications, such as bleeding and the risk of urinary tract infections and what to do if they occur.
- Ensure privacy and dignity.
- Include discussion regarding the frequency of intermittent catheterization and how to incorporate into the patient's usual daily routine.
- Explain the anatomy of the urinary tract, hygiene, and preparation of the catheter.
- Demonstrate how to open, hold, and use the catheter.
- Explain catheterization process, demonstrate process, and observe return demonstration by patient.
- Explore process to obtain supplies and assist with an informed choice of a catheter that suits the patient and their lifestyle.
- Provide information in an appropriate format (such as written materials or video, in appropriate language) to reinforce instruction.
- Allow the patient adequate time to ask questions.
- Provide information about how to recognize a urinary tract infection and other signs/symptoms to report to the health care team.
- Aids are available to help meet the challenges of intermittent self-catheterization for patients with poor eyesight, reduced mobility, and/or reduced manual dexterity.

The indwelling catheter has more than one lumen (open tube) within the catheter. In a double-lumen catheter, one lumen is connected directly to the balloon, which is inflated with sterile water; the other is the lumen through which the urine drains. The triple-lumen catheter provides an additional lumen for the instillation of irrigating solution. Figure 38-11 on page 1476 illustrates a triple-lumen, double-lumen, and straight (intermittent) catheter. Catheterization using an indwelling urethral catheter is discussed in Skills 38-2 and 38-3 on pages 1493 to 1505.

QSEN EVIDENCE-BASED PRACTICE (EBP)

Urinary catheterization is an intervention that can be associated with many potential adverse effects, including a high risk for catheter-associated infection. Nurses must work to ensure individualized care plans based on patient values, clinical expertise, evidence, and best-practice guidelines related to urinary catheterization.

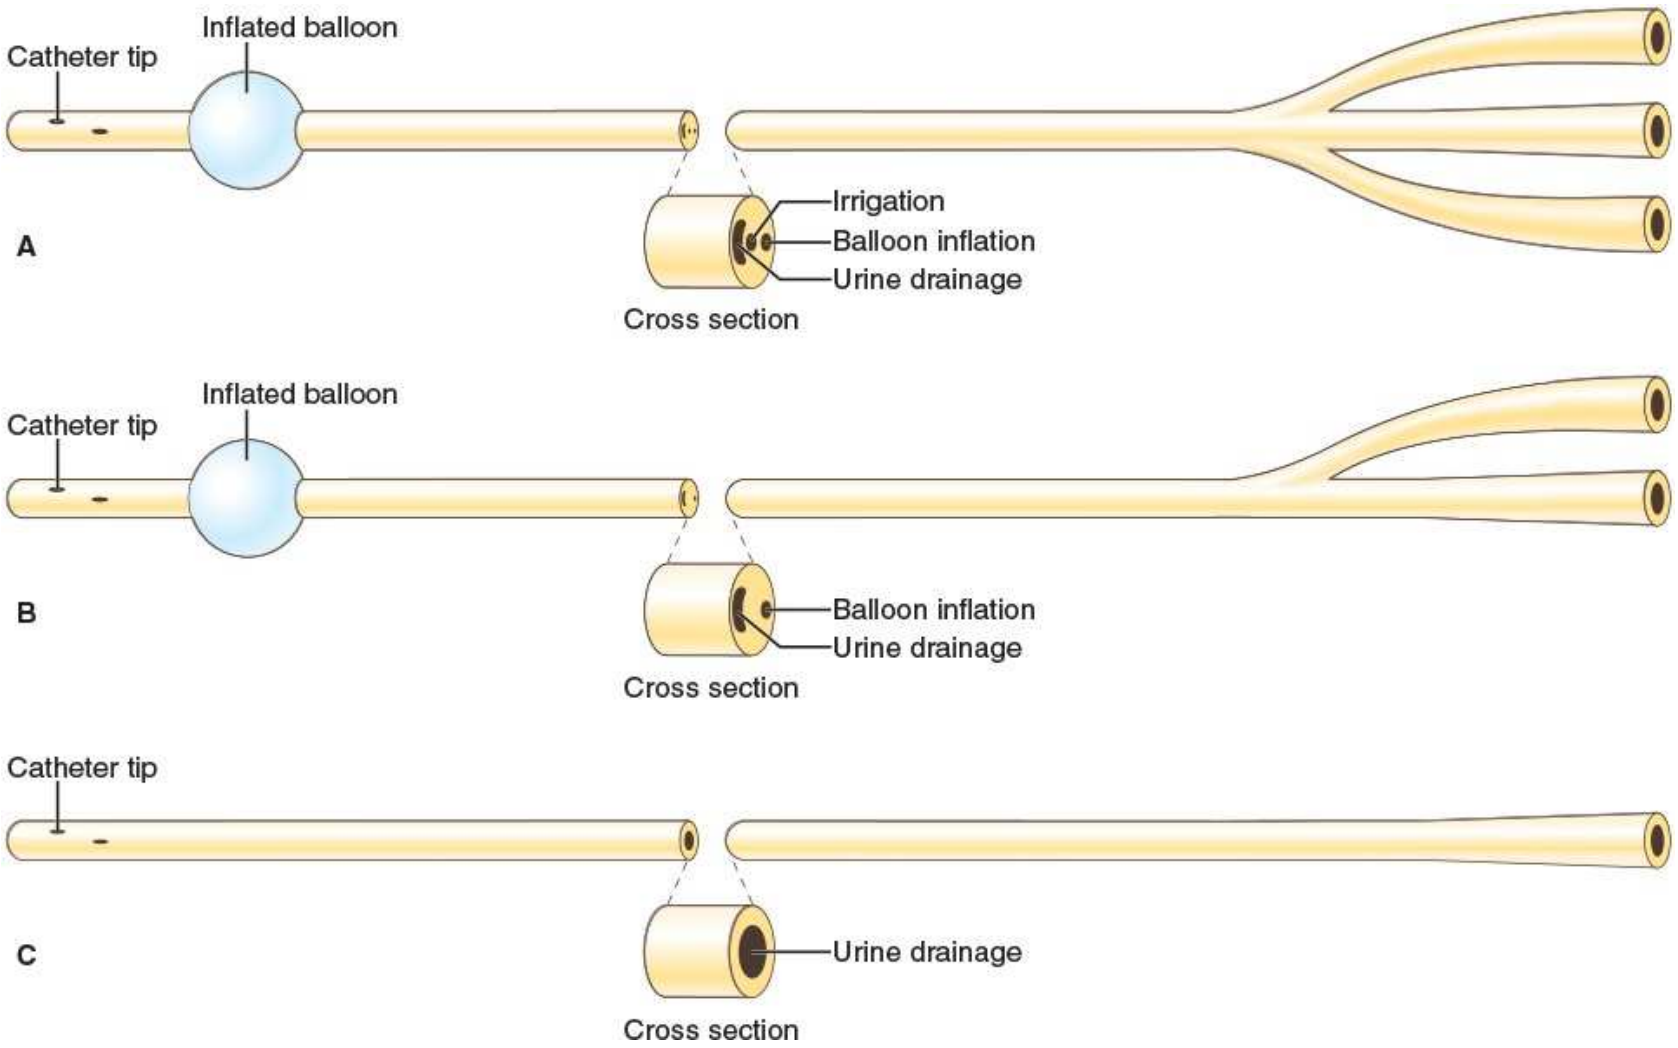

FIGURE 38-11. **A.** Triple-lumen indwelling catheter. **B.** Double-lumen indwelling catheter. **C.** Straight (intermittent) catheter.

A **suprapubic catheter** is an indwelling urinary catheter used for long-term continuous drainage. This type of catheter is inserted surgically through a small incision above the pubic area (Fig. 38-12). Suprapubic bladder drainage diverts urine from the urethra when injury, stricture, prostatic obstruction, or gynecologic or abdominal surgery has compromised the flow of urine through the urethra (Hill & Mitchell, 2018). A suprapubic catheter may be preferred over indwelling urethral catheters for long-term urinary drainage in patients for whom no other alternative is possible (Gibson et al., 2019). Suprapubic catheters are associated with decreased risk of contamination with organisms from fecal material, elimination of damage to the urethra, not interfering with sexual activity, increased comfort for patients with limited mobility, and lower risk of CAUTIs (Buehrle et al., 2020; Gibson et al., 2019; Hooton et al., 2010). The drainage tube may be secured with sutures and should be secured with a catheter fixation device or tape (Holroyd, 2019). Care of the patient with a suprapubic catheter includes skin care around the insertion site; care of the drainage tubing and drainage bag is the same as for an indwelling catheter (see Caring for Patients with an Indwelling Catheter).

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

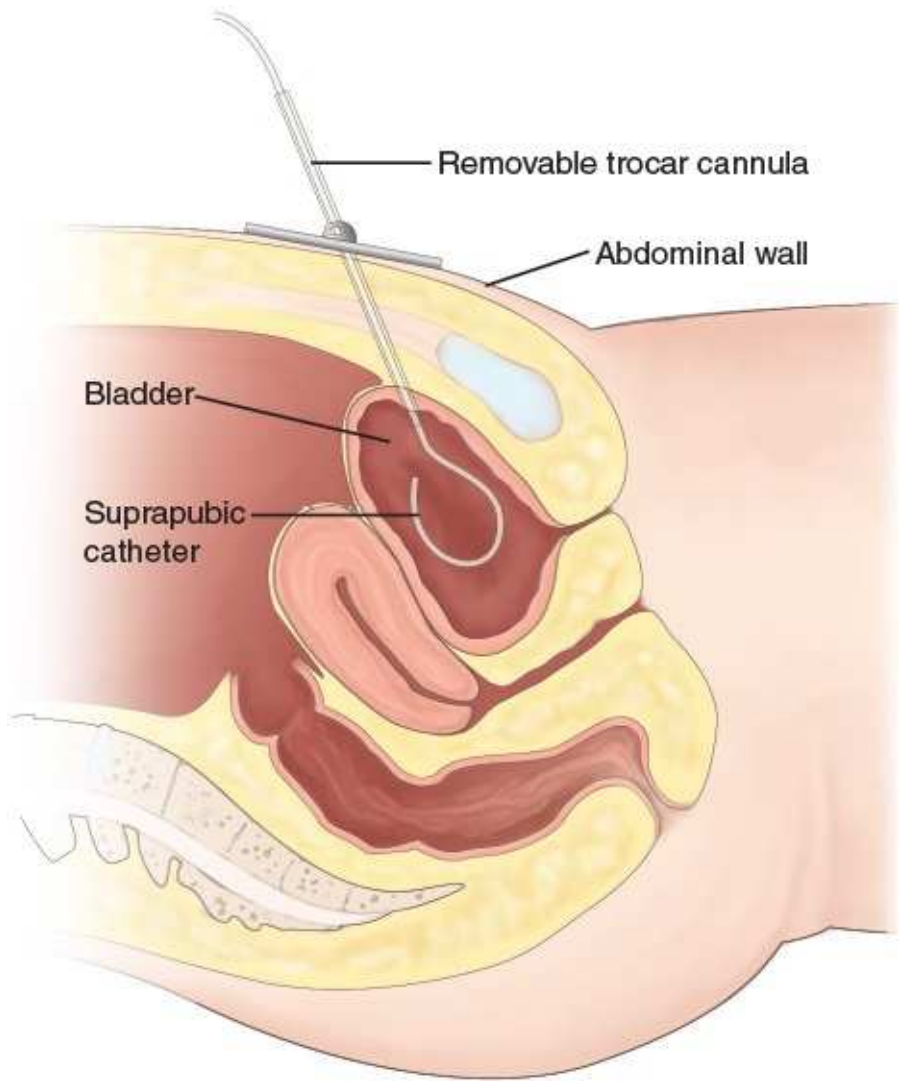

FIGURE 38-12. A suprapubic catheter positioned in the bladder.

CATHETER-ASSOCIATED HARM

UTI, injury, pain and bladder spasm, and sepsis are some of the hazards associated with introducing an instrument such as a catheter into the bladder (Davey, 2015; Fakih et al., 2016; Hill & Mitchell, 2018; Yates, 2017a). The male urethra is especially vulnerable to injury because of its longer length. An object forced through a stricture or an irregular opening from the wrong angle can seriously damage the urethra. Although the female urethra is shorter than the male urethra, it is also susceptible to damage if a catheter is forced through it. The mucous membrane lining the urethra is delicate and damaged easily by the friction resulting from the insertion of a catheter. Bacteria can enter the bladder when the catheter is inserted.

Indwelling catheters are associated with the development of a biofilm, a living layer of bacteria, on the surface of the catheter and drainage system, which may increase the risk of infection; bacteria within biofilms play a role in the development of CAUTI and are a growing concern (Gould et al., 2019; Pelling et al., 2019; Norris, 2020; Sabir et al., 2017). When the catheter is left in place, the organisms may move up the catheter lumen or the space between the catheter and the urethral wall. This asymptomatic condition in which bacteria are present in the urine is known as **bacteriuria**.

EQUIPMENT

The equipment used for catheterization is usually prepackaged in a sterile, disposable tray and is the same for patients with male or female genitalia. Most kits already contain a standard-sized catheter. Catheters are graded on the French (F) scale according to lumen size, with 12 to 16F gauge commonly used (Bardsley, 2015a; Beauchemin et al., 2018; Newman, 2013). The smallest appropriate indwelling urinary catheter that will allow effective drainage should be selected to aid in prevention of CAUTIs in the adult hospitalized patient (ANA, 2014; SUNA, 2021b; Yates, 2017a). A 14F, 5-mL or 10-mL balloon is usually appropriate, unless ordered otherwise (ANA, 2014). Smaller catheters usually are not necessary; a smaller lumen would be so small that it would increase the time necessary for emptying the bladder. Larger catheters distend the urethra and increase the discomfort of the procedure. Large-size catheters (18F or larger) can cause more erosion of the bladder neck and urethral mucosa, cause the formation of strictures, and can cause pain and discomfort (Herter & Wallace Kazer, 2010; Newman, 2013). Sizes 6F to 8F are used for infants and young children; sizes 8F to 12F catheters are commonly used for older children and adolescents (Kyle & Carman, 2021). As mentioned previously, the use of catheters with antimicrobial-coatings has been shown to reduce bacterial colonization and minimize biofilm formation and may be prescribed for use (Gould et al., 2019; Newman, 2013; Yates, 2016).

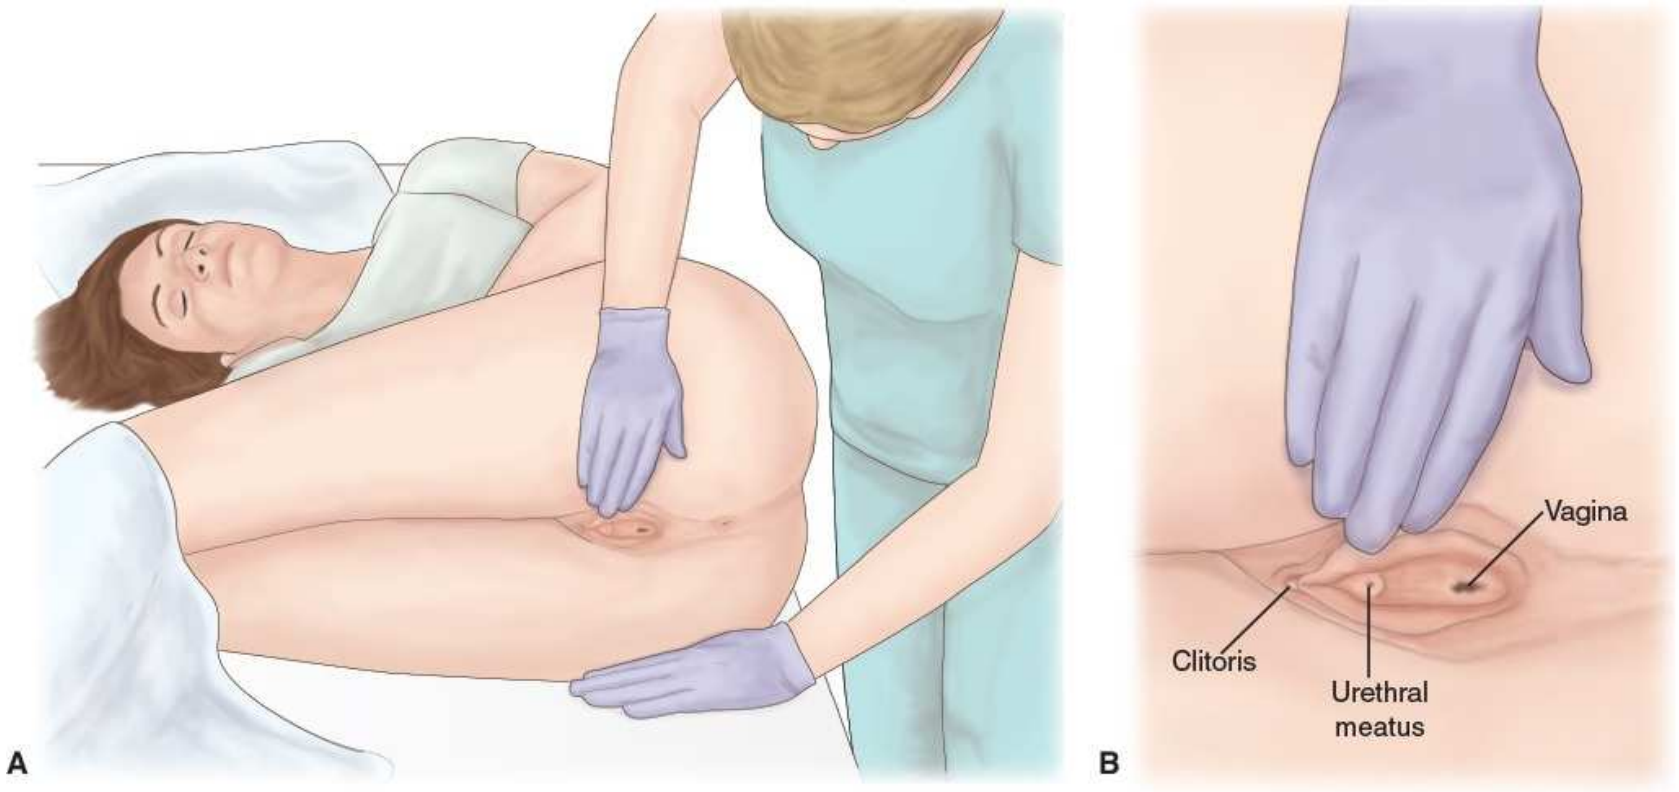

FIGURE 38-13. Demonstration of the side-lying position **(A)** and of how to expose the urinary meatus when catheterizing a patient with female genitalia in the side-lying position **(B)**.

PATIENT PREPARATION

Before the catheterization, explain the procedure to the patient and the reason for it. Tell the patient that catheter insertion produces a sensation of pressure and some discomfort. Explain that measures will be taken to avoid exposure and embarrassment. The more relaxed the patient is, the easier it will be to insert the catheter.

The most common patient position for catheter insertion is supine with the patient preferably on a solid surface, such as a firm mattress or a treatment table. Catheterizing a patient in a bed with a soft mattress, especially a patient with female genitalia, is not as satisfactory because the patient's pelvic surfaces are not firmly supported, and visualization of the meatus is difficult. Also, the patient may sink into the bed, causing the bladder to be lower than the outlet of the catheter. If the patient is in bed, supporting their buttocks on a firm cushion may be helpful. Patients with female genitalia should lie with their knees bent and legs spread apart (SUNA, 2021a; Yates, 2017b); patients with male genitalia should lie with their legs extended/straight (SUNA, 2021c; Yates, 2017a).

The Sims', or lateral, position is an alternate position for catheter insertion for patients with female genitalia. This position may allow better visualization and be more comfortable for the patient, especially if hip and knee movements are difficult. The smaller area of exposure is also less stressful for the patient. Allow the patient to lie on either side, depending on which position is easiest for the nurse and best for the patient's comfort. Place the patient's buttocks near the edge of the bed with their shoulders at the opposite edge and their knees drawn toward their chest. Lift the upper buttock and labia to expose the urinary meatus (Fig. 38-13).

URETHRAL CATHETER INSERTION

Nurses are often responsible for performing urinary catheterization, inserting indwelling catheters and caring for the patient with a catheter. Skill 38-2 (on pages 1493–1499) describes catheterization of the urinary bladder of a patient with female genitalia, and Skill 38-3 (on pages 1500–1505) describes catheterization of the urinary bladder of a patient with male genitalia. Some facilities have adopted a two-person urinary catheter insertion protocol, in which one nurse catheterizes the patient and one observes to ensure that the nurse inserting the catheter follows sterile technique and performs the procedure correctly (Belizario, 2015; Rhone et al., 2017). Implementation of the two-person urinary catheter insertion protocol has been shown to decrease CAUTI (Belizario, 2015; Fletcher-Gutowski & Cecil, 2019; Rhone et al., 2017).

Adhering to surgical asepsis is of utmost importance to help prevent UTIs. An inflated balloon holds the indwelling catheter in position in the bladder. The prefilled syringe included in the catheter kit contains the amount of sterile water needed to inflate the balloon to the desired spherical shape. It is important to use the entire amount provided by the manufacturer to avoid underinflation of the catheter balloon. A balloon that is only partially inflated could cause irritation and erosion to the mucosa in the bladder.

Some institutions' policies/procedures identify use of anesthetic gel should be considered before insertion of the catheter if it is the patient's first catheterization, or if a difficult catheterization is anticipated (SUNA, 2021a; SUNA, 2021d). Check for patient allergy before use of anesthetic gel and allow at least 5 minutes after administration before catheterization to ensure sufficient anesthetic effect (Yates, 2017b).

Properly secure an indwelling catheter to the thigh or abdomen to prevent movement and excessive force on the bladder neck or urethra, which leads to irritation or injury (Holroyd, 2019; SUNA, 2015; Yates, 2016). The indwelling catheter is connected to a drainage and collection system that must be properly positioned and secured to minimize the

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

risk for infection (refer to Fig. 38-6 [on page 1458] for examples of urine collection bags). The following techniques should be used to complete the closed urinary drainage system:

- Maintain a constant downward flow of urine. Check tubing frequently to ensure kinks and dependent loops (low points) are not present in the tubing (ANA, 2014; Gould et al., 2019; Wuthier et al., 2016). Check to see that the patient is not lying on the drainage tubing and compressing it.
- Keep the catheter drainage bag below the level of the bladder at all times (ANA, 2014; Gould et al., 2019).
- Keep the drainage bag off the floor at all times to reduce the risk of infection (ANA, 2014; Gould et al., 2019). The floor is grossly contaminated.
- Check that all connections are secure, and that no leakage is occurring.
- Maintain the closed drainage system (Gould et al, 2017).

See the accompanying Through the Eyes of a Student for a student's account of their experience with urinary catheterization.

CARING FOR PATIENTS WITH AN INDWELLING CATHETER

The following are important nursing measures used to care for patients with an indwelling catheter:

- Wash hands before and after caring for the patient.
- Use mild soap and water or a perineal cleanser to clean the perineal area thoroughly, especially around the meatus, daily and after each bowel movement. Rinse the area well. Do not use powders and lotions after cleaning. Do not use antibiotic or other antimicrobial cleaners or betadine at the urethral meatus (Gould et al., 2019; Herter & Wallace Kazer, 2010).

Through the Eyes of a Student

Remembering my first hospital experiences, I would have to say that doing my first catheterization was the scariest. I was working with a nurse on the maternity floor. Our patient had not voided in more than 8 hours and seemed to be in great discomfort. We palpated their abdomen to see if their bladder was distended, and it was. Because they didn't have an urge to void, we decided to straight catheterize them to lessen their discomfort. The nurse I was working with turned and handed me the kit. They said, "You know what to do, right?" Automatically I replied, "Sure."

My heart began to race. Of course, I knew the procedure, but I never actually did it on a real person. Not only was I nervous about doing the procedure, but I also didn't want to make their labor more painful. The nurse, out of courtesy, asked the patient if they minded if I did the procedure. Thank God, the patient had a soft side for a beginner. Smiling, they looked at me and said, "You know what you're doing, right?" Again, I said, "Sure." I began setting up to start the procedure. To my amazement, I really did remember how to prepare for a catheterization. When it was time to insert the catheter, I took a deep breath. Thankfully, it went in nice and smooth, and I reached the bladder in seconds. The urine began flowing through rapidly. It seemed like it would never stop. Amazingly, it filled the container. I removed the catheter, cleaned up, and let out my breath.

In summary, I was glad that I had the experience to do a catheterization. The nurse told me that I did a good job, which made me feel good. Also, my patient thanked me for relieving some of their discomfort and gave me a reassuring smile. As I look back now, it wasn't as bad as I had myself believing it would be. Even though it's invasive to the patient, sometimes it's necessary. I want to do everything I can to help my patients. Now, I look at all my new adventures as helping my patients feel better.

—Alysia Paxson, Holy Family College, Philadelphia

- Cleanse the catheter by cleaning gently from the meatus outward.
- Make sure that the patient maintains a generous fluid intake, unless contraindicated by other health concerns. This helps prevent infection and irrigates the catheter naturally by increasing urine output.
- Encourage the patient to be up and about, as ordered.
- Note the volume and character of urine, and record observations carefully. Observe the urine through the drainage tubing and in the collection container. Note and record the amount of urine on the patient's intake-and-output record every 8 hours. The collection container is calibrated, but the volume markings are only approximations. Empty the urine into a graduated container that is calibrated accurately for correct determination of output.
- Do not open the drainage system to obtain urine specimens or to measure urine. If the tubing becomes disconnected and the sterile closed drainage system has been compromised, replace the catheter and collecting system (ANA, 2014; SUNA, 2015). When emptying the drainage bag, make sure the drainage spout does not touch a contaminated surface.
- Teach the patient the importance of personal hygiene—especially the importance of careful cleaning after having a

bowel movement—and thorough, frequent hand hygiene.

- Promptly communicate any signs or symptoms of infection. These include a burning sensation and irritation at the meatus, cloudy urine, a strong odor to the urine, an elevated temperature, and chills.
- Help the patient take a shower for personal hygiene if possible. Remember to keep the collecting bag lower than the bladder to promote drainage.
- Consider evidence-based practice guidelines and facility policy to ensure that the catheter is removed at the earliest time possible, to limit use to the shortest duration possible (ANA, 2014; Gould et al., 2019; SUNA, 2015).
- Change indwelling catheters only as necessary. The interval between catheter changes varies and should be individualized for the patient, based on clinical symptoms: catheter encrustations, obstruction, leakage, bleeding, and CAUTIs (Gould et al., 2019; Herter & Wallace Kazer, 2010; Palka, 2014; SUNA, 2015).
- Patients who require long-term use of an indwelling catheter may experience self-care practice and catheter challenges. Patients need educational interventions to address fluid intake, bowel management, hygiene, and self-monitoring/management, including potential adverse events (Alex et al., 2020).

PATIENT EDUCATION

Teach patients who have an indwelling catheter how the system functions and how to care for the catheter and drainage system. Teaching points include keeping the tubing free of kinks, maintaining a constant downward flow of urine, maintaining an adequate fluid intake, and promptly reporting any unusual symptoms (Hill & Mitchell, 2018).

Several different urinary drainage systems are available. Nurses need to understand the options in order to provide appropriate patient teaching and support informed patient choice when selecting a drainage option (Yates, 2016). Closed drainage systems include a large, 2-L drainage bag (discussed in previous sections); a smaller drainage bag that can be secured to the leg (leg bag) that is not considered a closed system because of the need to regularly open the leg bag for drainage and connect to an overnight drainage bag (Newman, 2013); or a catheter valve (discussed below). Instruct patients to do the following when handling the drainage system:

- Reinforce the importance of hand hygiene, particularly before and after handling the catheter system, emptying the drainage bag, and personal hygiene.
- Secure the drainage bag below the level of the bladder.
- Empty the leg bag at regular intervals, to allow the bag to become no more than half to two thirds full (Shah, 2019b; Wilson, 2015b). A full drainage bag may cause reflux of urine into the bladder (bags that are not anti-reflux) or may pull away from its attachment on the leg. Use an antiseptic solution to cleanse the bag outlet before and after emptying or changing from a leg bag to a larger overnight drainage bag (Shah, 2019b; SUNA, 2015; Wilson, 2015b).
- Many leg bag systems have a silicone tube attachment that allows for a secure connection between the outlet and to a larger night urine collection bag (Newman, 2013; Yates, 2016).
- Drainage bags should be cleaned between uses according to the manufacturer's recommendations; suggested cleaning solutions vary and include dilute white vinegar or bleach solution (Bradley et al., 2018; Shah, 2019b).
- Leg bags should be changed in accordance with the manufacturer's recommendations; suggested replacement for reusable drainage bags varies from every 5 to 7 days (Wilson, 2015b; Yates, 2016) to every 15 to 30 days (Newman, 2013; Shah, 2019b).
- Leg bags can be used with indwelling urinary catheters, suprapubic catheters, and external urine collection devices.

CATHETER VALVES

Catheter valves are an alternative to use of a large urinary drainage or leg bag (Wilson, 2015b; Yates, 2016). A catheter valve is a small device like an outlet valve on a urine drainage bag that is inserted into the end of an indwelling catheter (Carr, 2019). These valves are used in place of a drainage bag with an indwelling urethral or suprapubic catheter. Urine continues to collect in the bladder instead of a drainage bag. The patient opens the valve to release urine every 3 to 4 hours (Yates, 2017c). Use of a catheter valve promotes bladder health and keeps function as normal as possible, reduces the risk for bladder neck and urethra trauma, and possibly reduces the buildup of biofilm and infection (Carr, 2019). Catheter valves also promote improved patient privacy and dignity, and may be more comfortable for patients (Carr, 2019; Yates, 2016). However, catheter valves may not be appropriate for use by patients with low bladder capacity, detrusor muscle overactivity, reduced sensation of bladder fullness, poor manual dexterity, or with alterations in cognitive function (Carr, 2019; Wilson, 2015b; Yates, 2016). Catheter valves should be changed every 5 to 7 days (Yates, 2017c). The same patient teaching points discussed related to drainage bags and leg bags are relevant to the changing of a catheter valve, as discussed in the previous section (Yates, 2016).

IRRIGATING THE INDWELLING CATHETER

The flushing of a tube, canal, or area with solution is called irrigation. Natural irrigation of the catheter through increased fluid intake by the patient is preferred. The purpose of an external catheter irrigation is to restore or maintain

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

its patency. A bladder irrigation rinses out the bladder and can also instill medication that acts directly on the bladder wall. Routine intermittent irrigation of long-term catheters is not recommended (Gould et al., 2019). Unless obstruction is anticipated, as might occur with bleeding after prostatic or bladder surgery, bladder irrigation is not recommended (Gould et al., 2019; SUNA, 2015). Irrigations might also be used to instill medications that will act directly on the bladder wall. Irrigating a catheter through a closed system is preferred to opening the catheter because opening the catheter could lead to contamination and infection (Gould et al., 2019). Closed-system irrigation via a triple-lumen catheter is suggested to prevent obstruction and maintain a closed system and is recommended to prevent the introduction of pathogens into the bladder (Fig. 38-14) (Gould et al., 2019).

REMOVING THE INDWELLING CATHETER

The removal of an indwelling catheter and the aftercare of the patient should include the following nursing measures:

- Perform hand hygiene before and after the procedure, and wear gloves.
- Check the health record to see how much water was used to inflate the catheter balloon (Yates, 2017d). Empty the catheter drainage bag, taking the time to ensure any urine in the tubing drains into the bag.
- Remove the catheter fixation device. Place a waterproof drape under the catheter where it enters the patient. Deflate the balloon before attempting to remove the catheter by inserting a syringe into the balloon inflation port to remove the same volume of water. Allow the pressure within the balloon to force the syringe plunger back and fill the syringe with water; do not pull on the plunger of the syringe (Yates, 2017d). Do not cut the tubing with scissors.
- Ask the patient to take several deep breaths to relax; ask the patient to exhale, and gently remove the catheter during exhalation (Yates, 2017d). Wrap the catheter in a towel or disposable waterproof drape. Dispose of catheter and drainage system according to facility policy.
- Clean the perineal area after the catheter is removed.
- Ensure that the patient's fluid intake is generous and record the patient's fluid intake as well as time and amount of fluid output for at least 24 hours (or according to facility policy) following catheter removal.
- Instruct the patient to void into a bedpan, urinal, or specimen hat, either in bed or in the bathroom.

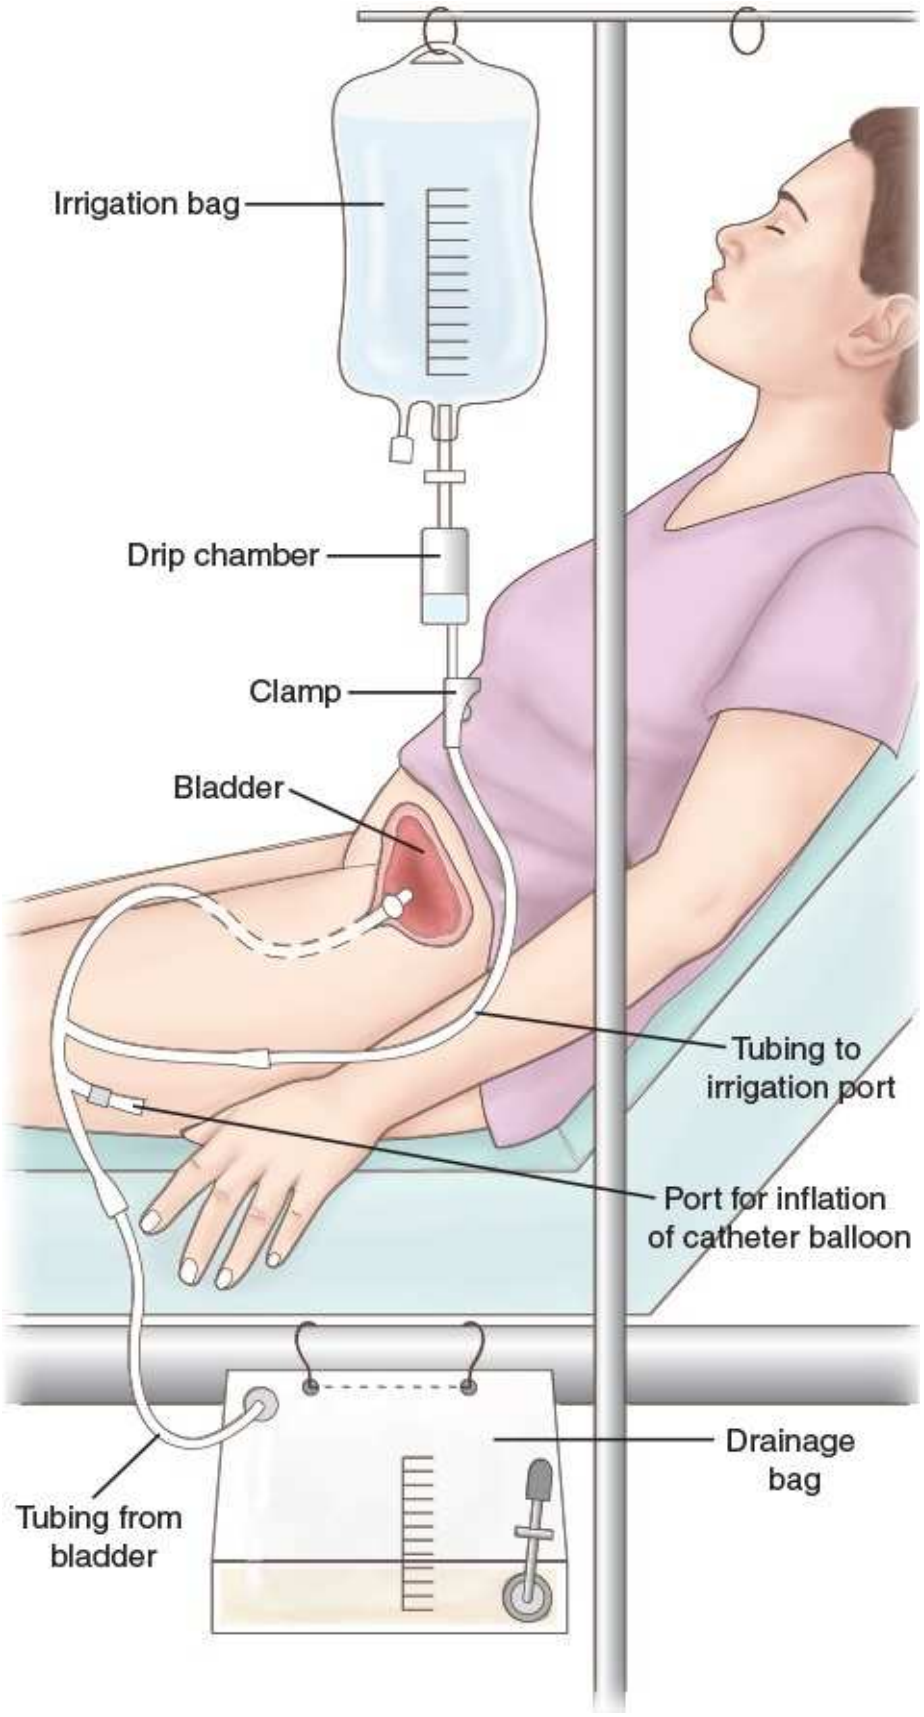

FIGURE 38-14. A continuous bladder irrigation (CBI) setup.

- Inform the patient that it may take a little while for the bladder to reestablish voluntary control and that an accident at this time is not unusual.
- Tell the patient that there may be a slight burning sensation or discomfort when voiding the first time or two after catheter removal as well as urgency and/or frequency.
- If the catheter was in place for more than a few days, decreased bladder muscle tone and swelling of the urethra may cause the patient to experience difficulty voiding or an inability to void. Monitor the patient for urinary retention.
- Check facility policy regarding the length of time the patient is allowed to accomplish successful voiding after catheter removal. If patient does not void within 8 to 10 hours of removal of the indwelling catheter (or timing according to facility policy), notify the health care team.
- Observe the urine carefully for any abnormalities. Document the volume of the first void to validate adequate emptying of the bladder post removal.
- Record and communicate any unusual signs or symptoms, such as discomfort, a burning sensation when voiding, bleeding, or changes in vital signs, especially the patient's temperature. Be alert to any signs or symptoms of infection and communicate them promptly.

Caring for a Patient With a Urologic Stent

Urologic stents are thin, soft hollow tubes inserted into the urinary system to provide drainage of the upper urinary tract, when obstruction of the ureter is present or anticipated (Beysens & Tailly, 2018). Stents are implemented as part of many urologic interventions, such as to facilitate healing after removal of renal calculi and prevent swelling of the

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

ureter, and to facilitate drainage and flow of urine from the kidney to the bladder in the presence of ureteral stricture or obstruction related to cancer or renal calculi (Badawy et al., 2019). The stent may be temporary (e.g., when placed in the ureters) (Fig. 38-15) or permanent (when positioned in the urethra). Temporary stents are usually made of a pliable material such as radiopaque silicone or polyurethane. Permanent stents are stronger and typically are made of a flexible metal mesh. Stents may be placed during surgery or cystoscopy.

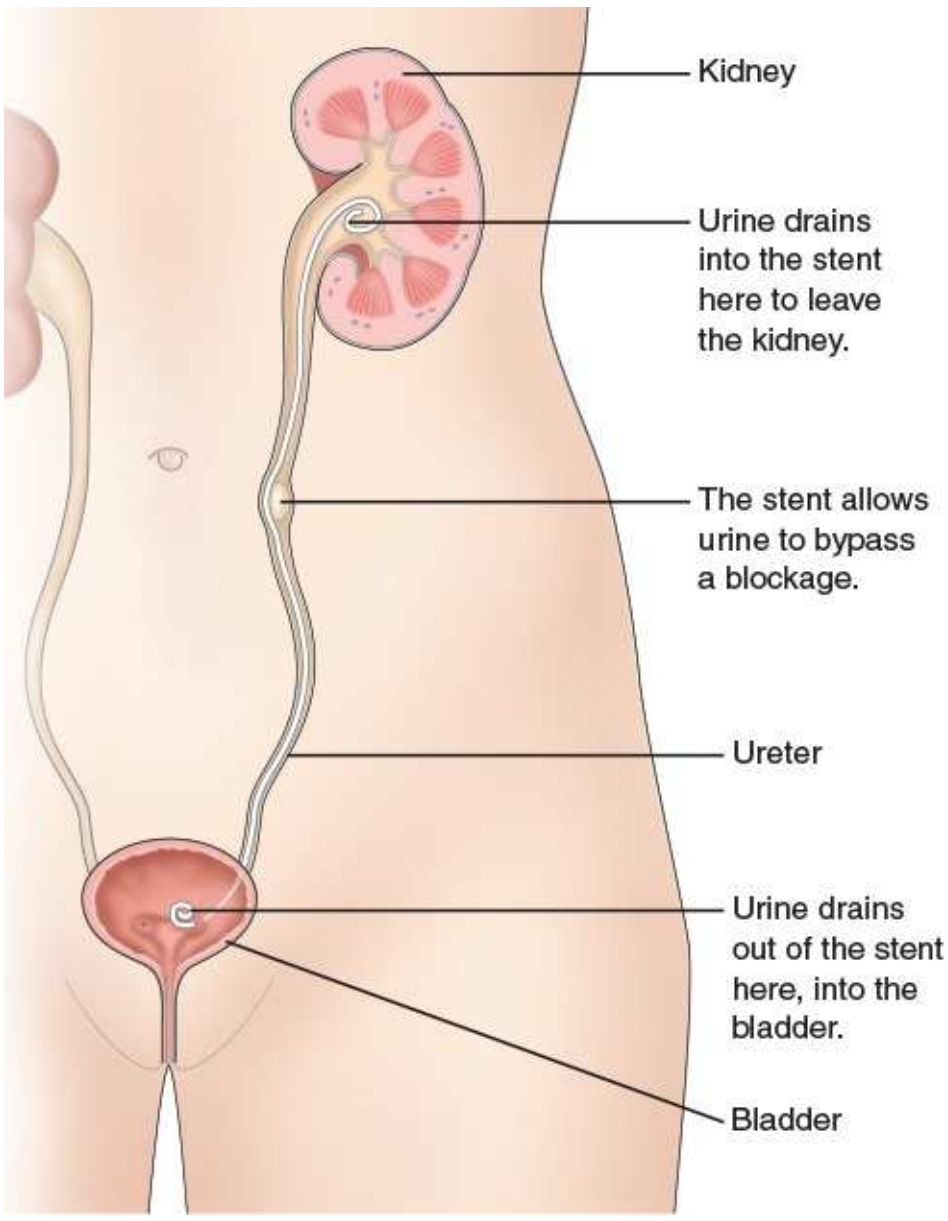

FIGURE 38-15. Ureteral stent.

Nursing responsibilities for patients with urologic stents include monitoring urine output, including color, consistency, and odor of the urinary output; monitoring for signs of infection or bleeding; and monitoring for decreased urine output, which could indicate obstruction of the stent. The stent could become obstructed because of bleeding or sediment. Obstruction of the stent may result in hydronephrosis (swelling of the kidney) and kidney damage and must be addressed immediately. Never irrigate a stent. If the stent has been brought to the surface of the skin, it is secured to maintain its position (Bauldoff et al., 2020). Instruct the patient with a urologic stent to maintain sufficient fluid intake to maintain adequate urine output. Patients should understand the need to notify the health care team immediately if the urine becomes bright red, severe pain occurs, the drainage pattern changes, or any sign of infection is present. Encourage the patient to wear a medical alert bracelet identifying the presence of a urologic stent at all times.

Caring for a Patient With a Urinary Diversion

Obstructions or tumors in the urinary tract may require some patients to have urinary flow diverted surgically. Urinary diversions may also be used as part of the treatment for patients with a neurogenic bladder, radiation cystitis, or congenital anomalies of the lower urinary tract. An ileal conduit is a type of incontinent cutaneous urinary diversion. An **ileal conduit** (also known as a urostomy) is the most common type of incontinent cutaneous urinary diversion (Berti-Hearn & Elliott, 2019; Goldberg et al., 2018). An ileal conduit involves a surgical resection of the small intestine, with transplantation of the ureters to the isolated segment of small bowel. This separated section of the small intestine is then brought to the abdominal wall, where urine is excreted through a stoma, a surgically created opening on the body surface. Figure 38-16 shows how the ureters are diverted in an ileal conduit. A **cutaneous ureterostomy** is another type of incontinent cutaneous urinary diversion in which the ureters are directed through the abdominal wall and attached to an opening in the skin. These cutaneous diversions are usually permanent, and the patient wears an external appliance to collect the urine because elimination of the urine from the stoma cannot be controlled voluntarily.

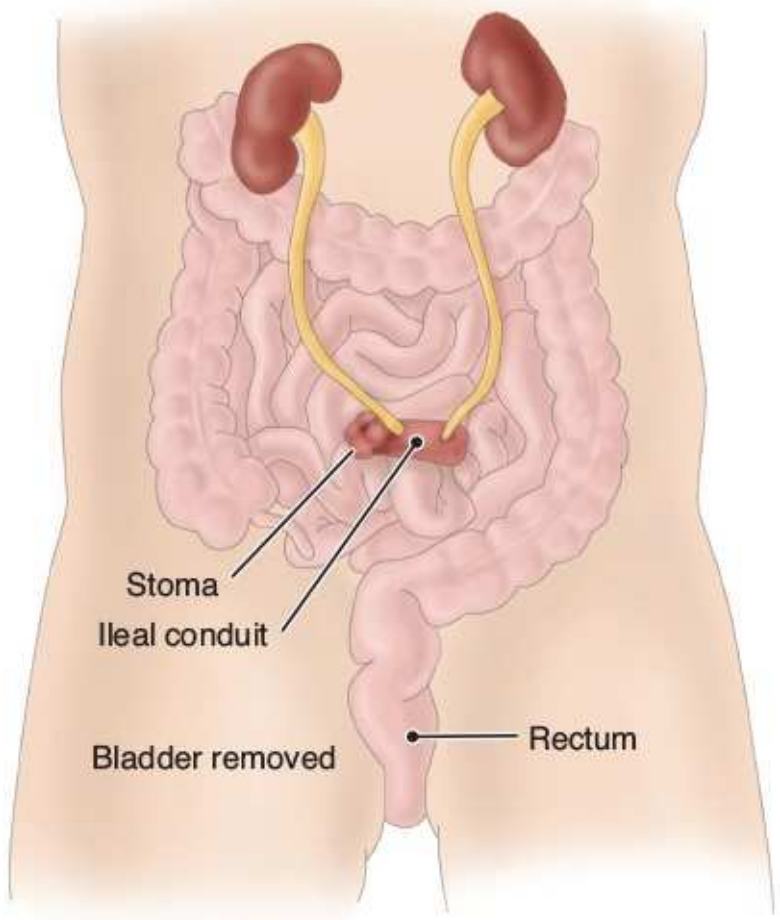

FIGURE 38-16. An ileal conduit. The ureters are brought to the separated segment of the ileum of the small intestine and a stoma is made where the urine is excreted.

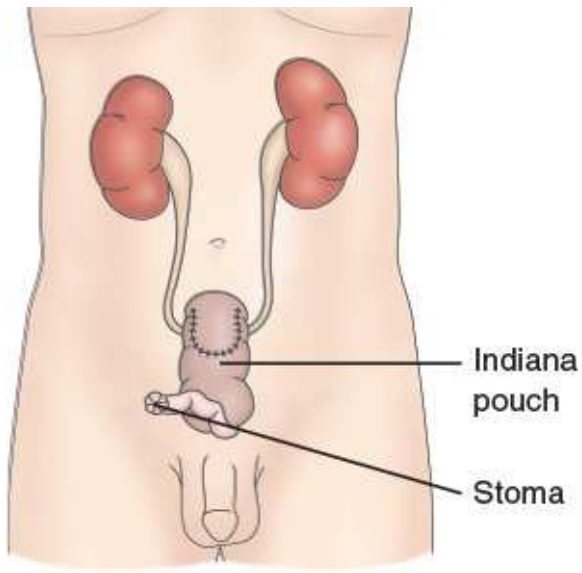

FIGURE 38-17. An Indiana pouch. The ureters are diverted into a segment of ileum and cecum to create an internal reservoir that holds urine and a catheterizable stoma. (*Source:* Reprinted with permission from Hinkle, J. L., Cheever, K. H., and Overbaugh, K. J. [2022]. Brunner & Suddarth's textbook of medical–surgical nursing [15th ed.]. Wolters Kluwer.)

Another option for diversion of urine is a **continent urinary diversion (CUD)** (e.g., the Indiana pouch and the Kock pouch). Figure 38-17 shows how the ureters are diverted into a segment of ileum and cecum in an Indiana pouch. This is a surgical alternative that uses a section of the intestine to create an internal reservoir that holds urine, with the creation of a catheterizable stoma. The external stoma or outlet must be catheterized at regular intervals to drain the urine that has collected in this reservoir.

GENERAL CARE GUIDELINES

Creation of a urinary diversion is a surgical procedure. Therefore, the patient needs physical and psychological support before and after surgery. This support can come from the patient's significant others as well as from members of the health care team and people who have had similar experiences. The ostomy created for the diversion requires specific physical care for which the nurse is initially responsible. The following guidelines help to promote the patient's physical and psychological comfort related to stoma care:

- Inspect the patient's stoma regularly. It should ideally protrude about 1 to 3 cm above skin level and be dark pink to red in color and moist (Berti-Hearn & Elliott, 2019; Stelton, 2019) (Fig. 38-18). A pale stoma may indicate anemia, and a dark or purple-blue stoma may reflect compromised circulation or ischemia. Bleeding around the stoma and its stem should be minimal. The edges of the stoma should appear secure to the surrounding skin (Stelton, 2019). The pulling away of the stoma from the peristomal skin is called *mucocutaneous separation* or *stoma dehiscence* (Stelton, 2019) and occurs more often in patients who are at risk for impaired healing, including patients with diabetes, poor nutritional status or who received high-dose steroid therapy or chemotherapy before

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

surgery (Butler, 2009). Notify the health care team promptly if bleeding persists or is excessive, if color changes occur in the stoma, or if it appears the stoma is separating from the peristomal skin (Stelton, 2019).

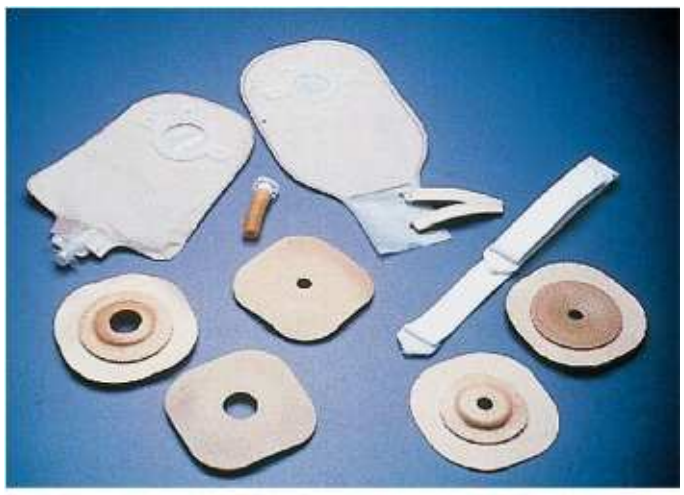

FIGURE 38-18. The appearance of a normal stoma is red and smooth, with a mucous membrane surface.

- Note the size of the stoma, which usually stabilizes within 6 to 8 weeks (Stelton, 2019). Most stomas protrude 1/2 to 1 inch from the abdominal surface and may initially appear swollen and edematous. The edema usually subsides after 6 weeks. If an abdominal dressing is in place over the surgical incision, check it frequently for drainage and bleeding. The dressing is usually removed after 24 hours.
- Keep the skin around the stoma site (peristomal area) clean and dry. If care is not taken to protect the skin around the stoma, irritation or infection may occur. Assess the peristomal (around the stoma) skin; peristomal skin should be intact and appear consistent with that of the rest of the abdomen, without pain or discomfort (Burch, 2018). In patients with light skin tones, the peristomal skin should not be reddened; in patients with darker skin tones, the skin should not have darker discolorations (Stelton, 2019). A leaking or ill-fitted stoma appliance will cause moisture-associated skin damage (Berti-Hearn & Elliott, 2019) (refer to the discussion earlier in the chapter). *Candida* or yeast infections can also occur around the stoma if the area is not kept dry.
- Measure the patient's fluid intake and output. Careful monitoring of the patient's urinary output is necessary to detect fluid imbalances and adequate functioning of the diversion.
- Keep the patient as free of odors as possible. If the patient has an external appliance, empty the appliance frequently.
- Patients with urinary diversions created using a portion of the gastrointestinal tract will experience the presence of mucus in the urine (Berti-Hearn & Elliott, 2019). The segment of the gastrointestinal tract continues to produce mucus as part of its normal functioning. This mucus production will decrease over time and is usually not a problem for patients with an ileal conduit (Berti-Hearn & Elliott, 2019). Mucus may be a problem for patients with a continent urinary diversion; mucus retention in the pouch can block the catheter used to empty the pouch. Working with an enterostomal nurse, these patients are taught to irrigate the pouch with normal saline solution using clean technique to clear mucus from the continent urinary diversion (NIDDK, 2020).
- Monitor the return of intestinal function and peristalsis. Initially after surgery, peristalsis is inhibited. Remember, patients with urinary diversions created using a portion of the gastrointestinal tract had a bowel resection as part of the procedure.
- Encourage the patient to participate in care and to look at the stoma. Patients normally experience emotional depression during the early postoperative period. Help the patient to cope by listening, explaining, and being available and supportive. A visit from a representative of the local ostomy support group may be helpful. Patients usually begin to accept their altered body image when they are willing to look at the stoma, make neutral or positive statements concerning the ostomy, and express interest in learning self-care.
- Provide support for the patient's physical, psychological, and social activities. Coping strategies must address body image concerns, permanent body changes, and the underlying health issue(s) that resulted in the surgery (Berti-Hearn & Elliott, 2019; Díaz et al., 2018). Encourage patients and their partners/families/caregivers to discuss concerns and to seek help and support (Berti-Hearn & Elliott, 2019; Chandler, 2020; Hill, 2020).

EXTERNAL APPLIANCES

The external appliance to collect the urine for patients with incontinent urinary diversions is typically a soft pouch that is either reusable or disposable. The upper part of the pouch has a firm faceplate several inches in diameter, with an opening the size of the stoma. Some faceplates are detachable from the pouch, while other appliances are one piece (Fig. 38-19). The plate surface is secured firmly around the stoma opening with a moisture-proof adherent so that no urine leakage occurs. Many patients also wear a supportive accessory, such as an elasticized belt that goes around the waist and connects to each side of the faceplate, for added support (Bird et al, 2019; Goldberg et al., 2018). The lower end of the appliance has a drainage valve, which is used for emptying.

Two-piece pouches

FIGURE 38-19. Two-piece appliances.

The patient needs to empty the appliance frequently, when it is 1/3 to 1/2 full (Berti-Hearn & Elliott, 2019). This is to prevent the pouch from becoming heavy with the weight of urine, causing tension on the faceplate, and possibly loosening the seal, leading to leakage or a decrease in appliance wear time (Berti-Hearn & Elliott, 2019). For most people, this means emptying the appliance several times a day. The pouch can also be attached to drainage tubing and a large collection bag to avoid having to frequently empty the appliance, such as during the night or when confined to bed. In home situations, urine collection tubing and receptacles designed to be placed under the bed can be used at night.

How frequently the appliance should be changed depends on the type being used and specific patient circumstances, but usually every 3 to 7 days (American Cancer Society, 2019; Berti-Hearn & Elliott, 2019; O'Flynn, 2018; Stelton, 2019). The appliance usually is changed after a time of low fluid intake, such as in the early morning. Urine production is less at this time, making changing the appliance easier. Skill 38-4 (on pages 1505–1509) describes how to change an appliance worn over an incontinent urinary diversion.

PATIENT EDUCATION

Patient teaching is one of the most important aspects of care and should include family members or others identified by the patient when appropriate. Patient education is essential for independence in self-care. Teaching can begin before surgery so that the patient has adequate time to absorb information.

Explain each aspect of care to the patient and what the patient's role will be when beginning self-care. As the patient assumes responsibility for self-care, teach the patient how to make the necessary observations, to be aware of indications of problems, and to recognize when to seek assistance. For these goals to be met, the patient and/or family member/caregivers should be able to:

- Explain the reason for the urinary diversion and the rationale for treatment.
- Identify situations/symptoms that require immediate reporting to the health care provider: the stoma darkens in color or causes unremitting pain; no urine comes from the stoma; or bloating, nausea, vomiting, or loss of appetite occur (Goldberg et al., 2018).
- Demonstrate self-care behaviors that effectively manage the diversion.
- Describe follow-up care and existing support resources.
- Report where supplies may be obtained in the community.
- Verbalize related fears and concerns.
- Demonstrate a positive body image.

The assistance of a wound, ostomy, and continence nurse (WOCN) can help the patient achieve these outcomes (Goldberg et al., 2018; Palmer, 2020). Refer the patient to an outpatient ostomy clinic or a home health care agency to access an ostomy nurse specialist (Goldberg et al., 2018). Refer the patient to a support group or organization like the United Ostomy Associations of America (http://www.ostomy.org/Home.html) for further information, resources, advocacy, and support.

Caring for a Patient Receiving Dialysis

Dialysis is used to treat patients who experience severely decreased or total loss of kidney function. Dialysis is a mechanical way of filtering waste products and excess electrolytes from the blood. There are two categories of dialysis: hemodialysis and peritoneal dialysis.

Hemodialysis involves a machine that does the work healthy kidneys normally perform by filtering harmful wastes, electrolytes, and fluid from the blood that would normally be eliminated in the patient's urine (Fig. 38-20). Patients receive a vascular access in order to receive hemodialysis. This vascular access, an arteriovenous (AV) fistula (a surgically created connection between an artery and a vein; Fig. 38-21A) or AV graft (a surgically created path between an artery and a vein using a flexible, synthetic tube; Fig. 38-21B), allows for access to the bloodstream. A temporary or permanent double-lumen central venous catheter can also be used to provide vascular access for hemodialysis (American Nephrology Nurses Association [ANNA], 2018). These vascular accesses are the point at which blood is removed from the patient's body for dialysis and then returned. The access allows the patient's blood to travel to the hemodialysis machine, which has a semipermeable membrane that filters the blood through diffusion, osmosis, and ultrafiltration (Hinkle et al., 2022). Toxins, wastes, and extra fluid are removed before the blood is returned to the patient (ANNA, 2018).

FIGURE 38-20. During hemodialysis, a machine does the work of the kidneys to filter wastes, electrolytes, and fluid from the body. (*Source:* Reprinted with permission from Craven, R., & Hirnle, C. [2017]. Fundamentals of nursing: Human health and function [8th ed.]. Wolters Kluwer.)

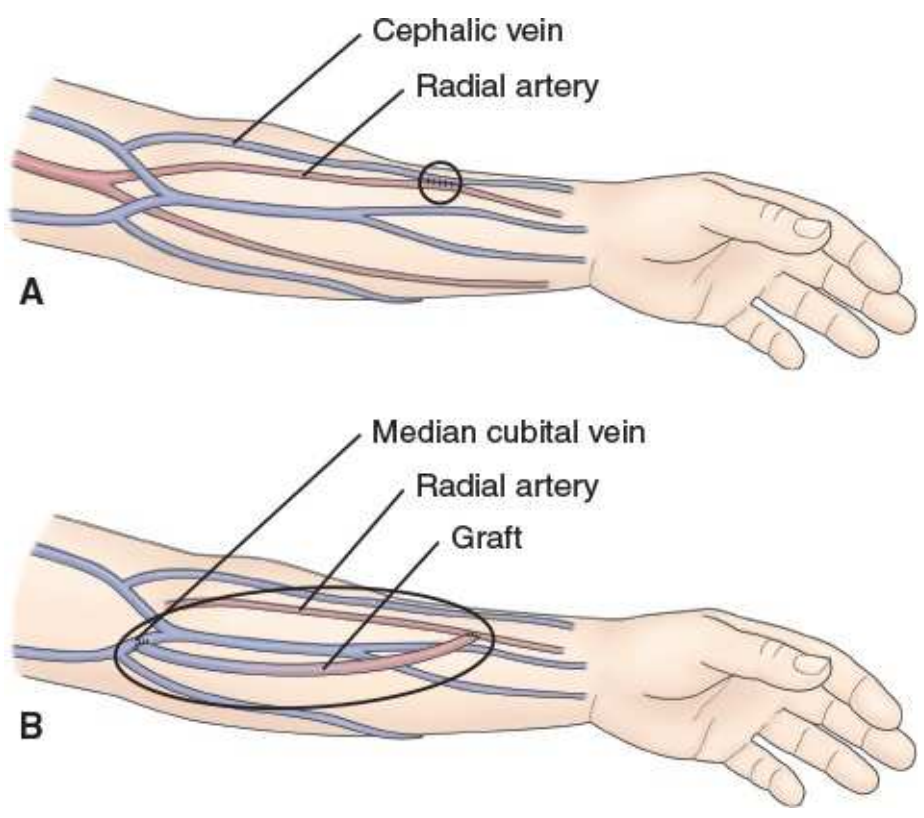

FIGURE 38-21. A. Arteriovenous fistula, created by connecting an artery and vein. **B.** Arteriovenous graft created by using a synthetic tube to form a path between an artery and vein. (*Source:* Reprinted with permission from Hinkle, J. L., Cheever, K. H., & Overbaugh, K. J. [2022]. Brunner & Suddarth's textbook of medical surgical nursing [15th ed.]. Wolters Kluwer.)

Peritoneal dialysis involves using blood vessels in the abdominal lining (peritoneum) to fill in for the kidneys, with the help of a fluid (dialysate) washed in and out of the peritoneal space. Diffusion and osmosis occur as waste products move from an area of higher concentration (the blood stream) to an area of lesser concentration (the dialysate fluid) through the peritoneum (Hinkle et al., 2022). Patients receive a catheter (a thin, soft, silicone rubber tube) surgically placed through the abdomen into the peritoneal cavity (Fig. 38-22). It is used to carry the dialysis solution

in and out of the patient's abdomen (Norris, 2020). Continuous ambulatory peritoneal dialysis (CAPD) is performed manually using small bags of dialysate (dialysis solution), 7 days a week with four to five exchanges of new solution each day (ANNA, 2019). Automated peritoneal dialysis (APD) is performed with the assistance of a machine overnight, while the patient sleeps. The exchange of dialysis solution is cycled by the machine, 7 days a week, for 8 to 10 hours a night (ANNA, 2019).

Patients need a strong sense of support to achieve success and patient teaching is a very important aspect of care for patients who will be receiving peritoneal dialysis (George, 2019a). Education should include family members or others identified by the patient when appropriate. Patients receiving peritoneal dialysis have to take an active role in their therapy, as they may be managing a large part of their care themselves (ANNA, 2019). Patient education is essential for self-management of this chronic condition (George, 2019b; Schaepe & Bergjan, 2015). Teaching should begin as soon as possible prior to the beginning of treatment so that the patient has adequate time to absorb information. Working with a nephrology nurse, these patients are taught to perform peritoneal dialysis, manage exit-site care, take the prescribed medication, monitor for complications, and follow dietary and fluid restrictions (George, 2019b). Refer patients to a support group or organization, such as the National Kidney Foundation (https://www.kidney.org/patients) for further information, resources, advocacy, and support (Schaepe & Bergjan, 2015).

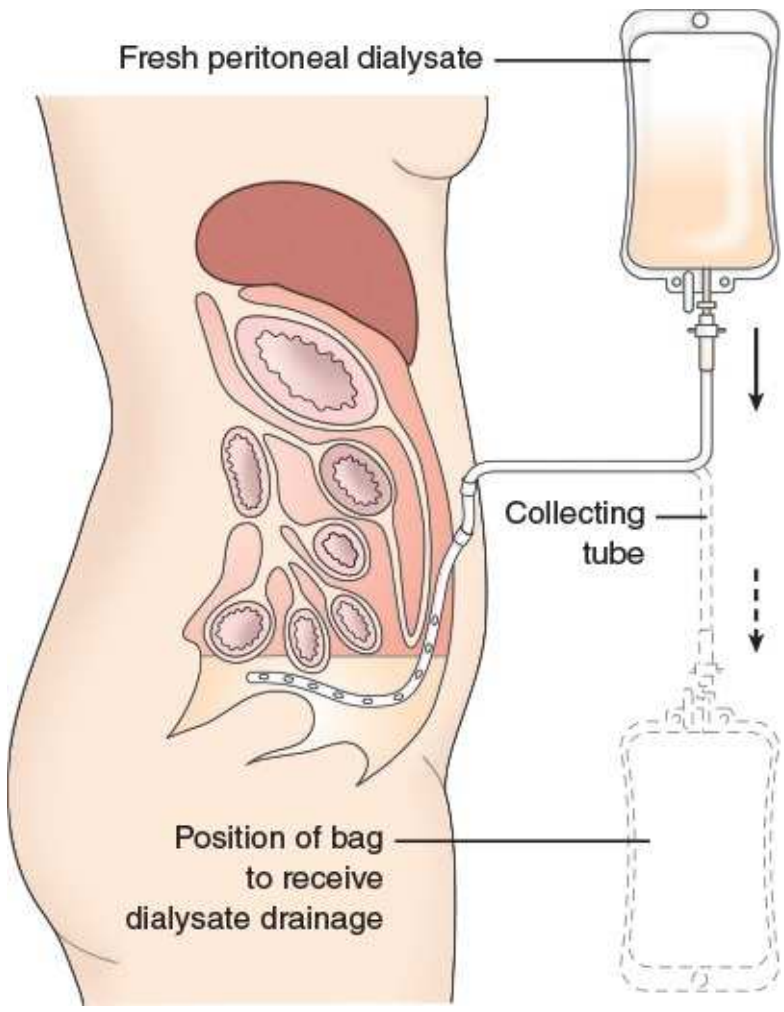

FIGURE 38-22. Peritoneal dialysis. (*Source:* Reprinted with permission from Hinkle, J. L., Cheever, K. H., & Overbaugh, K. J. [2022]. Brunner & Suddarth's textbook of medical surgical nursing [15th ed.]. Wolters Kluwer.)

Care of either access site is initially a nursing responsibility and includes assessment of the access site. Guidelines for Nursing Care 38-3 outlines care related to a hemodialysis access. Refer to Guidelines for Nursing Care 38-4 on page 1486 for care related to a peritoneal dialysis catheter.

Guidelines for Nursing Care 38-3

Caring for a Hemodialysis Access

- •Perform hand hygiene and put on PPE, if indicated.

- Identify the patient.
- Close the curtains around the bed and close the door to the room, if possible. Explain to the patient what you are going to do and why.
- Question the patient about the presence of muscle weakness and cramping, changes in temperature, and abnormal sensations.
- Put on gloves, if indicated.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

- Inspect the area over the access site for continuity of skin color, muscle strength, and the patient's ability to perform range of motion in the extremity/body part with the hemodialysis access.

- Palpate over the access site, feeling for a thrill or vibration. Palpate pulses above and below the site.

  Palpate the continuity of the skin temperature along and around the extremity. Check capillary refill. Remove gloves, if used, and perform hand hygiene.
- Auscultate over the access site with bell of stethoscope, listening for a bruit or vibration.
- Do not measure blood pressure, perform a venipuncture, or start an IV on the access arm.

- Remove PPE, if used. Perform hand hygiene.

Evaluating

Evaluation is an ongoing and deliberate part of the nursing process, comparing the patient's health status with previously defined expected outcomes. The nurse reflects on the effectiveness of a care plan to promote healthy urinary functioning by evaluating whether the patient has met the individualized patient goals specified in the plan. Adjustments in the plan of care are made accordingly. See the accompanying Nursing Care Plan 38-1 (on pages 1487–1489) for Mrs. Jaspers. Nursing care is considered effective if the patient expresses satisfaction with the urinary function measures and is able to (as appropriate, based on specific behaviors and criteria individualized for the patient situation):

- Produce a sufficient quantity of urine to maintain fluid, electrolyte, and acid–base balance
- Empty the bladder completely at regular intervals without discomfort
- Provide care for urinary diversion and know when to notify the health care team
- Develop a plan to modify any factors that contribute to current urinary problems or that might impair urinary functioning in the future
- Promote urinary functioning as appropriate for the person

Guidelines for Nursing Care 38-4

Caring for a Peritoneal Dialysis Catheter

- Perform hand hygiene and put on PPE, if indicated.

- Identify the patient.
- Close the curtains around the bed and close the door to the room, if possible. Explain to the patient what you are going to do and why.
- Assist the patient to a supine position. Expose the abdomen, draping the patient's chest with the bath blanket, exposing only the catheter site.
- Put on nonsterile gloves. Put on a facemask, and have the patient put a mask.
- Gently remove old dressing, noting odor, amount, and color of drainage; leakage; and condition of the skin around the catheter, then discard.

- Remove gloves and discard. Perform hand hygiene. Set up a sterile field. Open packages. Using aseptic technique, place two sterile gauze squares in a basin with antimicrobial agent. Leave two sterile gauze squares opened on the sterile field. Alternatively (based on facility's policy), place sterile antimicrobial swabs on the sterile field. Place the sterile applicator on field. Squeeze a small amount of the topical antibiotic on one of the gauze squares on the sterile field.
- Put on sterile gloves. Pick up the dialysis catheter with your nondominant hand. With the antimicrobial- or sterile normal saline–soaked gauze/swab, cleanse the skin around the exit site using a circular motion, starting at the exit site and then slowly going outward 2 inches (Bridger, 2019). Scabs or crusts should never be removed forcibly to avoid creating open areas susceptible to infection (George, 2019a). Movement of the catheter should be minimal in the immediate postoperative period (Bridger, 2019).
- Continue to hold the catheter with your nondominant hand. After the skin has dried, clean the catheter with an antimicrobial-soaked gauze, beginning at the exit site, going around the catheter, and then moving up to end of the catheter. Gently remove crusted secretions on the tube, if necessary.

- Apply the topical antibiotic to the catheter exit site, if prescribed.
- Place a sterile drain sponge around the exit site. Then place a 4 × 4 gauze over the exit site. Cover with a dressing.

- Remove gloves and then masks. Perform hand hygiene.

- Label the dressing with date, time of change, and your initials.
- Coil the exposed length of tubing and anchor the catheter to the patient's abdomen with tape or a commercial device (Bridger, 2019; George, 2019b).
- Assist the patient to a comfortable position. Cover the patient with bed linens. Place the bed in the lowest position.

- Remove additional PPE, if used. Perform hand hygiene.

REFLECTIVE PRACTICE LEADING TO PERSONAL LEARNING

Remember that the goal of reflective practice is to look at an experience, understand it, and learn from it. As you begin to develop expertise in implementing measures related to urinary elimination, reflect on your experiences—successes and failures—in order to improve your practice. How can you do it better next time? What did you learn today that can help you tomorrow? Begin your reflection by paying close attention to the following while performing urinary elimination interventions and providing nursing care:

- How did you prioritize the data you collected? What patterns in the data did you identify?
- What knowledge from your learning, personal experience, and intuition did you use to make decisions and develop your plan of care?
- Did your preparation and practice related to performing interventions related to urinary elimination result in your feeling confident in your ability to provide care? Did your competence and confidence inspire the patient's and family's/caregiver's trust?
- Did your commitment to engage your patients and families and to collaborate with your fellow students, instructor, and other members of the health care team as you implemented the care plan result in successful partnerships?
- How confident are you that the data you communicated and recorded accurately communicates the health status, health problems, issues, risks, and strengths of the patient? How successfully have you communicated this information to other members of the health care team?
- Were you aware of any cultural and/or ethnic beliefs or practices that may have influenced the patient's personal urinary elimination practices? Were you aware of any stereotypes or prejudices that might have negatively influenced the clinical encounter? If so, how did you address these?
- Did you need to modify the care plan as a result of ongoing assessments? Did you think of better interventions to produce the expected outcomes?
- As you concluded your care, did the patient and family/caregivers know your name, and know what to expect of you and nursing? Did the patient sense that you are respectful, caring, and competent to provide care?

Perhaps the most important questions to reflect on are: Are your patients and their families/caregivers better for having had *you* share in the critical responsibility of partnering with them to address their urinary elimination needs? Are your patients now receiving thoughtful, person-centered, prioritized, holistic, evidence-based treatment and care because of your efforts?

Nursing Care Plan for Elana Jaspers 38-1

Mrs. Elana Jaspers is an alert, 83-year-old adult whose husband of 59 years died 6 months ago. Although Mrs. Jaspers was adamant about wanting to live independently in their own home, arthritis severely restricted their movement and ability to manage. After a hospitalization for pneumonia, they were transferred to a long-term care facility 1 month ago. The admitting medical diagnoses included hypertension, osteoarthritis, and depression. A comprehensive nursing assessment of Mrs. Jaspers performed 1 month after their admission to a long-term care facility included the following notations:

- Continent of urine on admission
- At present, incontinent of urine one or two times a day; often found wet in the morning; states it is "too much bother to get into the bathroom"
- Sits in chair in room unless encouraged and assisted to walk, although capable of independent ambulation with care; progressive muscle atrophy and joint stiffness
- No identifiable pathology underlying incontinence
- Medications include a diuretic for hypertension and a tricyclic antidepressant
- Reddened skin in the perineal area

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

ACTUAL OR POTENTIAL HEALTH PROBLEMS AND NEED

Functional urinary incontinence

Etiology: difficult transition to long-term care facility, mobility deficit

Signs and Symptoms: incontinence of urine one or two times a day; feeling toileting is too much bother; mobility deficits secondary to osteoarthritis; diuretic and antidepressant therapy

EXPECTED OUTCOME

By the next monthly assessment, 5/1/25, the patient will:

- Verbalize the importance of getting to bathroom or toilet when they first feel the need to void

NURSING INTERVENTIONS	RATIONALE	EVALUATIVE STATEMENT
Assess the value the patient attaches to voluntary control of urination and urinary continence; counsel appropriately.	Unless the patient is committed to the care plan, goal achievement is impossible.	5/1/25 Outcome partially met. Patient has commented on the importance of regular toileting but still finds this "too much trouble" some days.
Teach the importance of complete bladder emptying at regular intervals and the harmful effects of ignoring the urge to void.	Patient understanding of the causes and harmful effects of urinary incontinence may motivate desire for reestablishment of voluntary control.	*Revision:* Reinforce value. *D. Mora, RN*
Assess patient's normal voiding habits at home and assist the patient to reestablish these. Initial reminders to toilet may be necessary.	Respect for the patient's normal voiding schedule and patterns communicates concern for the person and encourages patient achievement of goals.	

EXPECTED OUTCOME

By the next monthly assessment, 5/1/25, the patient will:

- Demonstrate the ability to walk to the bathroom using a cane to toilet herself

NURSING INTERVENTIONS	RATIONALE	EVALUATIVE STATEMENT
Assess the patient's motivation and ability to toilet herself independently. Work consistently with them to increase activity tolerance: encourage short walks throughout the day to increase mobility.	One response to experiencing the multiple losses associated with aging is to surrender all control and become increasingly dependent. Nonpathology-based incontinence is less likely to occur if the daily living of the person keeps them more mobile, flexible, oriented, and motivated. An older adult who seeks to take control and has a positive self-image is more continent.	5/1/25 Outcome met. Patient can safely walk to bathroom using cane and toilet herself when they want to. *D. Mora, RN*
Refer patient to occupational therapy for assistance with diagnosis and treatment if necessary.	The specialized skills of the occupational therapist may facilitate relearning toileting skills.	5/1/25 Outcome not met. Patient repeatedly neglects AM perineal care. *Revision:* Reteach both the importance and procedure of perineal care. Assess each AM. *D. Mora, RN*

EXPECTED OUTCOME

By the next monthly assessment, 5/1/25, the patient will:

- Decrease urinary incontinent episodes to less than three or four per week

NURSING INTERVENTIONS	RATIONALE	EVALUATIVE STATEMENT

Communicate to patient that the nurses *care* about them reestablishing urinary continence and believe they can do this. Use verbal reinforcement to reward "dry" days.	A common feeling of recently institutionalized older adults is *abandonment* and the sense that no one cares; response: "Why should I?" Communicating that the patient's progress toward goal achievement is valued by the nurses is an excellent encouragement to continue progress.	5/1/25 Outcome met. Patient in last week was completely dry for 4 of 7 days. Recorded four incontinent episodes. *D. Mora, RN*
Chart incontinent episodes and monitor progress; discuss this with patient.	This records progress with incontinent episodes and provides positive reinforcement.	

ACTUAL OR POTENTIAL HEALTH PROBLEMS AND NEED

Altered skin integrity

Etiology: functional urinary incontinence

Signs and Symptoms: reddened perineal area (skin still intact)

EXPECTED OUTCOME

By the next monthly assessment, 5/1/25, the patient will:

- Demonstrate healing of reddened perineal area

NURSING INTERVENTIONS	RATIONALE	EVALUATIVE STATEMENT
Assess skin for breakdown each AM and PM and after each incontinent episode.	Perineal care is often neglected or assigned to the least trained personnel in care settings. Prevention of incontinence-associated dermatitis (IAD) is critical; IAD not detected and treated early may progress to excessive excoriation, skin breakdown, and infection.	5/1/25 Outcome partially met. Perineal area is less inflamed. *Revision:* Continue to monitor perineal hygiene. *D. Mora, RN*
Teach the patient the importance of washing this area carefully with skin cleanser and water each AM and after incontinent episodes. Teach the importance of always cleaning and wiping the perineum from front to back to prevent autoinfection. Until incontinent episodes are eliminated, use of a skin protectant or barrier product after cleansing of the skin is indicated.	The patient who is doing self-care may neglect it entirely or use incorrect technique. Keeping the perineal area clean and dry promotes intact skin around the urinary meatus and the perineal area. Proper hygiene measures also decrease the possibility of bacteria or organisms migrating into the bladder.	
Encourage use of appropriate disposable incontinence products and stress the importance of replacing the briefs or pad as soon as possible after an episode of incontinence. Encourage use of cotton underwear and avoidance of nylon pantyhose, girdles, tight-fitting pants.	Use of appropriate absorbent products designed to wick moisture away from the skin and avoid overhydration of the skin is important to avoid alterations in skin integrity and increased risk of urinary tract infection. Nylon and tight-fitting products tend to hold moisture and may minimize airflow to the perineal area.	

SAMPLE DOCUMENTATION

4/3/25 Nursing

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

This AM, after an incontinent episode, Mrs. Jaspers began to talk about how hard it is to get adjusted to living here, and commented, “I feel like just giving up.” We talked about the importance of being as independent as possible and the dangers of becoming passively dependent. Nursing teaching and counseling included values of independently adhering to usual toileting schedule and importance of perineal hygiene. Two hours later, after lunch, Mrs. Jaspers walked to bathroom and toileted herself. Progress with urinary incontinence will continue to be monitored. Ability definitely present but encouragement needed.

D. Mora, RN

Skill 38-1

Assessing Bladder Volume Using an Ultrasound Bladder Scanner

DELEGATION CONSIDERATIONS

The assessment of bladder volume using an ultrasound bladder scanner is not delegated to assistive personnel (AP). Depending on the state's nurse practice act and the organization's policies and procedures, this procedure may be delegated to licensed practical/vocational nurses (LPN/LVNs). The decision to delegate must be based on careful analysis of the patient's needs and circumstances as well as the qualifications of the person to whom the task is being delegated. Refer to the Delegation Guidelines in Appendix A.

Equipment

- Bladder scanner
- Ultrasound gel or bladder scan gel pad
- Alcohol wipe or other sanitizer recommended by the scanner manufacturer and/or facility policy
- Clean gloves
- Paper towel or washcloth

IMPLEMENTATION

ACTION	RATIONALE
1. Review the patient's health record for any limitations in physical activity. Gather equipment.	Physical limitations may require adaptations in performing the skill. Assembling equipment provides for an organized approach to the task.
 2. Perform hand hygiene and put on PPE, if indicated.	Hand hygiene and PPE prevent the spread of microorganisms. PPE is required based on transmission precautions.
 3. Identify the patient.	Identifying the patient ensures the right patient receives the intervention and helps prevent errors.
4. Close the curtains around the bed and close the door to the room, if possible. Discuss the procedure with the patient and assess the patient's ability to assist with the procedure as well as personal hygiene preferences.	This ensures the patient's privacy. Discussion promotes reassurance and provides knowledge about the procedure. Dialogue encourages patient participation and allows for individualized nursing care.
5. Adjust the bed to a comfortable working height (VHACEOSH, 2016). Place the patient in a supine position. Drape the patient. Stand on the patient's right side if you are right-handed or on the patient's left side if you are left-handed.	Having the bed at the proper height prevents back and muscle strain. Proper positioning allows accurate assessment of bladder volume. Keeping the patient covered as much as possible promotes patient comfort and privacy. Positioning allows for ease of use of your dominant hand for the procedure.
6. Put on gloves.	Gloves prevent contact with blood and body fluids.
7. Press the ON button. Wait until the device warms up. Press the SCAN button to turn on the scanning screen.	Many devices require a few minutes to prepare the internal programs.
8. Press the appropriate biologic sex button. The icon for male or female will appear on the screen (Figure 1).	The device must be programmed for the biologic sex of the patient by pushing the correct button on it. If a patient with female genitalia has had a hysterectomy, the male button is pushed (AHRQ, 2020).
9. Clean the scanner head with the appropriate cleaner (Figure 2).	Cleaning the scanner head deters transmission of microorganisms.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

FIGURE 1. Identifying icon for patient's biologic sex. (*Source:* Used with permission from Shutterstock. *Photo by B. Proud.*)

FIGURE 2. Cleaning scanner head. (*Source:* Used with permission from Shutterstock. *Photo by B. Proud.*)

10. Gently palpate the patient's **symphysis pubis** (anterior midline junction of pubic bones). Place a generous amount of ultrasound gel (Figure 3A) or gel pad (Figure 3B) midline on the patient's abdomen, about 1 to 1.5 inches above the symphysis pubis. Alternatively, depending on facility policy, apply ultrasound gel to the scanner head (AHRQ, 2020).

    Palpation identifies the proper location and allows for correct placement of the scanner head over the patient's bladder.

11. Place the scanner head on the gel or gel pad, **with the directional icon on the scanner head toward the patient's head. Aim the scanner head toward the bladder (point the scanner head slightly downward toward the coccyx)** (Figure 4A). Press and release the scan button (Figure 4B).

    Proper placement allows for accurate reading of urine in the bladder (AHRQ, 2020; Widdall, 2015).

12. Observe the image on the scanner screen, which includes the volume measured and an aiming display with crosshairs. **If the crosshairs are not centered on the bladder image, adjust the scanner head and rescan until the bladder image is centered on the crosshairs** (Figure 5).

    This action allows for accurate reading of urine in the bladder.

FIGURE 3. **A.** Placing ultrasound gel about 1 to 1.5 inches above symphysis pubis. (*Source:* Used with permission from Shutterstock. *Photo by B. Proud*.) **B.** Gel pad.

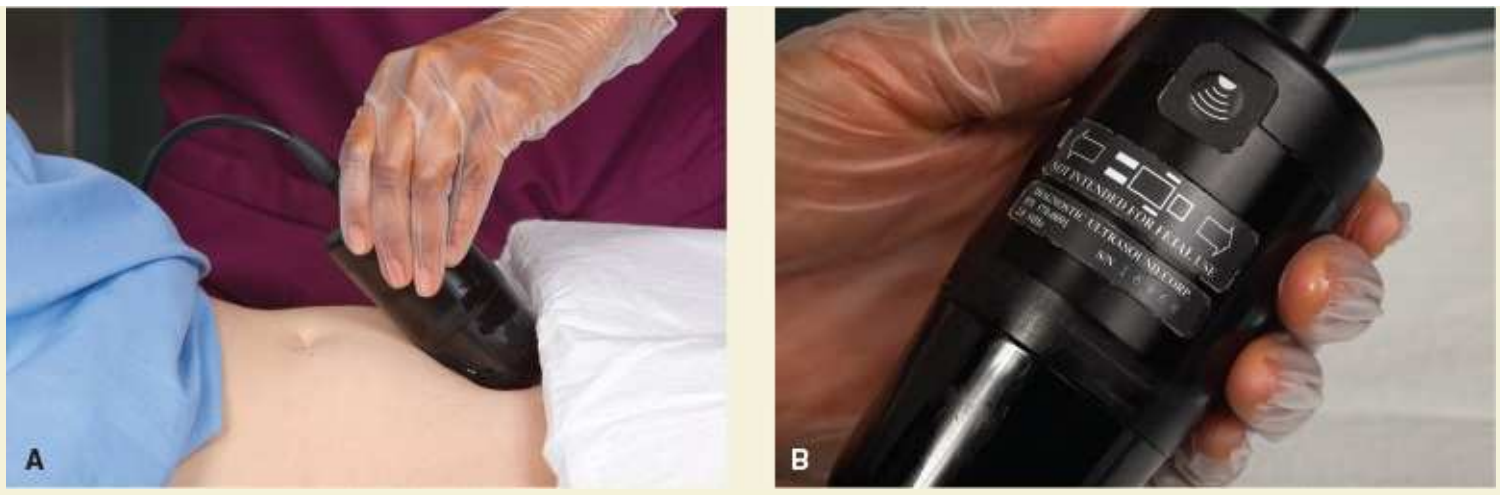

FIGURE 4. **A.** Positioning scanner head with directional icon toward patient's head and aiming the scanner head toward the bladder. **B.** Scan button. (*Source:* Used with permission from Shutterstock. *Photos by B. Proud.*)

FIGURE 5. Centering image on crossbars.

13. Once the image is centered, press and hold the DONE button until it beeps. Read the volume measurement on the screen. Print the results, if required, by pressing PRINT.	This action provides for accurate documentation of reading.
14. Use a washcloth or paper towel to remove the remaining gel from the patient's skin. Alternatively, gently remove the gel pad from the patient's skin. Return the patient to a comfortable position. Remove your gloves and perform hand hygiene. Ensure that the patient is covered.	Removal of the gel promotes patient comfort. Removing contaminated gloves prevents the spread of microorganisms. Hand hygiene prevents the spread of microorganisms.
15. Lower the bed height and adjust the head of the bed to a comfortable position. Reattach the call bell, if necessary.	These actions promote patient safety.
16. Put on gloves. Clean the scanner head according to the manufacturer's instructions and/or facility policy.	Cleaning equipment prevents transmission of microorganisms.
17. Remove gloves and any additional PPE, if used. Perform hand hygiene.	Proper removal of PPE reduces the risk for infection transmission and contamination of other items. Hand hygiene prevents the spread of microorganisms.

DOCUMENTATION

Guidelines

Document the assessment data that led to the use of the bladder scanner, relevant symptoms, the urine volume measured, and the patient's response.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

Sample Documentation

7/06/25 1130 Patient has not voided 8 hours after catheter removal. Patient denies feelings of discomfort, pressure, and pain. Bladder not palpable. Bladder scanned for 120 mL of urine. Patient encouraged to increase oral fluid intake to six 8-oz glasses of liquid today. Dr. Liu notified of assessment. Prescribed rescan in 4 hours if patient does not void.

—B. Clapp, RN

DEVELOPING CLINICAL REASONING AND CLINICAL JUDGMENT

UNEXPECTED SITUATIONS AND ASSOCIATED INTERVENTIONS

- *You press the wrong icon when initiating the scanner:* Turn scanner off and back on. Reenter information using the correct icon.
- *You have reason to believe the bladder is full, based on assessment data, but the scanner reveals little to no urine in the bladder:* Ensure proper positioning of the scanner head. Place a generous amount of ultrasound gel or gel pad midline on the patient's abdomen, about 1 to 1.5 inches above the symphysis pubis. Place the scanner head on the gel or gel pad, with the directional icon on the scanner head toward the patient's head. Aim the scanner head toward the bladder (point the scanner head slightly downward toward the coccyx). Ensure that the bladder image is centered on the crossbars.

SPECIAL CONSIDERATIONS

- Ensure use of an adequate amount of ultrasound gel. Do not use lubricant (Widdall, 2015).
- Bladder volume measurements may be inaccurate in the presence of intraabdominal fluid, such as ascites (Schallom et al., 2020).
- If the patient is very thin or obese, use more ultrasound gel (AHRQ, 2020).
- If the patient has a large amount of lower abdominal hair, apply the gel directly to the skin (AHRQ, 2020).
- Ask or assist patients who are overweight or have larger abdominal tissue to hold their abdomen up and away from area to be scanned to reduce risk for interference, resulting in inaccurate measurement (Widdall, 2015).
- The use of bladder scanning can be used to reduce catheterization rates and associated complications (Institute for Healthcare Improvement [IHI], 2011).
- Bladder scanning in combination with intermittent catheterization may be beneficial in the management of postoperative urinary retention to avoid placement of an indwelling catheter (IHI, 2011).

Skill 38-2 Catheterizing the Urinary Bladder of a Patient With Female Genitalia

DELEGATION CONSIDERATIONS

The catheterization of the urinary bladder is not delegated to assistive personnel (AP). Depending on the state's nurse practice act and the organization's policies and procedures, catheterization of the urinary bladder may be delegated to licensed practical/vocational nurses (LPN/LVNs). The decision to delegate must be based on careful analysis of the patient's needs and circumstances as well as the qualifications of the person to whom the task is being delegated. Refer to the Delegation Guidelines in Appendix A.

EQUIPMENT

- Sterile catheter kit that contains:
  - Sterile gloves
  - Sterile drapes (one of which is **fenestrated**)
  - Sterile catheter (use the smallest appropriate-size catheter that will allow effective drainage; a 14F with a 5- to 10-mL balloon is usually appropriate, unless another size is prescribed [ANA, 2014; SUNA 2021b; Yates, 2017a])
  - Antiseptic cleansing solution and cotton balls or gauze squares; antiseptic swabs (based on facility policy)
  - Lubricant
  - Forceps
  - Prefilled syringe with sterile water (sufficient to inflate indwelling catheter balloon)

- Sterile specimen container (if specimen is required)
- Anesthetic gel, as prescribed or indicated (see Assessments below)
- Flashlight or lamp
- Waterproof, disposable pad
- Sterile, disposable urine collection bag and drainage tubing (may be connected to catheter in catheter kit)
- Catheter-securing device
- Disposable gloves
- Additional PPE, as indicated
- Washcloth, skin cleanser, and warm water to perform perineal hygiene before and after catheterization

IMPLEMENTATION

ACTION	RATIONALE
1. Review the patient's health record for any limitations in physical activity. Confirm the prescribed intervention for indwelling catheter insertion.	Physical limitations may require adaptations in performing the skill. Verifying the prescribed intervention ensures that the correct intervention is administered to the right patient.
2. Gather equipment. Obtain assistance from another staff member, if necessary or based on facility policy.	Assembling equipment provides for an organized approach to the task. Assistance from another person may be required to perform the intervention safely.
 3. Perform hand hygiene and put on PPE, if indicated.	Hand hygiene and PPE prevent the spread of microorganisms. PPE is required based on transmission precautions.
 4. Identify the patient.	Identifying the patient ensures the right patient receives the intervention and helps prevent errors.
5. Close the curtains around the bed and close the door to the room, if possible. Discuss the procedure with the patient and assess the patient's ability to assist with the procedure. Ask the patient if they have any allergies, especially to latex or iodine.	This ensures the patient's privacy. Discussion promotes reassurance and provides knowledge about the procedure. Dialogue encourages patient participation and allows for individualized nursing care. Some catheters and gloves in kits are made of latex. Some antiseptic solutions contain iodine.
6. Provide good lighting. Artificial light is recommended (use of a flashlight requires an assistant to hold and position it). Place a trash receptacle within easy reach.	Good lighting is necessary to see the meatus clearly. A readily available trash receptacle allows for prompt disposal of used supplies and reduces the risk of contaminating the sterile field.
7. Assemble equipment on the overbed table or other surface within reach.	Arranging items nearby is convenient, saves time, and prevents unnecessary stretching and twisting of muscles on the part of the nurse.
8. Adjust the bed to a comfortable working height (VHACEOSH, 2016). Stand on the patient's right side if you are right-handed or on the patient's left side if you are left-handed.	Having the bed at the proper height prevents back and muscle strain. Positioning allows for ease of use of your dominant hand for catheter insertion.
9. Assist the patient to a dorsal recumbent position with their knees flexed, feet about 2 ft apart, and legs abducted. Drape the patient (Figure 1). Alternatively, the Sims', or lateral, position can be used. Place the patient's buttocks near the edge of the bed with their shoulders at the opposite edge and their knees drawn toward the chest (Figure 2). Allow the patient to lie on either side, depending on which position is easiest for the nurse and best for the patient's comfort. Slide a waterproof pad under the patient.	Proper positioning allows adequate visualization of the urinary meatus. Patients with female genitalia should lie with their knees bent and legs spread apart (SUNA, 2021a; Yates, 2017b). Embarrassment, chilliness, and tension can interfere with catheter insertion; draping the patient will promote comfort and relaxation. The Sims' position may allow better visualization and be more comfortable for the patient, especially if hip and knee movements are difficult. The smaller area of exposure is also less stressful for the patient. The waterproof pad will protect bed linens from moisture.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

FIGURE 1. Patient in dorsal recumbent position and draped properly.

FIGURE 2. Demonstration of side-lying position.

10. Put on clean gloves. Clean the perineal area with a washcloth, skin cleanser, and warm water, using a different corner of the washcloth with each stroke. Wipe from above the orifice downward toward the sacrum (front to back). Rinse and dry. Remove gloves. Perform hand hygiene again.	Gloves reduce the risk of exposure to blood and body fluids. Cleaning reduces microorganisms near the urethral meatus and provides an opportunity to visualize the perineum and landmarks before the procedure. Hand hygiene reduces the spread of microorganisms.
11. Prepare the urine drainage setup if a separate urine collection system is to be used. Secure it to the bed frame, according to the manufacturer's directions.	This facilitates connection of the catheter to the drainage system and provides for easy access.
12. Open the sterile catheterization tray on a clean overbed table using sterile technique.	Placement of equipment near the worksite increases efficiency. Sterile technique protects the patient and prevents transmission of microorganisms.
13. Put on sterile gloves. Grasp the upper corners of the drape and unfold the drape without touching nonsterile areas. Fold back a corner on each side to make a cuff over your gloved hands. Ask the patient to lift their buttocks and slide the sterile drape under them with your gloves protected by the cuff.	The drape provides a sterile field close to the meatus. Covering the gloved hands will help keep the gloves sterile while placing the drape.
14. Based on facility policy, position the fenestrated sterile drape. Place a fenestrated sterile drape over the perineal area, exposing the labia (Figure 3). (*Note:* The fenestrated drape is not shown in the remaining illustrations in order to provide a clear view of the procedure.)	The drape expands the sterile field and protects against contamination. Use of a fenestrated drape may limit visualization and is considered optional by some health care providers and/or facility policies.

FIGURE 3. Patient with fenestrated drape in place over perineum.

15. Place the sterile tray on the drape between the patient's thighs. If the patient is in the side-lying position, place the sterile tray near the patient's legs close to the sterile drape.	The sterile setup should be arranged so that the nurse's back is not turned to it, nor should it be out of the nurse's range of vision. This provides easy access to supplies.
16. Open all the supplies. Remove the cap from the prefilled sterile saline syringe and attach it to the balloon inflation port on the catheter. Open the package of antiseptic swabs. Alternatively, fluff cotton balls in a tray before pouring antiseptic solution over them. Open the specimen container if a specimen is to be obtained. If using anesthetic gel, remove the cap from the prefilled syringe. Open and squirt lubricant in the tray.	It is necessary to open all supplies and prepare for the procedure while both hands are sterile.
17. Remove the cover from the catheter and lubricate 1 to 2 inches of the catheter tip (SUNA, 2021b).	Lubrication facilitates catheter insertion and reduces tissue trauma (SUNA, 2021a).
18. With the thumb and one finger of your nondominant hand, spread the labia and identify the meatus (Figure 4). **Be prepared to maintain separation of the labia with one hand until the catheter is inserted and urine is flowing well and continuously.** If the patient is in the side-lying position, lift the upper buttock and labia to expose the urinary meatus (Figure 5).	Smoothing the area immediately surrounding the meatus helps to make it visible. Allowing the labia to drop back into position may contaminate the area around the meatus as well as the catheter. The nondominant hand is now contaminated.

FIGURE 4. Using dominant hand to separate and hold labia open.

FIGURE 5. Exposing urinary meatus with patient in side-lying position.

19. Use your dominant hand to pick up an antiseptic swab, or use forceps to pick up a cotton ball. **Clean one labial fold, top to bottom (from above the meatus down toward the rectum), then discard the swab/cotton ball** (Figure 6). Using a new swab/cotton ball for each stroke, continue to clean the other labial fold, then use a third to clean directly over the meatus. Discard each swab/cotton ball after one use.	Moving from an area where there is likely to be less contamination to an area where there is more contamination helps prevent the spread of microorganisms. Cleaning the meatus last helps reduce the possibility of introducing microorganisms into the bladder.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

FIGURE 6. Wiping perineum with cotton ball held by forceps. Wipe in one direction—from top to bottom.

20. If using anesthetic gel, with your noncontaminated, dominant hand, pick up the anesthetic syringe. Gently place nozzle of gel near the urethral orifice and apply some gel (SUNA, 2021b). Gently place nozzle at the meatus and slowly squeeze at least 5 mL of gel into the urethra (SUNA 2021b). Allow the gel to dwell for approximately 3 to 5 minutes before starting the catheter insertion (SUNA, 2021b). Additional lubrication with a water-based lubricant may not be needed.	The use of anesthetic gel is usually not necessary for patients with female anatomy but should be considered if it is the patient's first catheterization or if a difficulty catheterization is anticipated (SUNA, 2021a).
21. With your noncontaminated, dominant hand, place the drainage end of the catheter in a receptacle. If the catheter is pre-attached to the sterile tubing and drainage container (closed drainage system), position the catheter and setup within easy reach on the sterile field. Ensure that the clamp on the drainage bag is closed.	This facilitates drainage of urine and minimizes risk of contaminating sterile equipment.
22. **Using your dominant hand, hold the catheter 2 to 3 inches from the tip and insert slowly into the urethra (Figure 7). Advance the catheter until there is a return of urine (approximately 2 to 3 inches [4.8 to 7.2 cm]). Once urine drains, advance the catheter another 2 to 3 inches (4.8 to 7.2 cm). Do not force the catheter through the urethra into the bladder.** Ask the patient to breathe deeply, and rotate the catheter gently if slight resistance is met as the catheter reaches the external sphincter.	The female urethra is about 1.5 to 2.5 inches (3.6 to 6.0 cm) long. Applying force on the catheter is likely to injure mucous membranes. The sphincter relaxes and the catheter can enter the bladder easily when the patient relaxes. Advancing an indwelling catheter an additional 2 to 3 inches (4.8 to 7.2 cm) ensures placement in the bladder and facilitates inflation of the balloon without damaging the urethra.

FIGURE 7. Inserting catheter with dominant hand while nondominant hand holds labia apart.

23. Hold the catheter securely at the meatus with your nondominant hand. Use your dominant hand to inflate the catheter balloon (Figure 8). Inject the	Bladder or sphincter contraction could push the catheter out. The balloon anchors the catheter in place in the bladder. The manufacturer provides the appropriate

entire volume of sterile water supplied in a prefilled syringe. Remove the syringe from the port.

amount of sterile water for the size of the catheter in the kit; as a result, use the entire syringe provided in the kit. Removal of the syringe from the injection port prevents the sterile water from pushing back into the syringe and resulting balloon deflation.

24. Pull gently on the catheter after the balloon is inflated to feel resistance.

Improper inflation can cause patient discomfort and malpositioning of the catheter.

25. Attach the catheter to the drainage system if not already pre-attached (Figure 9).

The closed drainage system minimizes the risk for microorganisms being introduced into the bladder (Gould et al., 2019).

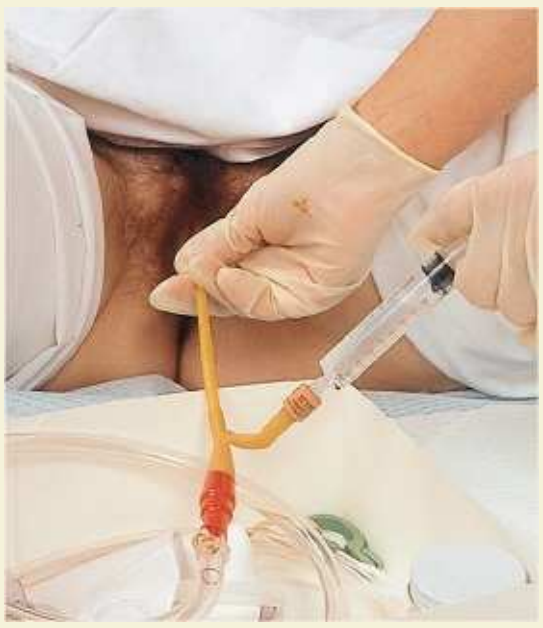

FIGURE 8. Inflating balloon of indwelling catheter.

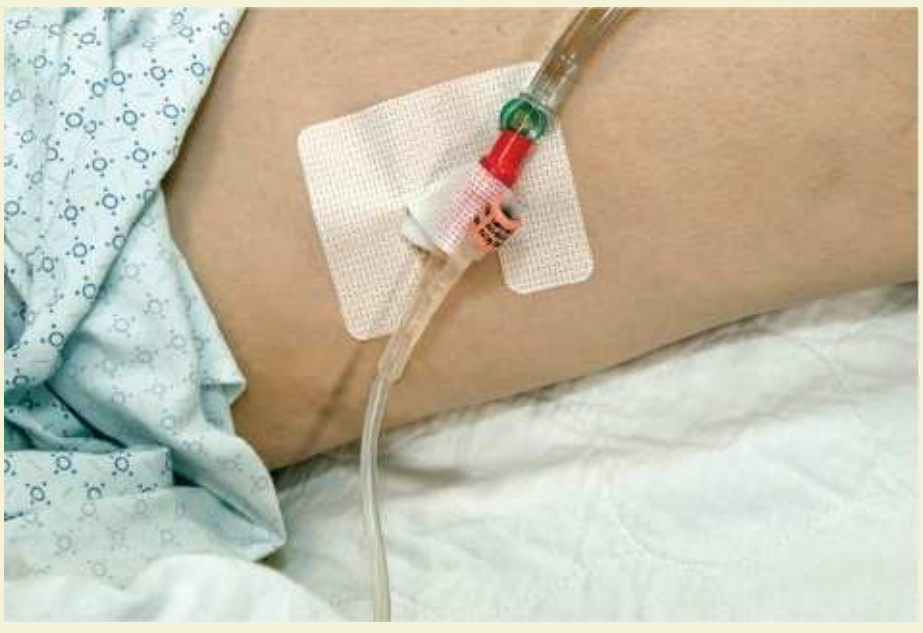
FIGURE 9. Attaching catheter to drainage bag.

26. Remove equipment and dispose of it according to facility policy. Discard the syringe in a sharps container. Wash and dry the perineal area, as needed.

Proper disposal prevents the spread of microorganisms. Placing the syringe in a sharps container prevents reuse. Cleaning promotes comfort and appropriate personal hygiene.

27. Remove gloves. Perform hand hygiene. **Secure the catheter tubing to the patient's inner thigh with a catheter-securing device (Figure 10).** Leave some slack in the catheter for leg movement.

Proper securement prevents tension on the catheter; reduces risk for catheter displacement, expulsion, migration, and trauma; and increases patient comfort (Holroyd, 2019). Hand hygiene prevents the spread of microorganisms. Whether to secure the drainage tubing over or under the leg depends on gravity flow, the patient's mobility, and the patient's comfort.



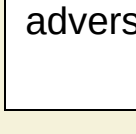


FIGURE 10. Catheter secured to leg.

28. Assist the patient to a comfortable position. Cover the patient with bed linens. Place the bed in the

Positioning and covering provides warmth and promotes comfort.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

lowest position.	
29. Secure the drainage bag below the level of the bladder. Check that the drainage tubing is not kinked and that movement of side rails does not interfere with the catheter or drainage bag.	This facilitates drainage of urine and prevents the backflow of urine (ANA, 2014; Gould et al., 2019).
30. Put on gloves. Obtain a urine specimen immediately, if needed, from the drainage bag. Label the specimen. Send the urine specimen to the laboratory promptly or refrigerate it.	The catheter system is sterile. Obtaining a specimen immediately allows access to the sterile system. Keeping the urine at room temperature may cause microorganisms, if present, to grow and distort laboratory findings.
 31. Remove gloves and additional PPE, if used. Perform hand hygiene.	Proper removal of PPE reduces the risk for infection transmission and contamination of other items. Hand hygiene prevents the spread of microorganisms.

DOCUMENTATION

Guidelines

Document the type and size of catheter and balloon inserted, as well as the amount of fluid used to inflate the balloon. Document the patient's tolerance of the activity. Record the amount of urine obtained through the catheter and any specimen obtained. Document any other assessments, such as unusual urine characteristics or alterations in the patient's skin. Record urine amount on intake and output record, if appropriate.

Sample Documentation

DocuCare Practice documenting catheterization of the female urinary bladder in *Lippincott DocuCare*.

7/14/25 0915 Patient's primary care provider notified of palpable bladder (3 cm below umbilicus) and the patient's inability to void; 750 mL of urine noted with bladder scan. A 14F Foley catheter inserted without difficulty; 10 mL of sterile water injected into balloon port; 700-mL clear yellow urine returned. Patient states, "Oh, I feel much better now." Bladder is no longer palpable. Patient tolerated procedure without adverse event.

—B. Clapp, RN

DEVELOPING CLINICAL REASONING AND CLINICAL JUDGMENT

UNEXPECTED SITUATIONS AND ASSOCIATED INTERVENTIONS

- *No urine flow is obtained, and you note that the catheter is in the vaginal orifice:* Leave the catheter in place as a marker. Obtain new sterile gloves and catheter kit. Start the procedure over and attempt to place the new catheter directly above the misplaced catheter. Once the new catheter is correctly in place, remove the catheter in the vaginal orifice. Because of the risk of cross-infection, never remove a catheter from the vagina and insert it into the urethra.
- *Patient moves legs during procedure:* If no supplies have been contaminated, ask the patient to hold still and continue with the procedure. If supplies have been contaminated, stop the procedure and start over. If necessary, get an assistant to remind the patient to hold still.
- *Urine flow is initially well established, and urine is clear, but after several hours flow dwindles:* Check the tubing for kinking. If patient has changed position, the tubing and drainage bag may need to be moved to facilitate drainage of urine.
- *Urine leaks out of the meatus around the catheter:* Do not increase the size of the indwelling catheter. Make sure the smallest-sized catheter with a 10-mL balloon is used. Large catheters cause bladder and urethral irritation and trauma. Large balloon-fill volumes occupy more space inside the bladder and put added weight on the base of the bladder. Irritation of the bladder wall and detrusor muscle can cause leakage. If leakage persists, consider an evaluation for urinary tract infection. Ensure that the correct amount of solution was used to inflate the balloon. Underfilling the balloon can cause the catheter to dislodge into the urethra, causing urethral spasm, pain, and discomfort. If you suspect underfill, do not attempt to push the catheter farther into the bladder. Remove the catheter and replace with a new catheter. Assess the patient for constipation. A bowel full of stool can cause pressure on the catheter lumen and prevent the drainage of urine. Implement interventions to prevent/treat constipation.

SPECIAL CONSIDERATIONS

General Considerations

- Some facilities have adopted a two-person urinary catheter insertion protocol, in which one nurse catheterizes the patient and one observes to ensure that the nurse inserting the catheter follows sterile technique and performs the procedure correctly (Belizario, 2015; Rhone et al., 2017). Implementation of the two-person urinary catheter insertion protocol has been shown to decrease CAUTI (Belizario, 2015; Fletcher-Gutowski & Cecil, 2019; Rhone et al., 2017).
- The use of anesthetic gel is usually not necessary for patients with female anatomy but should be considered if it is the patient's first catheterization or if a difficulty catheterization is anticipated (SUNA, 2021a).
- Check for patient allergy before use of anesthetic gel. Anesthetic gel instilled into the patient's urethra should be administered at 3 to 5 minutes before catheterization to ensure sufficient anesthetic effect (SUNA, 2021b).
- Be familiar with facility policy and/or primary health care provider guidelines for the maximum amount of urine to remove from the bladder at the time of insertion.
- If the patient is unable to lift their buttocks or maintain the required position for the procedure, the assistance of another staff member may be necessary to place the drape under the patient and to help the patient maintain the required position.
- Supplies can be opened and prepared on the overbed table, moving the tray onto the bed just before cleansing the patient.
- If there is not an immediate flow of urine after the catheter has been inserted, several measures may prove helpful:
  - Have the patient take a deep breath, which helps to relax the perineal and abdominal muscles.
  - Rotate the catheter slightly, because a drainage hole may be resting against the bladder wall.
  - Raise the head of the patient's bed to increase pressure in the bladder area.
  - Assess the patient's intake to ensure adequate fluid intake for urine production.
  - Assess the catheter and drainage tubing for kinks and occlusion.
- If the catheter cannot be advanced, have the patient take several deep breaths. Rotate the catheter half a turn and try to advance it. If you are still unable to advance, remove the catheter. Notify the health care team.
- Some catheter kits do not contain the catheter. This allows you to select a catheter and balloon size separately.
- Maintain a constant downward flow of urine. Check tubing frequently to ensure kinks and dependent loops (low points) are not present in the tubing (ANA, 2014; Gould et al., 2019; Wuthier et al., 2016). Check to see that the patient is not lying on the drainage tubing and compressing it.
- Keep the catheter drainage bag below the level of the bladder at all times (ANA, 2014; Gould et al., 2019).
- Keep the drainage bag off the floor at all times to reduce the risk of infection (ANA, 2014; Gould et al., 2019). The floor is grossly contaminated.

Infant and Child Considerations

- Size 6F to 8F is used for infants and young children (Kyle & Carman, 2021). Size 8F to 12F catheters are commonly used for older children (Kyle & Carman, 2021).
- Distraction, such as blowing bubbles, deep breathing, or singing a song, can help the child relax.
- Consider use of lidocaine jelly to anesthetize and lubricate the area before insertion of the catheter, decreasing the child's discomfort and anxiety. Refer to facility policy regarding prescribing requirements and use.

Community-Based Care Considerations

- Intermittent catheterization, performed by the patient or a caregiver in the home, may be necessary for patients with spinal cord injuries or other neurologic conditions. Although the risk for UTI is always present, practice guidelines support the use of clean, rather than sterile, technique in the home environment (Bardsley, 2015a; Beauchemin et al., 2018; Gould et al., 2019; Wilson, 2015a). The procedure for self-intermittent catheterization is essentially the same as that used by the nurse to catheterize a patient, using clean, nonsterile technique (Collins, 2019; Leach, 2018). Box 38-6 outlines important information related to patient intermittent self-catheterization (ISC).
- Single-use catheters and no-touch catheters are options for use for ISC in the home setting (Beauchemin et al., 2018). The past practice of catheter reuse in community settings, instructing patients to wash and reuse the same catheter for multiple catheterizations, is not recommended; no evidence-based guidelines on cleaning or disposing of a reused catheter are available (Beauchemin et al., 2018; Newman, 2019b).

Skill 38-3

Catheterizing the Urinary Bladder of a Patient With Male

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

DELEGATION CONSIDERATIONS

The catheterization of the urinary bladder is not delegated to assistive personnel (AP). Depending on the state's nurse practice act and the organization's policies and procedures, catheterization of the urinary bladder may be delegated to licensed practical/vocational nurses (LPN/LVNs). The decision to delegate must be based on careful analysis of the patient's needs and circumstances as well as the qualifications of the person to whom the task is being delegated. Refer to the Delegation Guidelines in Appendix A.

EQUIPMENT

- Sterile catheter kit that contains:
  - Sterile gloves
  - Sterile drapes (one of which is fenestrated)
  - Sterile catheter (use the smallest appropriate-size catheter, usually a 14F catheter with a 5- to 10-mL balloon [ANA, 2014; SUNA, 2021d; Yates, 2017a])
  - Antiseptic cleansing solution and cotton balls or gauze squares; antiseptic swabs
  - Lubricant
  - Forceps
  - Prefilled syringe with sterile water (sufficient to inflate indwelling catheter balloon)
  - Sterile basin (usually base of kit serves as this)
  - Sterile specimen container (if specimen is required)
  - Anesthetic gel, as prescribed or indicated (See Assessments below)
  - Flashlight or lamp
  - Waterproof, disposable pad
  - Sterile, disposable urine collection bag and drainage tubing (may be connected to catheter in catheter kit)
  - Catheter-securing device
  - Disposable gloves
  - Additional PPE, as indicated
  - Washcloth, skin cleanser, and warm water to perform perineal hygiene before and after catheterization

IMPLEMENTATION

ACTION	RATIONALE
1. Review the patient's health record for any limitations in physical activity. Confirm the prescribed intervention for indwelling catheter insertion.	Physical limitations may require adaptations in performing the skill. Verifying the prescribed intervention ensures that the correct intervention is administered to the right patient.
2. Gather equipment. Obtain assistance from another staff member, if necessary.	Assembling equipment provides for an organized approach to the task. Assistance from another person may be required to perform the intervention safely.
 3. Perform hand hygiene and put on PPE, if indicated.	Hand hygiene and PPE prevent the spread of microorganisms. PPE is required based on transmission precautions.
 4. Identify the patient.	Identifying the patient ensures the right patient receives the intervention and helps prevent errors.
5. Close the curtains around the bed and close the door to the room, if possible. Discuss the procedure with the patient and assess the patient's ability to assist with the procedure. Ask the patient if they have any allergies, especially to latex or iodine.	This ensures the patient's privacy. Discussion promotes reassurance and provides knowledge about the procedure. Dialogue encourages patient participation and allows for individualized nursing care. Some catheters and gloves in kits are made of latex. Some

	antiseptic solutions contain iodine.
6. Provide good lighting. Artificial light is recommended (use of a flashlight requires an assistant to hold and position it). Place a trash receptacle within easy reach.	Good lighting is necessary to see the meatus clearly. A readily available trash receptacle allows for prompt disposal of used supplies and reduces the risk of contaminating the sterile field.
7. Assemble equipment on the overbed table or other surface within reach.	Arranging items nearby is convenient, saves time, and prevents unnecessary stretching and twisting of muscles on the part of the nurse.
8. Adjust the bed to a comfortable working height (VHACEOSH, 2016). Stand on the patient's right side if you are right-handed, or the patient's left side if you are left-handed.	Having the bed at the proper height prevents back and muscle strain. Positioning allows for ease of use of your dominant hand for catheter insertion.
9. Position the patient on their back with their thighs slightly apart. Drape the patient so that only the area around the penis is exposed. Slide a waterproof pad under the patient.	Proper positioning allows adequate visualization of the urinary meatus. This prevents unnecessary exposure and promotes warmth. The waterproof pad will protect bed linens from moisture.
 10. Put on gloves. Clean the genital area with a washcloth, skin cleanser, and warm water. Clean the tip of the penis first, moving the washcloth in a circular motion from the meatus outward. Wash the shaft of the penis using downward strokes toward the pubic area. Rinse and dry. Remove gloves. Perform hand hygiene.	Gloves reduce the risk of exposure to blood and body fluids. Cleaning the penis reduces microorganisms near the urethral meatus. Hand hygiene reduces the spread of microorganisms.
11. Prepare the urine drainage setup if a separate urine collection system is to be used. Secure it to the bed frame according to the manufacturer's directions.	This facilitates connection of the catheter to the drainage system and provides for easy access.
12. Open the sterile catheterization tray on a clean overbed table or other flat surface, using sterile technique.	Placement of equipment near the worksite increases efficiency. Sterile technique protects the patient and prevents the spread of microorganisms.
13. Put on sterile gloves. Open the sterile drape and place it on the patient's thighs. Place the fenestrated drape with the opening over the penis (Figure 1).	The drape provides a sterile field close to the meatus.
14. Place the catheter setup on or next to the patient's legs on the sterile drape.	The sterile setup should be arranged so that the nurse's back is not turned to it, nor should it be out of the nurse's range of vision. This provides easy access to supplies.
15. Open all the supplies. Remove the cap from the prefilled sterile saline syringe and attach it to the balloon inflation port on the catheter. Open the package of antiseptic swabs. Alternatively, fluff cotton balls in a tray before pouring antiseptic solution over them. Open the specimen container if a specimen is to be obtained. If using anesthetic gel, remove the cap from the prefilled syringe. Open and squirt lubricant in the tray.	It is necessary to open all supplies and prepare for the procedure while both hands are sterile. The use of anesthetic gel inserted in the urethra prior to catheterization is an option in for patients with male anatomy and should be considered if it is the patient's first catheterization or if a difficulty catheterization is suspected (SUNA, 2021d).
16. Remove the cover from the catheter and lubricate 5 to 7 inches of the catheter tip (SUNA, 2021d).	Lubrication facilitates catheter insertion, reduces urethral trauma, and reduces discomfort during insertion (SUNA, 2021d).
17. Lift the penis with your nondominant hand. Retract the foreskin in an uncircumcised patient. **Be prepared to keep your hand in this position until the catheter is inserted and urine is flowing well**	The hand touching the penis becomes contaminated. Cleansing the area around the meatus and under the foreskin in the uncircumcised patient helps prevent infection. Moving from the meatus toward the base

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

and continuously. Use your dominant hand to pick up an antiseptic swab, or use forceps to pick up a cotton ball. **Using a circular motion, clean the penis, moving from the meatus down the glans of the penis (Figure 2). Repeat this cleansing motion two more times, using a new swab/cotton ball each time. Discard each swab/cotton ball after one use.**

of the penis prevents bringing microorganisms to the meatus.

FIGURE 1. Patient lying supine with fenestrated drape +over penis.

FIGURE 2. Lifting penis with gloved nondominant hand and cleaning meatus with cotton ball held with forceps in gloved dominant hand.

18. Hold the penis with slight upward tension and perpendicular to the patient's body at a 90-degree angle to the patient's thighs (SUNA, 2021d). If using anesthetic gel, use your noncontaminated dominant hand to pick up the anesthetic syringe. Gently insert the tip of the syringe with anesthetic into the meatus and inject approximately 5 to 10 mL into the urethra (SUNA, 2021d) (Figure 3). Allow the gel to dwell for approximately 3 to 5 minutes before starting the catheter insertion (SUNA, 2021d).

This position extends the urethra and straightens the curvature of the penis (SUNA, 2021d). The use of anesthetic gel inserted in the urethra prior to catheterization is an option in for patients with male anatomy and should be considered if it is the patient's first catheterization or if a difficulty catheterization is suspected (SUNA, 2021d).

19. With your noncontaminated, dominant hand, place the drainage end of the catheter in a receptacle. If the catheter is pre-attached to the sterile tubing and drainage container (closed drainage system), position the catheter and setup within easy reach on the sterile field. Ensure that the clamp on the drainage bag is closed.

This facilitates drainage of urine and minimizes risk of contaminating sterile equipment.

20. Use your noncontaminated, dominant hand to pick up the catheter and hold it 3 to 4 inches from the tip. Ask the patient to bear down as if voiding. **Insert the catheter tip into the meatus (Figure 4). Ask the patient to take deep breaths. Advance the catheter about 7 to 10 inches into the urethra; urine should begin to flow through the tubing. Once urine flow is established, insert the catheter two more inches further, to the bifurcation or "Y" juncture of the ports (SUNA, 2021d). Do not use force to introduce the catheter.** If the catheter resists entry, ask the patient to breathe deeply and rotate the catheter slightly.

Bearing down eases the passage of the catheter through the urethra. The male urethra is about 20 cm long. Having the patient take deep breaths or twisting the catheter slightly may ease the catheter past resistance at the sphincters. Insert indwelling catheters in patients with male genitalia to the catheter bifurcation (the "Y" level created by the balloon filling and urinary drainage ports) to assure the balloon is within the bladder and to avoid inadvertent inflation of the balloon in the urethra (ANA, 2014; SUNA, 2021d).

FIGURE 3. Inserting syringe into urethra and instilling lubricant.

FIGURE 4. Inserting catheter using dominant hand.

21. Hold the catheter securely at the meatus with your nondominant hand. Use your dominant hand to inflate the catheter balloon. Inject the entire volume of sterile water supplied in the prefilled syringe. Once the balloon is inflated, the catheter may be gently pulled back into place. **Replace the foreskin, if present, over the catheter.** Lower the penis.	Bladder or sphincter contraction could push the catheter out. The balloon anchors the catheter in place in the bladder. The manufacturer provides the appropriate amount of solution for the size of the catheter in the kit; as a result, use the entire syringe provided in the kit.
22. Pull gently on the catheter after the balloon is inflated to feel resistance.	Improper inflation can cause patient discomfort and malpositioning of the catheter.
23. Attach the catheter to the drainage system, if necessary.	The closed drainage system minimizes the risk for microorganisms being introduced into the bladder (Gould et al., 2019).
24. Remove equipment and dispose of it according to facility policy. Discard the syringe in a sharps container. Wash and dry the perineal area, as needed.	Proper disposal prevents the spread of microorganisms. Placing the syringe in a sharps container prevents reuse. Cleaning promotes comfort and appropriate personal hygiene.
 25. Remove gloves. Perform hand hygiene. **Secure the catheter tubing to the patient's inner thigh or lower abdomen (with the penis directed toward the patient's chest) with a catheter-securing device.** Leave some slack in the catheter for leg movement.	Proper securement prevents tension on the catheter; reduces risk for catheter displacement, expulsion, migration, and trauma; and increases patient comfort (Holroyd, 2019). Hand hygiene prevents the spread of microorganisms. Whether to take the drainage tubing over or under the leg depends on gravity flow, the patient's mobility, and the comfort of the patient.
26. Assist the patient to a comfortable position. Cover the patient with bed linens. Place the bed in the lowest position.	Positioning and covering provides warmth and promotes comfort.
27. Secure the drainage bag below the level of the bladder. Check that the drainage tubing is not kinked and that movement of the side rails does not interfere with the catheter or drainage bag.	This facilitates drainage of urine and prevents the backflow of urine (ANA, 2014; Gould et al., 2019).
28. Put on gloves. Obtain a urine specimen immediately, if needed, from the drainage bag. Label the specimen. Send the urine specimen to the laboratory promptly or refrigerate it.	The catheter system is sterile. Obtaining a specimen immediately allows access to the sterile system. Keeping the urine at room temperature may cause microorganisms, if present, to grow and distort laboratory findings.
 29. Remove gloves and additional PPE, if used. Perform hand hygiene.	Proper removal of PPE reduces the risk for infection transmission and contamination of other items. Hand hygiene prevents the spread of microorganisms.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

DOCUMENTATION

Guidelines

Document the type and size of catheter and balloon inserted as well as the amount of fluid used to inflate the balloon. Document the patient's tolerance of the activity. Record the amount of urine obtained through the catheter and any specimen obtained. Document any other assessments, such as unusual urine characteristics or alterations in the patient's skin. Record the urine amount on the intake and output record, if appropriate.

Sample Documentation

DcuCare Practice documenting catheterization of the male urinary bladder in *Lippincott DocuCare*.

7/14/25 1830 Patient unable to void for 8 hours and reports, "I feel like I have to go to the bathroom." Bladder scanned for 540-mL urine. Primary care provider notified; 10-mL prescribed 2% lidocaine jelly instilled before catheterization; 14F Foley catheter inserted without difficulty; 10 mL of sterile water injected into 5-mL balloon port; 525-mL clear yellow urine returned. Patient reports decreased bladder pressure. Patient tolerated procedure without adverse event.

—B. Clapp, RN

DEVELOPING CLINICAL REASONING AND CLINICAL JUDGMENT

UNEXPECTED SITUATIONS AND ASSOCIATED INTERVENTIONS

- *You cannot insert the catheter past 3 to 4 inches; rotating the catheter and having the patient breathe deeply are of no help:* If still unable to place the catheter, notify the health care team. Repeated catheter placement attempts can traumatize the urethra. Anticipate the possible insertion of a coudé catheter by a urologist or advanced practice professional.
- *Patient is obese or has a retracted penis:* Have an assistant available to place their fingers on either side of the pubic area and press backward to bring the penis out of the pubic cavity. Hold the patient's penis up and forward. The catheter still needs to be inserted to the bifurcation; the length of the urethra has not changed.
- *Urine leaks out of meatus around the catheter:* Do not increase the size of the indwelling catheter. Make sure the smallest-sized catheter with a 10-mL balloon is used. Large catheters cause bladder and urethral irritation and trauma. Large balloon-fill volumes occupy more space inside the bladder and put added weight on the base of the bladder. Irritation of the bladder wall and detrusor muscle can cause leakage. If leakage persists, consider an evaluation for urinary tract infection. Ensure that the correct amount of solution was used to inflate the balloon. Underfilling the balloon can cause the catheter to dislodge into the urethra, causing urethral spasm, pain, and discomfort. If you suspect underfill, do not attempt to push the catheter farther into the bladder. Remove the catheter and replace with a new catheter. Assess the patient for constipation. A bowel full of stool can cause pressure on the catheter lumen and prevent the drainage of urine. Implement interventions to prevent/treat constipation.
- *Urine flow is initially well established, and urine is clear, but after several hours, urine flow dwindles:* Check the tubing for kinking. If the patient has changed position, the tubing and drainage bag may need to be moved to facilitate drainage of urine.

SPECIAL CONSIDERATIONS

General Considerations

- Some facilities have adopted a two-person urinary catheter insertion protocol, in which one nurse catheterizes the patient and one observes to ensure that the nurse inserting the catheter follows sterile technique and performs the procedure correctly (Belizario, 2015; Rhone et al., 2017). Implementation of the two-person urinary catheter insertion protocol has been shown to decrease CAUTI (Belizario, 2015; Fletcher-Gutowski & Cecil, 2019; Rhone et al., 2017).
- Assess for the need to use anesthetic gel; the use of anesthetic gel inserted in the urethra prior to catheterization is an option in for patients with male anatomy and should be considered if it is the patient's first catheterization or if a difficulty catheterization is suspected (SUNA, 2021d).
- Check for patient allergy before use of anesthetic gel. Anesthetic gel instilled into the patient's urethra should be administered at least 5 minutes before catheterization to ensure sufficient anesthetic effect (Yates, 2017b).
- Be familiar with facility policy and/or primary health care provider guidelines for the maximum amount of urine to remove from the bladder at the time of insertion.
- Supplies can be opened and prepared on the overbed table, moving the tray onto the bed just before cleansing the

patient.

- If there is not an immediate flow of urine after the catheter has been inserted, several measures may prove helpful:
  - Have the patient take a deep breath, which helps to relax the perineal and abdominal muscles.
  - Rotate the catheter slightly because a drainage hole may be resting against the bladder wall.
  - Raise the head of the patient's bed to increase pressure in the bladder area.
  - Assess the patient's intake to ensure adequate fluid intake for urine production.
  - Assess the catheter and drainage tubing for kinks and occlusion.
  - Urethral strictures, false passages, prostatic enlargement, and postsurgical bladder-neck contractures can make urethral catheterization difficult and may require the services of a urologist. If there is any question as to the location of the catheter, do not inflate the balloon. Remove the catheter and notify the health care team (SUNA, 2021c).
- If the catheter cannot be advanced, having the patient take several deep breaths may be helpful. Rotate the catheter half a turn, and try to advance it. If you are still unable to advance it, remove the catheter. Notify the health care team.
- Some catheter kits do not contain the catheter. This allows you to select a catheter and balloon size separately.
- Maintain a constant downward flow of urine. Check tubing frequently to ensure kinks and dependent loops (low points) are not present in the tubing (ANA, 2014; Gould et al., 2019; Wuthier et al., 2016). Check to see that the patient is not lying on the drainage tubing and compressing it.
- Keep the catheter drainage bag below the level of the bladder at all times (ANA, 2014; Gould et al., 2019).
- Keep the drainage bag off the floor at all times to reduce the risk of infection (ANA, 2014; Gould et al., 2019). The floor is grossly contaminated.

Infant and Child Considerations

- Size 6F to 8F is used for infants and young children (Kyle & Carman, 2021). Size 8F to 12F catheters are commonly used for older children (Kyle & Carman, 2021).
- Distraction, such as blowing bubbles, deep breathing, or singing a song, can help the child relax.
- Consider the use of lidocaine jelly to anesthetize and lubricate the area before insertion of the catheter, decreasing the child's discomfort and anxiety. Refer to facility policy regarding prescribing requirements and use.

Older Adult Considerations

- If resistance is met while inserting a catheter, and rotating does not help, it is important to never force the catheter. The resistance may be caused by enlargement of the prostate gland, which is commonly seen in men over age 50 years. A special crook-tipped catheter called a coudé catheter, inserted by the urologist or advanced practice professional, may be required to maneuver past the prostate gland.

Community-Based Care Considerations

- Intermittent catheterization, performed by the patient or a caregiver in the home, may be necessary for patients with spinal cord injuries or other neurologic conditions. Although the risk for UTI is always present, and practice guidelines support the use of clean, rather than sterile, technique in the home environment (Bardsley, 2015a; Beauchemin et al., 2018; Gould et al., 2019; Wilson, 2015a). The procedure for self-intermittent catheterization is essentially the same as that used by the nurse to catheterize a patient, using clean, nonsterile technique (Collins, 2019; Leach, 2018). Box 38-6 (p. 1475) outlines important information related to patient intermittent self-catheterization (ISC).

Skill 38-4

Emptying and Changing a Stoma Appliance on a Urinary Diversion

DELEGATION CONSIDERATIONS

The emptying of a stoma appliance on a urinary diversion may be delegated to assistive personnel (AP) as well as to licensed practical/vocational nurses (LPN/LVNs). The changing of a stoma appliance on a urinary diversion may be delegated to LPN/LVNs. The decision to delegate must be based on careful analysis of the patient's needs and circumstances as well as the qualifications of the person to whom the task is being delegated. Refer to the Delegation Guidelines in Appendix A.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

EQUIPMENT

- Premoistened disposable washcloths or
  - Basin with warm water
  - Skin cleanser, towel, washcloth
- Silicone-based adhesive remover
- Gauze squares
- Skin protectant, such as Skin-Prep™
- Ostomy appliance
- Stoma-measuring guide
- Graduated container
- Ostomy belt (optional)
- Disposable gloves
- Additional PPE, as indicated
- Waterproof, disposable pad
- Small plastic trash bag

IMPLEMENTATION

ACTION	RATIONALE
1. Gather equipment.	Assembling equipment provides for an organized approach to the task.
 2. Perform hand hygiene and put on PPE, if indicated.	Hand hygiene and PPE prevent the spread of microorganisms. PPE is required based on transmission precautions.
 3. Identify the patient.	Identifying the patient ensures the right patient receives the intervention and helps prevent errors.
4. Close the curtains around the bed and close the door to the room, if possible. Explain to the patient what you are going to do and why. Encourage the patient to observe or participate, if possible and as appropriate.	This ensures the patient's privacy. Explanation relieves anxiety and facilitates engagement. Having the patient observe or assist encourages self-acceptance and helps the patient develop self-care skills.
5. Assemble equipment on the overbed table or other surface within reach.	Arranging items nearby is convenient, saves time, and prevents unnecessary stretching and twisting of muscles on the part of the nurse.
6. Assist the patient to a comfortable sitting or lying position in bed or a standing or sitting position in the bathroom. If the patient is in bed, adjust the bed to a comfortable working height (VHACEOSH, 2016). Place a waterproof pad under the patient at the stoma site.	Either position should allow the patient to view the procedure in preparation for learning to perform it independently. Lying flat or sitting upright facilitates smooth application of the appliance. Having the bed at the proper height prevents back and muscle strain. A waterproof pad protects linens and the patient from moisture.
Emptying the Appliance	
7. Put on gloves. Hold the end of the appliance over a bedpan, toilet, or measuring device. Remove the end cap from the spout. Open the spout and empty the contents into the bedpan, toilet, or measuring device (Figure 1).	Gloves protect the nurse from exposure to blood and body fluids. Emptying the pouch before handling it reduces the likelihood of spilling the excretions.
8. Close the spout. Wipe the spout with toilet tissue. Replace the cap.	Drying the spout removes any urine.

9. Remove equipment. Remove gloves. Perform hand hygiene. Assist the patient to a comfortable position.	Proper removal of PPE prevents the transmission of microorganisms. Positioning ensures patient comfort. Hand hygiene prevents the spread of microorganisms.
10. If the appliance is not to be changed, place the bed in the lowest position. Remove additional PPE, if used. Perform hand hygiene.	Lowering the bed promotes patient safety. Proper removal of PPE reduces the risk for infection transmission and contamination of other items. Hand hygiene prevents the spread of microorganisms.

FIGURE 1. Emptying urine into graduated container.

Changing the Appliance

11. Place a disposable waterproof pad on the overbed table or other work area. Open the premoistened disposable washcloths or set up the washbasin with warm water and the rest of the supplies. Place a trash bag within reach.	The pad protects the surface. Organization facilitates performance of the procedure.
12. Put on gloves. Place a waterproof pad under the patient at the stoma site. Empty the appliance, if necessary, as described in Steps 6 to 8.	The waterproof pad protects linens and the patient from moisture. Emptying the contents before removal prevents accidental spillage of fecal material.
13. Put on gloves. Use two hands to gently remove the appliance faceplate, starting at the top and keeping the abdominal skin taut (Figure 2). Remove the appliance faceplate from the skin by pushing the skin from the appliance rather than pulling the appliance from the skin (Figure 3). Apply a silicone-based adhesive remover by spraying or wiping with the remover wipe, as indicated.	Gloves prevent contact with blood and body fluids. The seal between the surface of the faceplate and the skin must be broken before the faceplate can be removed. Harsh handling of the appliance can damage the skin and impair the development of a secure seal in the future. Silicone-based adhesive remover loosens the adhesive bond to make removal easier and less likely to damage the skin and is particularly beneficial for patients with fragile skin and those at increased risk for medical adhesive–related skin injury/stripping (Collier, 2019; LeBlanc et al., 2019; Swift et al., 2020).

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

FIGURE 2. Gently removing appliance faceplate from skin.

FIGURE 3. Pushing skin from appliance rather than pulling appliance from skin.

14. Place the appliance in the trash bag, if disposable. If reusable, set it aside to wash in lukewarm soap and water and allow it to air dry after the new appliance is in place.	Thorough cleaning and airing of the appliance reduces odor and deterioration of the appliance. For aesthetic and infection control purposes, used appliances should be discarded appropriately.
15. Clean the skin around the stoma with mild skin cleanser and water or a cleansing agent and a washcloth (Figure 4). Remove all old adhesive from the skin; additional adhesive remover may be used. Do not apply lotion to the peristomal area.	Cleaning the skin removes excretions and old adhesive and skin protectant. Excretions or a buildup of other substances can irritate and damage the skin. Lotion will prevent a tight adhesive seal.
16. Gently pat the area dry. **Make sure the skin around the stoma is thoroughly dry.** Assess the stoma and the condition of the surrounding skin.	Careful drying prevents trauma to the skin and stoma. An intact, properly applied urinary collection device protects skin integrity. Any change in color and size of the stoma may indicate circulatory problems.
17. Place one or two gauze squares over the stoma opening (Figure 5).	Continuous drainage must be absorbed to keep the skin dry during appliance change.

FIGURE 4. Cleaning stoma with cleansing agent and washcloth.

FIGURE 5. Placing one or two gauze squares over stoma opening.

18. Apply skin protectant/barrier film to a 2-inches (5-cm) radius around the stoma, and allow it to dry completely, which takes about 30 seconds.	The skin needs protection from the potentially excoriating effect of the appliance adhesive (WOCN, 2018). The skin must be perfectly dry before the appliance is placed to get good adherence and to prevent leaks.
19. Lift the gauze squares for a moment and measure the stoma opening, using the measurement guide. Replace the gauze. Trace the same-size opening on the back center of the appliance. Cut the opening 1/8 inch (2 to 3 mm) larger than the stoma size (Hill, 2020) (Figure 6). Use a finger to gently smooth the	The appliance should fit snugly around the stoma, with only 1/8 inch of skin visible around the opening. A faceplate opening that is too small can cause trauma to the stoma. If the opening is too large, exposed skin will be irritated by urine. Wafer edges may be uneven after cutting and could cause irritation to

wafer edges after cutting. Check that the spout is closed, and the end cap is in place.	and/or pressure on the stoma. A closed spout and secured end cap prevent urine from leaking from the appliance.
20. Remove the paper backing from the appliance faceplate. Quickly remove the gauze squares and discard appropriately; ease the appliance over the stoma. Gently press them onto the skin while smoothing over the surface (Figure 7). Apply gentle, even pressure to the appliance for approximately 30 seconds (Burch, 2019; Hill, 2020).	The appliance is effective only if it is properly positioned and adhered securely. Pressure on the faceplate allows the faceplate to mold to the patient's skin and improves the seal.
21. Secure the optional belt to the appliance and around the patient.	An elasticized belt helps support the appliance for some people.

FIGURE 6. Cutting the faceplate opening 1/8 inch larger than stoma size.

FIGURE 7. Applying faceplate over stoma.

 22. Remove gloves. Perform hand hygiene. Assist the patient to a comfortable position. Cover the patient with bed linens. Place the bed in the lowest position.	Removing gloves reduces risk of transmission of microorganisms. Hand hygiene prevents the spread of microorganisms. Positioning and covering provide warmth and promote comfort. The bed in the lowest position promotes patient safety.
23. Put on gloves. Remove or discard any remaining equipment and assess the patient's response to the procedure.	The patient's response may indicate acceptance of the ostomy as well as the need for health teaching.
 24. Remove gloves and additional PPE, if used. Perform hand hygiene.	Proper removal of PPE reduces the risk for infection transmission and contamination of other items. Hand hygiene prevents the spread of microorganisms.

DOCUMENTATION

Guidelines

Document the procedure, including the appearance of the stoma, condition of the peristomal skin, characteristics of the urine, the patient's response to the procedure, and pertinent patient teaching.

Sample Documentation

7/23/25 1245 Ileal conduit appliance changed. Mr. Jones present. Mrs. Jones asking questions about care for ileal conduit, states, "I don't know if I'll ever be able to care for this thing at home." Tearful at times. Patient encouraged to express feelings. Patient agreed to talk with wound, ostomy, and continence nurse about concerns. Mr. Jones very supportive, also asking appropriate questions. Patient states they would like to watch change one more time before they attempt to do it. Stoma is moist and

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

red, peristomal skin intact, draining yellow urine with small amount of mucus.

—B. Clapp, RN

DEVELOPING CLINICAL REASONING AND CLINICAL JUDGMENT

UNEXPECTED SITUATIONS AND ASSOCIATED INTERVENTIONS

- *You remove appliance and find an area of skin excoriated:* Make sure that the appliance is not cut too large. Skin that is exposed inside of the ostomy appliance will become excoriated. Assess for the presence of a fungal skin infection. Consult with the wound, ostomy, and continence nurse to identify appropriate treatment. Cleanse the skin thoroughly and pat dry. Apply products made for excoriated skin before placing the appliance over the stoma. Frequently check the faceplate to ensure that a seal has formed and that there is no leakage. Document the assessment findings and related interventions in the patient's record.
- *Faceplate is leaking after applying a new appliance:* Remove the appliance, clean the skin, and start over.
- *You are ready to place the faceplate and notice that the opening is cut too large:* Discard the appliance and begin over. A faceplate that is cut too large may lead to excoriation of the skin and leakage.
- *Stoma is dark brown or black:* The stoma should appear pink to red, shiny, and moist. Alterations may indicate compromised circulation. If the stoma is dark brown or black, suspect ischemia and necrosis. Notify the health care team immediately.

SPECIAL CONSIDERATIONS

- Patients with urinary diversions created using a portion of the gastrointestinal (GI) tract will experience the presence of mucus in the urine (Berti-Hearn & Elliott, 2019). The segment of the GI tract continues to produce mucus, as part of its normal functioning. This mucus production does not decrease over time but is usually not a problem for patients with an ileal conduit (Berti-Hearn & Elliott, 2019).
- Key components in postoperative education before the patient is discharged from the hospital include assessment and care of the stoma and peristomal skin, pouch emptying, changing the appliance, drainage collectors, common complications, clothing, fluid guidelines, medications, and obtaining supplies (Goldberg et al., 2018).

DEVELOPING CLINICAL REASONING AND CLINICAL JUDGMENT

. Review the Nursing Care Plan 38-1 on pages 1487–1489 to help you develop your clinical reasoning and clinical judgment skills.

. The daughter of an older adult who is about to be discharged to the daughter's home requests that a catheter be inserted in their mother to make home care easier. The patient knows when they need to void but needs assistance to get to the bathroom. How do you respond to the daughter's request?

. If you encountered the following situations when providing patient care, how would you react and what would you do?

- A 6-year-old refuses to give a urine sample.
- Frank blood appears in the urine of a patient who has no history of urinary problems.
- When you ask for a urine sample, a teenager asks, "This won't reveal drugs, will it?"
- A young person reports painful urination with burning.
- An older adult reports frequency and pain when voiding.

PRACTICING FOR NCLEX

. A new graduate nurse and their preceptor must collect several urine specimens for laboratory testing. Which techniques for urine collection by the graduate nurse are performed incorrectly, requiring the preceptor to intervene? Select all that apply.

a. Catheterizing a patient to collect a sterile urine sample for routine urinalysis
b. Collecting a clean-catch urine specimen in the morning and storing it at room temperature until an afternoon pick-up
c. Collecting a sterile urine specimen from the collection bag of a patient's indwelling catheter
d. Collecting about 3 mL of urine from a patient's indwelling catheter to send for a urine culture
e. Planning to collect a sterile specimen from a patient with a urinary diversion by catheterizing the stoma
f. Discarding the first urine of the day when performing a 24-hour urine specimen collection on a patient

. A nurse caring for older adults in an extended-care facility performs regular assessments of the patients' urinary functioning. Which patients would the nurse identify as at risk for urinary retention? Select all that apply.

a. Patient who is diagnosed with an enlarged prostate

b. Patient who is on bedrest
c. Patient who is diagnosed with vaginal prolapse
d. Older adult patient with dementia
e. Patient who is taking antihistamines to treat allergies
f. Patient who has difficulty walking to the bathroom

. A nurse in the gynecology clinic is preparing an educational brochure to teach patients how to prevent UTIs. Which teaching points would the nurse include? Select all that apply.

a. Wear underwear with a cotton crotch.
b. Take baths rather than showers.
c. Drink of six to eight 8-oz glasses of liquid per day.
d. Urinate before and after intercourse.
e. After defecation, dry the perineal area from the front to the back.
f. Observe the urine for color, amount, odor, and frequency.

. A patient who has pneumonia has had a fever for 3 days. What characteristics would the nurse anticipate related to the patient's urine output?

a. Decreased amount and highly concentrated
b. Decreased amount and very pale like water
c. Increased amount and very concentrated
d. Increased amount and dilute appearing

. The health care provider has ordered an indwelling catheter to be inserted to relieve urinary retention in a male patient with prostate enlargement. What consideration will the nurse keep in mind when performing this procedure?

a. The male urethra is more vulnerable to injury during insertion.
b. In the hospital, a clean technique is used for catheter insertion.
c. The catheter is inserted 2 to 3 inches into the meatus.
d. Since it uses a closed system, the risk for UTI is absent.

. A nurse is caring for a patient with an enlarged prostate who has had an indwelling catheter for several weeks. A prescription for continuous bladder irrigation (CBI) is written after the patient developed hematuria post cystoscopy. The nurse teaches the patient the purpose of CBI is to prevent what situation?

a. Catheter infection due to long-term use
b. Need to flush the catheter of organisms post procedure
c. Blood clots that could block the catheter
d. Need for increased fluid intake

. A nurse is caring for a patient who has a urinary diversion (urostomy) after cystectomy (removal of the bladder) to treat bladder cancer. What interventions are indicated for this patient? Select all that apply.

a. Measuring the patient's fluid intake and output
b. Keeping the skin around the stoma moist
c. Emptying the appliance frequently
d. Reporting any mucus in the urine to the primary care provider
e. Encouraging the patient to look away when changing the appliance
f. Monitoring the return of intestinal function and peristalsis

. A nurse is changing the stoma appliance on a patient's ileal conduit. Which finding requires the nurse to follow up with the provider?

a. Stoma is moist.
b. Skin around the stoma is irritated.
c. Urine is leaking from the stoma.
d. Stoma is a purple-black color.

. A postoperative patient is having difficulty voiding and reports suprapubic pressure. What action can the nurse take to promote voiding?

a. Pouring cold water over the patient's fingers and perineum
b. Assessing bladder residual using the bladder scanner
c. Immediately encouraging the patient to void
d. Recommending an indwelling catheter

. A nurse caring for a patient who just began hemodialysis assesses the patient's AV fistula. Nursing documentation

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

includes: "5/10/25 0930 AV fistula in the right forearm negative for thrill and bruit. Patient denies pain and tenderness." Which finding is essential for the nurse report to the health care provider?

a. Thrill and bruit are absent.
b. Area is without redness or swelling.
c. Patient denies pain and tenderness.
d. Trace edema of the fingers is present.

. A nurse is caring for an alert, ambulatory, older adult with urinary frequency who has difficulty making it to the bathroom in time. Which nursing intervention is most appropriate to include in the care plan for this patient?

a. Explaining that incontinence is an expected occurrence with aging
b. Asking the patient's family/caregivers to purchase incontinence pads for the patient
c. Teaching the patient how to perform PFMT exercises at regular intervals
d. Inserting an indwelling catheter to prevent skin breakdown

. A nurse is caring for a patient who is taking phenazopyridine (a urinary tract analgesic) for a UTI. The patient states, "My urine was bright orange-red today; I think I'm bleeding. Something is terribly wrong." How will the nurse best respond?

a. "The medication causes a red-orange tinge to the urine; it is expected."
b. "I will test your urine for blood."
c. "This may be the result of an injury to your bladder."
d. "I'll hold the medication and let the provider know you are allergic to the drug."

. A nurse is caring for a male patient who had a urinary sheath applied following hip surgery. What nursing interventions are appropriate to include when caring for this patient? Select all that apply.

a. Preventing the tubing from kinking to maintain free urinary drainage
b. Changing the sheath weekly and provide hygiene
c. Fastening the sheath tightly to prevent the possibility of leakage
d. Having the patient maintain bedrest to prevent the sheath from slipping off
e. Leaving 1 to 2 inches (2.5 to 5 cm) beyond the tip of the penis
f. Ensuring the device does not restrict blood flow.

. A nurse receives a prescription to catheterize a patient following surgery. What nursing action reflects correct technique?

a. Planning to use different equipment for catheterization of male versus female patients
b. Selecting the smallest appropriate size indwelling urinary catheter
c. Sterilizing the equipment prior to insertion
d. Avoiding filling the balloon with sterile water to prevent pressure on tissues

. A nurse in the emergency room is teaching a patient how to collect a midstream urine specimen. What instructions will the nurse give the patient? Select all that apply.

a. Wash your hands with soap and water.
b. Open the container and place the lid face down on the counter.
c. Separate your labia and wipe with the antiseptic towelettes in the kit.
d. Without letting go of the labia, void a small amount into the toilet or collection hat.
e. Lean the collection container against the urinary opening and void into the container.
f. Void an ounce, then remove the container and finish voiding in the toilet.

. A nurse on a pediatric surgical unit notes a 10-year-old child has developed nocturnal enuresis. What health concern will the nurse plan for?

a. Constipation
b. Bedwetting after the age of toilet training
c. Patient who is manipulative
d. Infection

. A nursing student hears in report that their patient is receiving a nephrotoxic medication. The student plans care to include what action?

a. Teaching the patient to expect increased voiding
b. Assessing for kidney damage
c. Preventing urinary incontinence
d. Observing for nocturia

ANSWERS WITH RATIONALES

. **d, e, f.** A urine culture requires about 3 mL of urine, whereas routine urinalysis requires at least 10 mL of urine. The preferred method of collecting a sterile urine specimen from a urinary diversion is to catheterize the stoma. For a 24-hour urine specimen, the nurse should discard the first voiding, then collect all urine voided for the next 24 hours. A sterile urine specimen is not required for a routine urinalysis. Urine chemistry is altered after urine stands at room temperature for a long period of time. A specimen from the collection drainage bag may not be fresh urine and could result in an inaccurate analysis.

. **a, c, e.** Urinary retention occurs when urine is produced normally but is not excreted completely from the bladder. Factors associated with urinary retention include medications such as antihistamines, an enlarged prostate, or vaginal prolapse. Being on bedrest, having dementia, and having difficulty walking to the bathroom may place patients at risk for urinary incontinence.

. **a, c, e, f.** It is recommended that a healthy adult drink six to eight 8-oz glasses of fluid daily, dry the perineal area after urination or defecation from the front to the back, and observe the urine for color, amount, odor, and frequency. It is also recommended to wear underwear with a cotton crotch, take showers rather than baths, and drink two glasses of water before and after sexual intercourse and void immediately after intercourse. Observing urine characteristics will not prevent a UTI; however, this observation may help a patient notice an infection.

. **a.** Fever and diaphoresis cause the kidneys to conserve body fluids. Thus, the urine is concentrated and decreased in amount.

. **a.** Because of the length of the male urethra and need to insert the catheter 6 to 8 inches, it is more prone to injury. The nurse inserts the catheter for a female patient 2 to 3 inches. This procedure requires surgical asepsis to prevent introducing bacteria into the urinary tract. The presence of an indwelling catheter places the patient at risk for a UTI.

. **c.** Post procedure **c**ontinuous bladder irrigation, in the presence of hematuria, prevents stasis of blood and clot formation potentially obstructing urine output. In the absence of hematuria, clots or debris, natural irrigation of the catheter through increased fluid intake by the patient is preferred. It is preferable to avoid catheter irrigation unless necessary to relieve or prevent obstruction (Gould et al., 2009; SUNA, 2015).

. **a, c, f.** Urinary diversion involves the surgical creation of an alternate route for excretion of urine. When caring for a patient with a urinary diversion, the nurse should measure the patient's fluid intake and output to monitor fluid balance, change the appliance frequently, monitor the return of intestinal function and peristalsis, keep the skin around the stoma dry, watch for mucus in the urine as a normal finding, and encourage the patient to participate in care and look at the stoma.

. **d.** The stoma should appear pink to red, shiny, and moist; a dark brown or purple-blue stoma may reflect compromised circulation. The nurse contacts the health care provider immediately. A urostomy is incontinent; urine leakage is expected.

. **b.** Factors associated with urinary retention include medications, an enlarged prostate, and vaginal prolapse. Assist the patient to void when the patient first feels the urge. Assessing for residual urine will not promote voiding; rather, it will determine the volume of urine in the bladder. Cold water would cause the patient to tighten their muscles.

. **a.** The nurse palpates and auscultates over the access site, feeling for a thrill or vibration and listening for the bruit or swishing sound. Presence of the thrill and bruit are normal findings, indicating patency of the access. Decreased or absent thrill and/or bruit indicates a that there is an issue with the patency of the access, which could be a result of narrowing or clotting of the access, resulting in poor blood flow. No report of pain, redness, or swelling is a normal finding. A trace of edema is not a priority.

. **c.** Pelvic floor exercises (Kegel exercises) may help a patient regain control of the micturition. Incontinence is not a normal consequence of aging. Using absorbent products may remove motivation from the patient and caregiver to seek evaluation and treatment of the incontinence; they should be used only after careful evaluation by a health care provider. Due to risk for infection, an indwelling catheter is the last choice of treatment.

. **a.** Phenazopyridine, a urinary tract analgesic, can cause orange or orange-red urine; the nurse educates the patient to expect this change.

. **a, e, f.** Maintaining free urinary drainage is a nursing priority. Institute measures to prevent the tubing from becoming kinked and urine from backing up in the tubing. The catheter should be allowed to drain freely through tubing that is not kinked. Nursing care of a patient with a urinary sheath includes skin care to prevent excoriation. Remove the condom daily and wash the penis with soap and water, and dry it carefully. Care must be taken to fasten the sheath securely enough to prevent leakage, yet not so tightly as to constrict the blood vessels in the area. The tip of the tubing should extend 1 to 2 inches (2.5 to 5 cm) beyond the tip of the penis to prevent irritation to the sensitive glans area. Confining a patient to bedrest increases the risk for hazards of immobility.

. **b.** The smallest appropriate indwelling urinary catheter should be selected to aid in prevention of CAUTIs in the adult hospitalized patient (ANA, 2014; SUNA, 2015). The equipment used for catheterization is usually prepackaged in a sterile, disposable tray and is the same for both male and female patients. Most kits already contain a standard-sized catheter. Catheters are graded on the French (F) scale according to lumen size, with 12 to 16Fr gauge commonly used

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

(Bardsley, 2015a; Beauchemin et al., 2018; Newman, 2013). A 14F, 5-mL or 10-mL balloon is usually appropriate, unless ordered otherwise (ANA, 2014).

- **a, c, d, e.** The nurse gives these instructions to collect the midstream/clean-catch urine specimen: Wash your hands with soap and water. Open the collection cup, and place the lid face up; do not touch the inside. Separate the labia and cleanse the urinary opening with soap and water or towelettes included in the kit. Void about 1 oz. (30 mL) into the toilet, then move the collection cup close to the urinary opening and void about 1 oz (no less than 2 teaspoons) into the container. Pass the remainder of the urine into the toilet. Without touching the inside of the lid, close the cup and return it to the nurse.
- **b.** Urinary incontinence of urine past the age of toilet training is termed enuresis. Hospitalization may cause regression of toileting habits.
- **b.** Nephrotoxic medications are those capable of causing kidney damage. The nurse can assess I&O, quality of the urine, and renal function blood tests to detect this problem. Urinary frequency, incontinence, and getting up at night to void (nocturia) are not effects of nephrotoxic medications.

Bowel Elimination

Jeremy Green

Jeremy, age 4, has been attending day care since his mother returned to work 6 months ago. He presents at the hospital with a history of liquid stools, six to seven times a day, for the last 3 days.

Alberta Franklin

Alberta, age 55, has recently undergone abdominal surgery that resulted in the creation of a sigmoid colostomy. Her stoma is bright red and moist and draining semisoft brown stool. Her ostomy appliance needs to be changed.

Leroy Cobbs

Leroy, newly diagnosed with cancer, is taking acetaminophen with codeine for pain. He comes to the outpatient health center with constipation. “Nobody told me I would get so constipated,” he says. “It’s been almost a week, and I’m still not moving my bowels normally. I didn’t know anything could hurt so bad. I’ll take my chances with the cancer pain in the future rather than take more pain meds and have this happen again.”

Learning Outcomes

After completing the chapter, you will be able to accomplish the following:

. Describe the anatomy and physiology of bowel elimination.
. Identify variables that influence bowel elimination.
. Assess bowel elimination using appropriate interview questions and physical assessment skills.
. Assist with stool collection for laboratory analysis and direct and indirect visualization studies of the gastrointestinal tract.
. Diagnose actual and potential health problems and needs related to bowel elimination that may be addressed through nursing intervention.
. Describe appropriate nursing interventions to promote regular bowel habits.
. Describe appropriate nursing interventions when administering laxatives and antidiarrheals.
. Demonstrate appropriate nursing interventions when administering enemas, rectal suppositories, rectal catheters, and when performing digital removal of stool.
. Describe appropriate nursing interventions to ease defecation.
. Plan and provide nursing care for a patient with an ostomy.
. Plan, implement, and evaluate nursing care related to selected actual and potential health problems and needs associated with alterations in bowel elimination.

Valsalva maneuver

Expectations about bowel elimination, usual patterns of defecation, and the ease with which a person speaks about bowel problems differ widely among people. Although most people have experienced minor acute bouts of diarrhea or constipation, some people experience severe or chronic alterations in bowel elimination that affect their fluid and electrolyte balance, hydration, nutritional status, skin integrity, comfort, and self-concept. Moreover, many illnesses, diagnostic tests, medications, and surgical treatments can affect bowel elimination.

This chapter discusses the anatomy and physiology of bowel elimination and the factors that influence this process. A guide for assessing bowel elimination, including diagnostic studies of the gastrointestinal (GI) tract and their associated nursing responsibilities, is presented. Potential and actual health problems and needs related to bowel elimination are provided, and patient outcomes related to optimal bowel function are identified. In addition, the chapter presents nursing strategies to meet those goals. The accompanying Reflective Practice display illustrates nursing strategies addressing bowel diversions. The concluding care plan illustrates the use of specific nursing interventions to resolve bowel elimination problems and needs.

ANATOMY AND PHYSIOLOGY

The GI tract, also known as the alimentary tract or canal, extends from the mouth to the **anus**, the outlet of the GI tract. The anatomy of the GI tract is shown in Figure 39-1. The stomach and small intestine are discussed briefly. The major organ involved with bowel elimination is the large intestine, which will be discussed in greater detail.

Stomach

The stomach is a hollow, J-shaped, muscular organ located in the left upper portion of the abdomen. The stomach stores food during eating, secretes digestive fluids, churns food to aid in digestion, and pushes the partially digested food, called chyme, into the small intestine. The pyloric sphincter, a muscular ring that regulates the size of the opening at the end of the stomach, controls the movement of chyme from the stomach into the small intestine.

Small Intestine

The small intestine is about 18 to 20 ft (5.5 to 6 m) long and about 1 to 1.5 inches (2.2 to 3.8 cm) wide (Jensen, 2019). The small intestine is made up of three parts: the first is the duodenum, the middle section is the jejunum, and the distal section that connects with the large intestine is the ileum (Fig. 39-2). The small intestine secretes enzymes that digest proteins and carbohydrates. Digestive juices from the liver and pancreas enter the small intestine through a small opening in the duodenum. The small intestine is responsible for digestion of food and absorption of nutrients into the bloodstream.

Large Intestine

The connection between the ileum of the small intestine and the large intestine is the ileocecal, or ileocolic, valve. This valve normally prevents contents from entering the large intestine prematurely and prevents waste products from returning to the small intestine.

The large intestine, the primary organ of bowel elimination, is the lower, or distal, part of the GI tract. The large intestine, also known as the colon, extends from the ileocecal valve to the anus. The large intestine (colon) in adults is about 5 to 6 ft (1.5 to 1.8 m) long, but variations in length are normal (Jensen, 2019; Norris, 2020). Width also varies; at its narrowest point, the colon is about 1 inch (2.5 cm) wide; at its widest point, it is about 3 inches (7.5 cm). The diameter of the colon decreases from the cecum to the anus (see Fig. 39-2).

QSEN Reflective Practice: Cultivating QSEN Competencies

CHALLENGE TO TECHNICAL SKILLS

Although nursing students learn the steps of a psychomotor skill in the simulation practice laboratory, it is often quite a different situation when they are asked to perform the skill for the first time on their own. I found this to be true the first time that I had to perform colostomy care independently.

I met Alberta Franklin while working as a nursing extern this summer. Ms. Franklin was a 55-year-old female who had recently undergone abdominal surgery and creation of a sigmoid colostomy. They required a new colostomy bag, and I was asked to change the bag. Although care for a patient with a colostomy does not require the computerized technology found in an ICU, it does require technical skills. I had practiced changing colostomy bags in the nursing skills lab and had observed nurses changing the colostomy bag in the hospital. I had even previously changed a colostomy bag while being supervised by a nurse. Although I was not completely comfortable with the situation, I agreed to change the bag. I quickly

reviewed the steps in the protocol book and went into the patient's room. I measured the colostomy and then cut the bag to the appropriate size. Unfortunately, I had measured the colostomy incorrectly, and the bag was too large, so I had to leave the room and get more supplies. After a few more obstacles, I was able to adhere a properly fitting bag to the patient—but not before the patient correctly guessed that this was the first time I had performed this skill! Their ability to guess that I had never performed this skill before illustrates a need to improve my technical competence.

Thinking Outside the Box: Possible Courses of Action

- Refuse to provide the care and ask another nurse to change the colostomy bag.
- Observe a nurse performing the care one more time.
- Check protocol and perform the care, knowing that I could call a nurse if needed.
- "Wing it" and hope that I remember what I had learned in lab.

Evaluating a Good Outcome: How Do I Define Success?

- Patient receives safe care.
- Patient's needs are met.
- Nurse demonstrates technical competency with the skill.

Personal Learning: Here's to the Future!

I think that my actions were appropriate. Although I was unsure about my technical skills regarding colostomy care, I performed the skill adequately. In addition, I reviewed the appropriate steps, and I knew that I could summon the assistance of a nurse in case if I needed to. I also made sure that I knew where the nurse was so that if I did need help, I wouldn't waste any time looking for help. Therefore, I ensured that the patient's safety would not be compromised. Although at that time I would have preferred to have another nurse perform the colostomy change, I am glad that I completed this technical skill independently. Observing another person performing a skill can be beneficial, but there comes a point when you must "spread your wings" and complete the skill on your own. Of course, this philosophy regarding spreading your wings applies only to certain technologies: It would be inappropriate to use this philosophy if it compromised patient safety. However, in instances like this one, where patient safety is not compromised and the appropriate teaching and training have been completed, I think it is appropriate to take action. If you don't, the various skills required to care for patients can become extremely intimidating and overwhelming. As a result, fear increases, which can possibly threaten a patient's safety and lead to injury.

Elizabeth Nalli, Georgetown University

QSEN SELF-REFLECTION ON QUALITY AND SAFETY COMPETENCIES DEVELOPING KNOWLEDGE, SKILLS, AND ATTITUDES FOR CONTINUOUS IMPROVEMENT

How do you think you would respond in a similar situation? Why? What does this tell you about yourself and about the adequacy of your skills for professional practice? Do you agree with the criteria that the nursing student used to evaluate a successful outcome? Are there any other criteria that would be appropriate to use? Did the nursing student meet the criteria? Why or why not? What *knowledge, skills,* and *attitudes* do you need to develop to continuously improve the quality and safety of care for patients like Ms. Franklin?

Patient-Centered Care: How could you involve the patient as a partner in coordinating Ms. Fanklin's care to minimize frustration on the part of the patient and student? What interventions should the nursing student implement to provide care based on respect for the patient's preferences, values, and needs? What might you have done to prevent the numerous trips in and out of the patient's room? Did the nursing student's actions adhere to ethical and legal principles? If not, describe what principles were violated.

Teamwork and Collaboration/Quality Improvement: What communication skills do you need to improve to ensure that you function as a member of the patient-care team? What skills do you need to initiate requests for help and to obtain assistance when needed?

Safety/Evidence-Based Practice: What actions or behaviors by the nursing student might have provided clues to the patient that this was the nursing student's first independent attempt at the skill? What skills do you need to improve to ensure that patients in your care receive the best nursing care possible?

Informatics: Can you identify the essential information that must be available in Ms. Franklin's electronic

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

health record to support safe patient care and coordination of care? What information should be documented in the electronic health record regarding the student's assessment and interventions? Can you think of other ways to respond to or approach the situation?

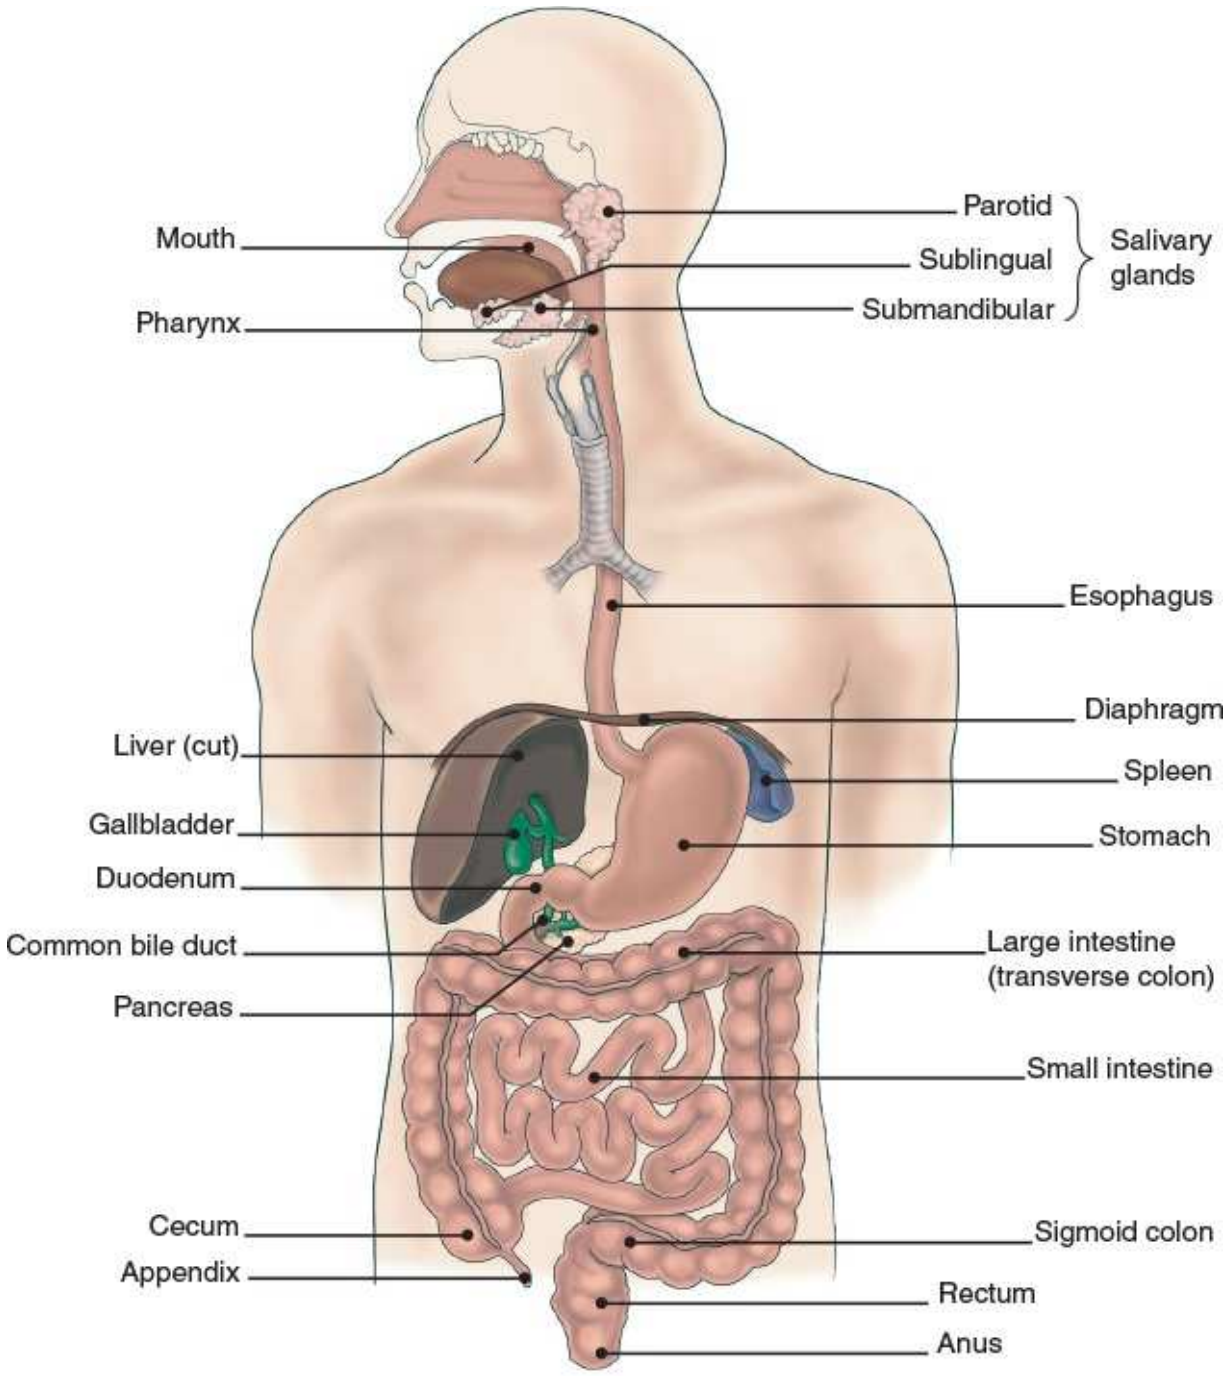

FIGURE 39-1. Organs of the gastrointestinal tract.

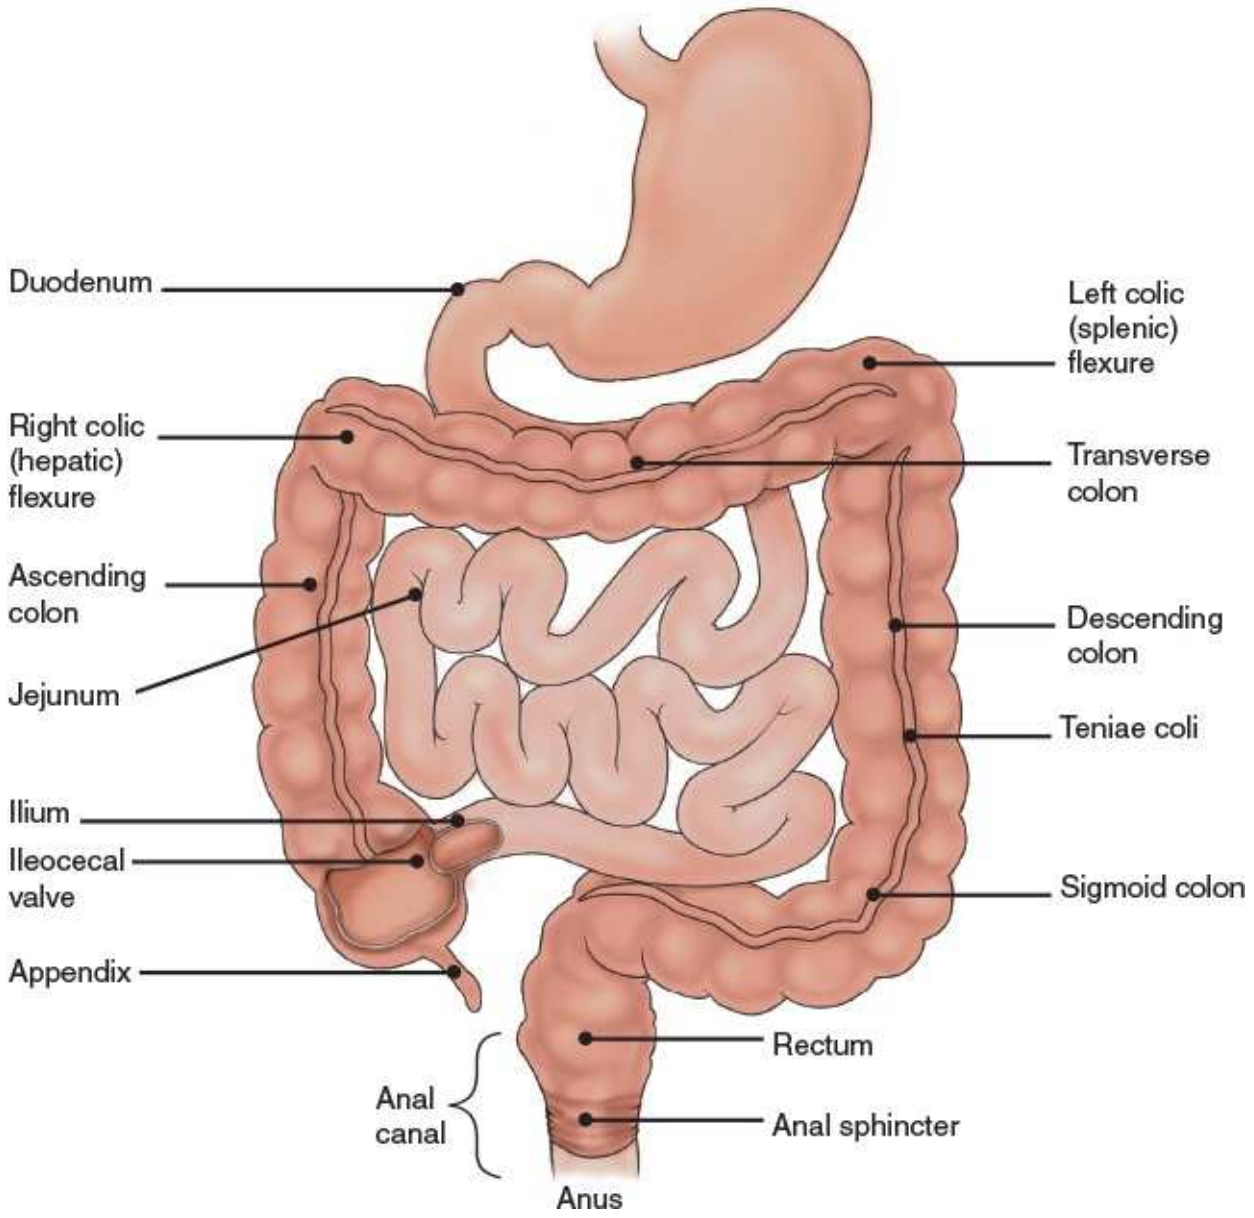

FIGURE 39-2. The small and large intestines.

From the cecum, the first part of the large intestine, the digestive contents enter the colon, which consists of several segments. The ascending colon extends from the cecum upward toward the liver, where it turns to cross the abdomen. This turn is called the hepatic flexure. Upon turning, this portion of the colon becomes the transverse colon, crossing the abdomen from the right to the left. The colon then turns at the splenic flexure to become the descending colon. The descending colon passes down the left side of the body to the sigmoid, or pelvic, colon.

The sigmoid colon contains **feces**, solid waste products that have reached the distal end of the colon and are ready for excretion. Once excreted, feces are called **stool**. The sigmoid colon empties into the rectum, the last part of the large intestine. The rectum is about 5 inches (12 cm) and includes the anal canal. In the rectum, three transverse folds of tissue are present that may help to hold the fecal material in the rectum temporarily. Vertical folds also are present, each of which contains an artery and a vein. If the veins become abnormally distended, **hemorrhoids** occur.

The rectum is empty except immediately before and during **defecation** (the process of bowel elimination; a bowel movement). Feces are excreted from the rectum through the anal canal, which is approximately 1 to 1.5 inches (2.5 to 3.8 cm) long, and out through an opening called the anus.

Functions of the large intestine include the absorption of water, the formation of feces, and the expulsion of feces from the body. Bacteria that reside in the large intestine act on food residue while it makes its way through the large intestine. Bacterial action produces vitamin K and some of the B-complex vitamins. The products of digestion, chyme, move from the small intestine, passing through the ileocecal valve, and enter the cecum. Approximately 1,500 mL of chyme enters the large intestine daily. Its contents are liquid or watery. While passing through the large intestine, most water is absorbed. About 1.5 L of liquid is absorbed daily by the intestinal tract (Kiela & Ghishan, 2016), allowing for the formed, semisolid consistency of the normal stool. When absorption does not occur properly, such as when the waste products pass through the large intestine rapidly, the stool is soft and watery. Conversely, if the stool remains in the large intestine too long, or if too much water is absorbed, the stool becomes dry and hard.

Recall **Alberta Franklin**, the woman who had surgery that resulted in the creation of a sigmoid colostomy.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

Knowledge of normal GI function would help the nurse in developing a teaching plan for this patient about the ostomy and what to expect in relation to bowel function.

Nervous System Control

The autonomic nervous system innervates the muscles of the colon. The parasympathetic nervous system stimulates movement, while the sympathetic system inhibits movement. Contractions of the circular and longitudinal muscles of the intestine, **peristalsis**, move waste products along the length of the intestine continuously (Fig. 39-3). Mass peristaltic sweeps occur several times a day in most people, propelling the fecal mass forward. Mass peristalsis often occurs after food has been ingested, accounting for the urge to defecate that often occurs after meals. Timing nursing interventions to evacuate bowel contents with this natural urge to defecate is helpful. Normal colonic transit time is 24 to 28 hours (Norris, 2020).

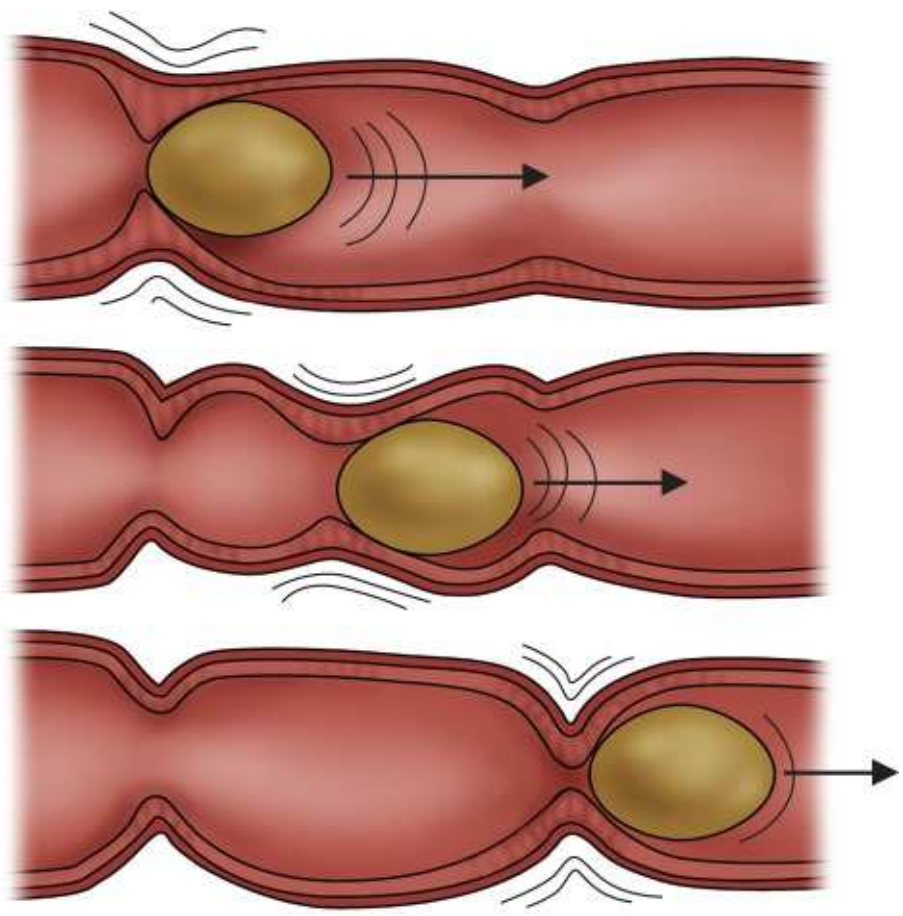

FIGURE 39-3. Peristaltic movements in the intestine.

After passing through the sigmoid colon, the waste products enter the rectum, where they are stopped from exiting by the anal sphincters (Fig. 39-4). The internal sphincter in the anal canal and the external sphincter at the anus control the discharge of feces and **flatus** (intestinal gas). The internal sphincter consists of involuntary smooth muscle tissue that is innervated by the autonomic nervous system. Motor impulses are carried by the sympathetic system (thoracolumbar) and inhibitory impulses by the parasympathetic system (craniosacral). These two divisions of the autonomic nervous system function antagonistically in a dynamic equilibrium. The external sphincter at the anus has striated muscle tissue and is under voluntary control. The levator ani muscle reinforces the action of the external sphincter and is controlled voluntarily.

Defecation

Defecation refers to the emptying of the large intestine. Two centers govern the reflex to defecate, one in the medulla and a subsidiary one in the spinal cord. When parasympathetic stimulation occurs, the internal anal sphincter relaxes and the colon contracts, allowing the fecal mass to enter the rectum.

The rectum becomes distended by the fecal mass, the primary stimulus for the defecation reflex. Rectal distention leads to an increase in the intrarectal pressure, causing the muscles to stretch and thereby stimulating the defecation reflex and subsequently the urge to eliminate.

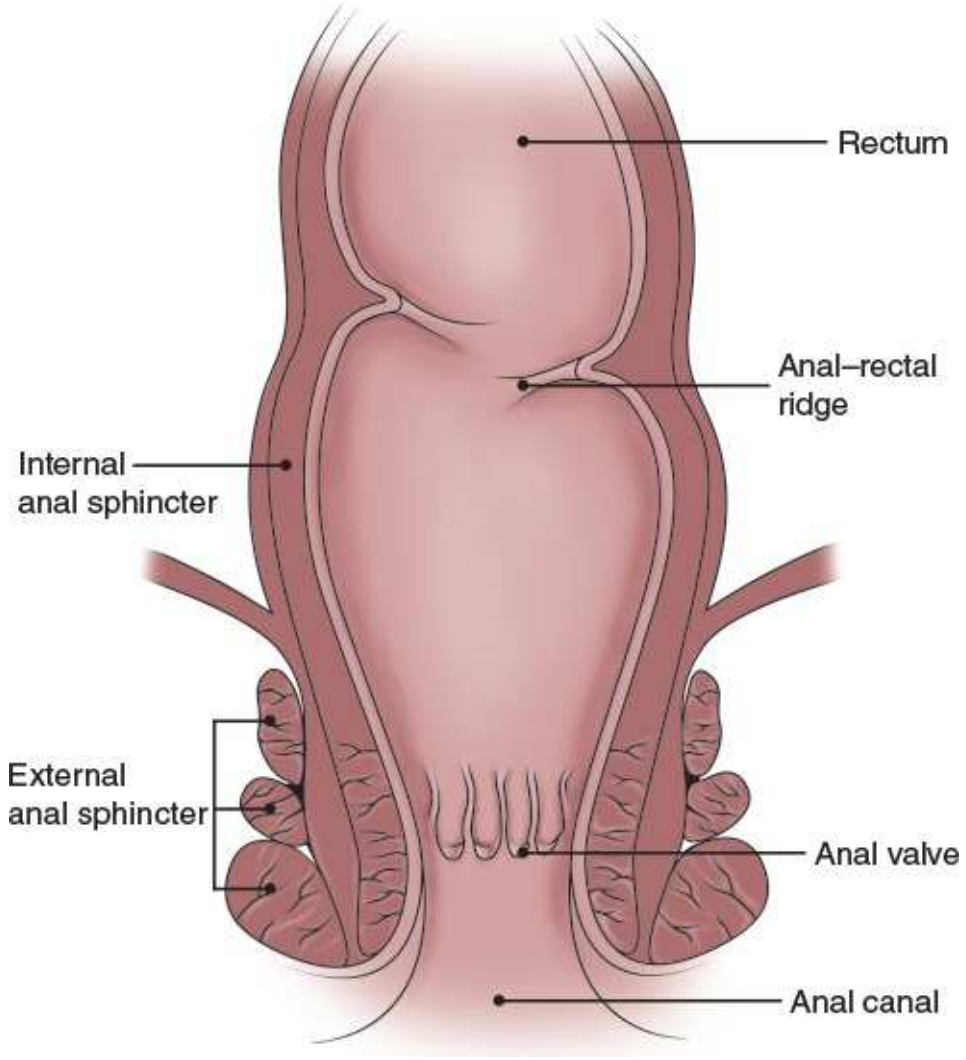

FIGURE 39-4. Interior view of the rectum and anal canal.

The external anal sphincter, which is under voluntary control, is constricted or relaxed at will. During the act of defecation, several additional muscles aid in the process. Voluntary contraction of the muscles of the abdominal wall by holding one's breath, contracting the diaphragm, and closing the glottis increases intraabdominal pressure up to four or five times the normal pressure, which helps expel feces. Simultaneously, the muscles on the pelvic floor contract and aid in expulsion of the fecal mass. Defecation is eased by flexing the thigh muscles, which increases abdominal pressure, and by the sitting position, which increases downward pressure on the rectum. If the urge to defecate is ignored, defecation often can be delayed voluntarily by contracting the external anal sphincter and pelvic floor muscles.

When a person bears down to defecate, the increased pressures in the abdominal and thoracic cavities result in decreased blood flow to the atria and ventricles, thus temporarily lowering cardiac output. Once bearing down ceases, the pressure is lessened, and a larger-than-normal amount of blood returns to the heart. This act may cause the heart rate to slow (vagal response) and result in syncope in some patients (Hinkle et al., 2022). Therefore, this action of bearing down, termed the **Valsalva maneuver**, may be contraindicated in people with cardiovascular problems and other illnesses.

The act of defecation is usually painless. If the bowels move at regular intervals and the stools are formed and soft, functional problems involving frequency of elimination seldom occur. Many people become concerned if they do not have a daily bowel movement. However, normal elimination patterns can vary widely among people. Although many adults pass one stool each day, other healthy people have more frequent or less frequent bowel movements. Some people have a bowel movement two or three times a week; others, two or three times a day.

FACTORS AFFECTING BOWEL ELIMINATION

Various factors can affect bowel elimination. Interference with the normal functioning of elimination from the intestines can occur in health as well as during illness. Elimination can be affected by a person's developmental stage, daily patterns, the amount and quality of fluid or food intake, the level of activity, lifestyle, emotional states, pathologic processes, medications, and procedures, such as diagnostic tests and surgery.

Developmental Considerations

Age affects what a person eats and the body's ability to digest nutrients and eliminate wastes. The stools of an infant are markedly different from those of an older adult. Because patients are often reluctant to discuss their bowel habits and stool characteristics, nurses need to be familiar with bowel concerns pertinent to each developmental group.

Infant

The stool characteristics depend on whether the infant is being fed breast milk or formula. Breast milk is easier for the infant's intestines to break down and absorb. Breastfed babies have more frequent stools; the stools are yellow to golden and loose, and usually have little odor. The stools of formula-fed infants vary from yellow to brown, are paste-like in consistency, and have a stronger odor because of the decomposition of protein. The stools of both breastfed and formula-

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

fed infants may have curds and mucus. Infants have no voluntary control over bowel elimination.

The number of stools infants pass varies greatly. For example, breastfed infants can pass from 2 to 10 stools daily, whereas bottle-fed infants typically pass 1 or 2 stools daily. At age 1 year, all infants commonly pass 1 or 2 stools a day. Parents may mistakenly interpret the infant's liquid stool as **diarrhea**. Diarrhea is an increase in frequency, and/or a change in consistency of stools (passage of three or more stools a day) (Dunlap & Patterson, 2020; Kyle & Carman, 2021). True diarrhea requires evaluation. Some children have bowel movements only once every 2 to 3 days. Teach parents that as long as the stools are soft, the child is not constipated (Kyle & Carman, 2021). **Constipation** (dry, hard stool; infrequent difficult passage of stool; and/or the incomplete passage of stool) should be reported to the infant's health care provider (Kyle & Carman, 2021). Constipation not related to a health issue is often initially managed with dietary manipulation, such as increased fiber and fluids (Kyle & Carman, 2021).

The consistent use of suppositories and laxatives is discouraged. Infants with persistent constipation require evaluation for structural defects.

Toddler

Between ages 18 and 24 months, the nerve fibers innervating the internal and external anal sphincters become fully developed, at which point voluntary control of defecation becomes possible. Voluntary defecation requires intact muscular, sensory, and nervous structures. Successful bowel training also includes awareness by the toddler of the need to defecate, the ability to communicate this need, the wish to please the significant person involved in bowel training, and praise and reinforcement for the toddler's successful behavior. Daytime bowel control is normally attained by 30 months of age, but the age varies with each child.

Assessment of a child's readiness for toilet training includes (AAP, n.d.; Kyle & Carman, 2021):

- Ability to indicate wants and needs verbally
- Motor skills to sit on and rise from the potty chair
- Showing an interest in the potty
- Willingness to follow instructions

Help parents to understand that physiologic maturity is the first priority for successful bowel training. Discourage the use of punishment or shame for a lack of readiness to become toilet-trained or for elimination accidents. Cultures approach toilet training differently. In some cultures, toilet training begins before the child is 1 year old; in other cultures, it may not be considered until the child is near 5 years old. It is important to recognize cultural influences on this parenting responsibility while promoting flexibility. Reassure parents that any regression of toileting skills that occurs during a child's illness or hospitalization is to be expected and is usually short-lived.

School-Age Child, Adolescent, and Adult

From childhood into adulthood, defecation patterns vary in quantity, frequency, and rhythmicity. Many people worry needlessly about normal stool characteristics or bowel habits; others may not understand the significance of changes in bowel habits. Emphasize that the use of over-the-counter laxatives and enemas can have serious consequences and that any problems prompting such use need to be evaluated. Irritable bowel syndrome (IBS), which is common in the adult population, can present with constipation, diarrhea, or alternating bouts of both (Norris, 2020). The symptoms may be brought on by diet and psychological and physiological stress (Norris, 2020).

Focus on the Older Adult

NURSING STRATEGIES TO ADDRESS AGE-RELATED CHANGES AFFECTING BOWEL ELIMINATION

Age-Related Changes	Nursing Strategies
Slowing of GI motility with increased stomach-emptying time	• Encourage small, frequent meals. • Discourage heavy activity after eating. • Encourage a high-fiber, low-fat diet. • Encourage adequate fluid intake. • Discourage regular use of laxatives. • Develop a daily routine to move bowels. The optimal time is usually 2 hours after awakening and after breakfast. • Evaluate medication regimen for possible adverse effects.
Decreased muscle tone/incontinence	• Provide easy access to the bathroom. • Use assistive devices when necessary (raised toilet seat, grab bars, walker). • Ensure safety when ambulating (e.g., skid-proof

	slippers). • Encourage participation in a bowel-retraining program.
Weakening of intestinal walls with greater incidence of diverticulitis	• Encourage a high-fiber diet and adequate fluid intake. • Teach patients not to ignore the urge to have a bowel movement. • Encourage regular exercise.

Older Adult

Constipation is often a chronic problem for older adults. Peristalsis is slowed (Touhy & Jett, 2018). The rectal receptors in older adults have a decreased response to stretching, which can lead to a decreased urge to move the bowels despite a large amount of stool in the rectum (Mounsey et al., 2015). However, these changes usually do not cause problems with defecation; constipation is not a normal part of aging (Touhy & Jett, 2018). Constipation is more often a side effect of medications, life habits, immobility, inadequate fluid intake and lack of attention to the urge to defecate (Pont et al., 2019; Touhy & Jett, 2018). Diarrhea, **fecal impaction** (prolonged retention or an accumulation of fecal material that forms a hardened mass in the rectum), or **fecal incontinence** (involuntary or inappropriate passing of stool or flatus) can also result from physiologic or lifestyle changes. See the accompanying Focus on the Older Adult box.

Daily Patterns

Most people have individual patterns of bowel elimination involving frequency, timing considerations, position, and place. Changes in any of these patterns may upset a person's routine and lead to constipation. For example, many people defecate after breakfast, when the gastrocolic and duodenocolic reflexes cause mass propulsive movements in the large intestine. If this urge to defecate is ignored because the person finds the time or place inconvenient, the feces remain in the rectum until the defecation reflex is initiated again. Meanwhile, water continues to be absorbed from the unexpelled feces, which makes the stool dry, hard, and painful to pass.

In order to defecate, most people assume the squatting or slightly forward-sitting position with the thighs flexed. In either position, increased pressure is placed on the abdomen, as well as downward pressure on the rectum; both facilitate defecation. Obtaining the same results when seated on a bedpan is difficult. Embarrassment may further inhibit defecation. In addition, for most people, defecation is a private affair experienced easily only in the comfort of their own bathroom. Defecation may be difficult in a shared health care facility room with only a curtain for privacy.

Food and Fluid

Both the type and the amount of foods eaten and the amount of fluids ingested affect elimination. A high-fiber diet of 25 to 38 g of fiber (USDA & USDHHS, 2020) and a daily fluid intake of at least 2,000 mL (Academy of Nutrition and Dietetics, 2020, as cited in Dudek, 2022) facilitate bowel elimination. High-fiber foods, such as whole grains and bran, dried peas and beans, and fresh fruits and vegetables, increase the bulk in fecal material. Bulkier feces increase the pressure on the intestinal wall, which serves as a stimulus for peristalsis. As a result, feces move more quickly through the colon, allowing less time for water to be reabsorbed. Subsequently, the stool is soft and easy to pass.

People digest and tolerate foods differently. Food intolerance may alter bowel elimination, possibly resulting in diarrhea, gaseous distention, and cramping. For example, people who lack the enzyme lactase, which helps to break down the simple sugar lactose found in milk and milk products, cannot digest milk; this is called lactose intolerance. These people often experience excessive intestinal gas and diarrhea when they ingest milk, as the small intestine pulls fluid into the bowel through osmosis to assist in moving the dairy product out of the body.

Activity and Muscle Tone

Regular exercise improves GI motility and muscle tone, whereas inactivity decreases both. Adequate tone in the abdominal muscles, the diaphragm, and the perineal muscles is essential for ease of defecation. Patients on prolonged bedrest and those with decreased mobility are prime candidates for constipation (Norris, 2020).

Lifestyle

Many individual, family, and sociocultural variables influence a person's usual elimination habits. The long-term effects of bowel training may result in a person's (1) acceptance of bowel elimination as a normal life process, (2) preoccupation with bowel elimination, or (3) feeling that bowel elimination is a "dirty" process. Rituals associated with bowel elimination, cleanliness considerations, the language used to talk about bowel elimination or reluctance to discuss it, individual responses to involuntary passage of flatus (gas), and so on, vary widely among people. A person's daily schedule, occupation, and leisure activities may contribute to a habit of defecating at regular times or to an irregular pattern. Nurses who role model good health behaviors are more effective teachers. Use the Promoting Health 39-1 display for yourself before using it with others.

Promoting Health 39-1

BOWEL ELIMINATION

Use the assessment checklist to determine how well you are meeting your needs related to bowel elimination. Then develop a prescription for self-care by choosing appropriate behaviors from the list of suggestions.

Assessment Checklist

☐ almost always ☐ sometimes ☐ almost never

☐	☐	☐	1. I have a regular bowel elimination pattern, satisfactory to support comfort and activities of daily living.
☐	☐	☐	2. I eat a diet high in fiber.
☐	☐	☐	3. I exercise regularly.
☐	☐	☐	4. I have an adequate intake of fluids.

Self-Care Behaviors

1. Normal defecation patterns differ in each person. It does not matter how often someone moves their bowels as long as the stool is soft and passes easily. Eat a balanced diet, including high-fiber foods, such as fruits, vegetables, and nuts.
2. Follow a regular exercise program to engage in activity that requires moderate effort, such as brisk walking for a total of 2 ½ hours or more a week.
3. Do not ignore the urge to defecate.
4. Establish a routine, if needed (1 hour after meals is usually best).
5. Avoid prolonged use of over-the-counter medications or enemas to treat constipation.
6. Drink at least 2,000 mL of water per day if approved by your health care provider.
7. Seek medical assistance for any change in the characteristics of or presence of blood in the stool.

Information to promote effective bowel elimination, such as information about elimination problems, fecal incontinence, and GI diseases, is available online.

Psychological Variables

Psychological stress affects the body in many ways. In some people, anxiety seems to have a direct effect on GI motility, and diarrhea accompanies periods of high anxiety. In the fight-or-flight response, when the body mobilizes itself for intense action, blood is shunted away from the stomach and intestines, resulting in a slowing of GI motility. People who chronically worry and those with certain personality types who tend to hold onto problems and negative feelings may experience frequent constipation.

Pathologic Conditions

Numerous pathologic processes may change a person's usual bowel elimination habits. Changes in stool characteristics or frequency may be one of the first clinical manifestations of a disease. For example, when a patient reports stool has become narrower or ribbon-like, a tumor may be obstructing normal stool passage through the colon (Colon Cancer Coalition, n.d.). Similarly, a parent's report that a child's stools are frequent, bulky, greasy, and foul smelling suggests cystic fibrosis. This requires further evaluation and consultation with a health care provider, especially if other clinical manifestations are present.

Medications may also influence the appearance of the stool for a variety of reasons. Any drug with the potential to cause GI bleeding (e.g., anticoagulants, aspirin products) may cause the stool to appear pink to red to black (Karch, 2020). Iron salts result in a black stool from the oxidation of iron (MFMER, 2020a). Bismuth subsalicylate used to treat diarrhea can also cause black stools (MFMER, 2020a). Antidiarrheals may cause a white discoloration or speckling in the stool (MFMER, 2020a). Antibiotics may cause a green-gray color related to impaired digestion.

Diarrhea and constipation may also be a sign of potential disease processes. Diarrhea or constipation may result from pathologic conditions such as diverticulitis (inflammation and/or infection of a diverticulum, a small, bulging pouch in the colon) (Dunlap & Patterson, 2020). Diarrhea may result from bacterial and viral infection, malabsorption syndromes (the inability of the digestive system to absorb one or more of the major vitamins, minerals, or nutrients), neoplastic diseases (tumors), diabetic neuropathy (damage to nerve cells), hyperthyroidism, and chemotherapy (Dunlap & Patterson, 2020; Dunlap, 2021).

Outbreaks of food poisoning can result in severe GI symptoms, including diarrhea. For example, infections caused by certain types of *Escherichia coli,* particularly dangerous for young children (age <10 years) and older adults, can progress quickly to life-threatening hematologic and renal complications (MFMER, 2020b). Severe abdominal cramping

followed by watery or bloody diarrhea may signal a microbial infection, which can be confirmed by a stool sample. Supportive treatment, careful monitoring, and attentive nursing care are essential.

Constipation may be the result inadequate fiber in the diet, a change in lifestyle (e.g., lack of exercise), poor fluid intake, and ignoring or delaying the urge to defecate (Bauldoff et al., 2020). Constipation may also occur as a result of metabolic, neurologic, or psychological disorders, such as diseases within the colon or rectum (e.g., tumors), IBS, and injury to, or degeneration of, the spinal cord (Bauldoff et al., 2020). Medications, such as opioid analgesics and calcium-channel blockers, may also cause constipation (Bauldoff et al., 2020; Mitchell, 2019a). Changes in color, contents, odor, and appearance of stool may be related to conditions that traumatize the stomach or intestines, or that interfere with normal digestion. As a result, evaluation of stool may be an important component of the assessment of a patient (Mitchell, 2019a).

Intestinal obstruction occurs when the normal flow of intestinal contents through the intestinal tract is inhibited or blocked (Bauldoff et al., 2020). Mechanical obstructions result from pressure on the intestinal walls. Common causes of mechanical obstruction are tumors of the colon or rectum, diverticulum, adhesions from scar tissue, stenosis, strictures, and hernia and volvulus (twisting of a part of the colon). Nonmechanical (or functional) obstructions result from an inability of the intestinal musculature to move the contents through the bowel. Examples of causes of nonmechanical obstruction include diseases that weaken or paralyze the intestinal walls such as muscular dystrophy, diabetes mellitus, and Parkinson disease. Manipulation of the bowel during surgery may also result in paralytic ileus, a nonmechanical obstruction (Bauldoff et al., 2020). The effects of surgery are further detailed later in the chapter.

Medications

Medications are available that can promote peristalsis (**laxatives**) or inhibit peristalsis (antidiarrheal medications) (Karch, 2020). These are discussed later in the chapter. There are also other types of medications that may affect bowel elimination and stool characteristics. Opioids are a common cause of medication-induced constipation and can result in significant distress for the patient. The enteric neurons control major body functions such as bowel control. Opioid-binding receptors are found in the enteric neurons in the GI tract. The binding of the opioid to these receptor sites interrupts peristalsis, causing slowed movement of stool through the colon, resulting in increased reabsorption of fluid in the large intestine. Antacids containing aluminum, iron sulfate, and anticholinergic medications also decrease GI motility, with the potential to also cause constipation.

Remember **Leroy Cobbs**, the patient described at the beginning of the chapter who developed severe constipation resulting from the opioid analgesic used to control the cancer pain. Had the possible adverse effects of opioids been addressed in the patient's medication teaching plan when the drug was first prescribed, the risk for constipation could have been reduced. In addition, the teaching plan could have addressed measures to counteract the effects of the medication.

Many medications can cause diarrhea as a side effect. For example, diarrhea is a potential adverse effect of treatment with antibiotics such as amoxicillin clavulanate. In this situation, using antidiarrheal drugs is not recommended because its use would prolong the exposure of the intestinal mucosa to the irritating effect of the antibiotic. Medications with magnesium, such as over-the-counter antacids, can also cause diarrhea. Metformin, a common medication used to treat type 2 diabetes mellitus, can cause diarrhea. The resulting diarrhea can often become bothersome or severe enough with these and other medications that the drugs may need to be discontinued.

Because antibiotics are used so extensively in the health care setting, many patients are at risk for infection with *Clostridioides difficile (C. difficile)* (formerly known as *Clostridium difficile),* a health care–associated infection (HAI) (CDC, 2020a; Ragusa et al., 2018). When a patient is receiving treatment with broad-spectrum antibiotics, there is a disruption in the normal intestinal flora, allowing the microorganism to flourish within the intestine. *C. difficile* causes intestinal mucosal damage and inflammation, resulting in diarrhea and abdominal cramping. *C. difficile* spores are shed in feces and are relatively resistant to disinfectants. These microorganisms can be spread on the hands of health care providers after contact with equipment or surfaces contaminated with the microorganism. It is important to institute contact precautions for infected patients. Consider environmental surfaces and items close to the patient, such as the side rails and overbed table, to be contaminated. The use of gloves and gowns for every patient encounter, even short care intervals, is important to prevent the spread, as well as hand hygiene using soap and water (CDC, 2020b). Gloves are important because hand sanitizer doesn't kill *C. difficile* and handwashing might not be sufficient (CDC, 2020b).

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

Intensified environmental cleaning on a daily basis and upon patient discharge or transfer is required (CDC, 2020b).

Diagnostic Studies

Diagnostic studies may affect a patient's usual bowel elimination pattern. For example, patients may need to fast for diagnostic studies. The ingestion of barium during diagnostic procedures, such as a barium enema, may result in constipation or impaction if it is not completely eliminated after the procedure. In addition, the stress of hospitalization and waiting for the results of studies, combined with changes in food intake, can severely alter a patient's usual elimination patterns. The bowel preparation used for bowel cleansing before certain diagnostic studies of the GI tract can interfere with the normal timing of a patient's bowel movements. Refer to Table 39-2 in the Teaching About Laxatives section for additional information related to the use of laxatives.

Surgery and Anesthesia

Direct manipulation of the bowel during abdominal surgery inhibits peristalsis, causing a condition termed postoperative **paralytic ileus** (Bauldoff et al., 2020). This temporary stoppage of peristalsis normally lasts 3 to 5 days. Many times, the patient is receiving opioids for pain relief, which can exacerbate the situation. If this condition persists, distention and symptoms of acute obstruction may occur, possibly resulting in the need for surgical intervention. Inhaled general anesthetic agents also inhibit peristalsis by blocking the parasympathetic impulses to the intestinal musculature. However, local and regional anesthetics have little effect on peristalsis.

NURSING PROCESS FOR BOWEL ELIMINATION

Assessing

Assessment of the GI tract and bowel elimination includes pertinent patient history, physical assessment, and diagnostic studies.

Nursing History

Patients may be reluctant to initiate a conversation about their bowel status, so include pertinent bowel elimination questions in each comprehensive nursing history. The accompanying Focused Assessment Guide 39-1 provides some appropriate questions for health history assessment related to bowel elimination. If the patient is experiencing any disturbance in bowel elimination, conduct a more detailed assessment, directing attention to the factors described earlier that may influence bowel elimination.

Patients who are critically ill or who have impaired cognition may be incapable of reporting their bowel status accurately. Record the patient's daily bowel status to look for clues to impending problems. While making daily rounds, ask patients who can give reliable answers when they moved their bowels last and chart the response. If the patient cannot provide this information, the nurse or ancillary staff who assists the patient with bowel elimination records any bowel movement.

Physical Assessment

Examination of the abdomen is discussed in Chapter 27. Refer to this chapter for details and additional information related to the assessment of the GI system. An overview of examination techniques that may be helpful when assessing the functioning of the GI tract is described here.

ABDOMEN

The sequence for abdominal assessment proceeds from inspection, auscultation, and percussion to palpation. Inspection and auscultation are performed before palpation because palpation may disturb normal peristalsis and bowel motility. Advanced health care providers usually perform percussion of the abdomen, as this is an advanced assessment skill. Place the patient comfortably in the supine position with the abdomen exposed, the chest and pubic area draped, and the knees slightly flexed. Encourage the patient to urinate prior to the examination so that the bladder is empty.

Focused Assessment Guide 39-1

BOWEL ELIMINATION

Factors to Assess	Questions and Approaches
Usual patterns of bowel elimination	How often do you move your bowels? Any special time of the day? What does your stool look like? • Frequency

	• Time of day • Description of usual stool characteristics (amount, consistency, shape, color, odor) • Do you ever have to strain to move your bowels? • Have you ever had to remove hard stool with your finger to help you move your bowels?
Aids to elimination	Do you use anything to help move your bowels? • Natural aids (liquids, food) • Pharmacologic aids (laxatives) • Enemas
Recent changes in bowel elimination	Have you noticed any changes in your stool recently? Have you noticed any change in the color of your stool? Have you noticed any blood in your stool? (May need to ask patient about color blindness.) Have you noted a difference in the appearance of your stool (narrowing, presence of mucus)?
Problems with bowel elimination	Are your bowels causing you any problem now? • Nature of disturbance • Onset and frequency • Causes (*physical:* food and fluid intake, exercise status, history of surgery or illnesses influencing GI tract; psychosocial; medicine related) • Severity • Symptoms • Interventions attempted and results
Presence of a bowel diversion (normal routine, history of problems)	What is your usual routine with your colostomy or ileostomy? Do you have any problems caring for your colostomy or ileostomy? Are there activities you are no longer able to perform because of your colostomy or ileostomy?

Inspection

Observe the contour of the abdomen, noting any masses, scars, or areas of distention. Significant findings may include the presence of asymmetry, swelling, distention (inflation) or protrusion (projection).

Auscultation

Traditionally, bowel sounds are assessed in all four quadrants of the abdomen. Using the diaphragm of a warmed stethoscope, listen for bowel sounds in all abdominal quadrants, using a systematic, clockwise approach. Listen carefully for bowel sounds (gurgles and clicks) and note their frequency and character (usually occur at a rate of 5 to 34 per minute) (Bickley et al., 2021). Current evidence suggests bowel sounds radiate widely over the abdomen and listening in all four quadrants is not necessary; assessment of presence and hypoactivity (decreased; <5/minute)/hyperactivity (increased; >34/minute) is sufficient (Bickley et al., 2021; Jarvis & Eckhardt, 2020). Before deciding that bowel sounds are absent, listen in the epigastric and umbilical area of the abdomen for 2 minutes or longer (Bickley et al., 2021). If the patient has a nasogastric (NG) tube in place, disconnect it from suction during this assessment to allow for accurate interpretation of sounds. Keep in mind that the timing of the patient's most recent meal or a full bladder may also affect the examination.

Significant findings include decreased (hypoactive) bowel sounds; increased (hyperactive) bowel sounds; and absent bowel sounds. Decreased bowel sounds indicate diminished bowel motility, common following abdominal surgery or associated with peritonitis or late bowel obstruction (Bickley et al., 2021; Jarvis & Eckhardt, 2020). Increased bowel sounds indicate increased bowel motility, commonly caused by diarrhea, gastroenteritis, or early/partial bowel obstruction (Jarvis & Eckhardt, 2020).

Palpation

Perform light palpation in each quadrant. Watch the patient's face for nonverbal signs of pain during palpation. Palpate each quadrant in a systematic manner, noting muscular resistance, tenderness, enlargement of the organs, or masses. If the patient reports abdominal pain, palpate the area of pain last. If the patient's abdomen is distended, note the presence of firmness or tautness.

ANUS AND RECTUM

Perform a superficial examination each time you wash a patient's anal area or assist with bowel evacuation. The nurse's skill level determines the extent of further rectal examination. Advanced practice professionals usually conduct physical assessments of the rectum and anus. Refer to a health assessment text for details.

Inspection is used to assess the anal area, which normally has increased pigmentation and some hair growth. Assess for lesions, ulcers, **fissures** (linear break on the margin of the anus), inflammation, and external hemorrhoids (dilated veins appearing as reddened protrusions). Ask the patient to bear down as though having a bowel movement. Assess for the appearance of internal hemorrhoids or fissures. Normally, there is no protrusion of tissue. Inspect the perineal area for areas of skin irritation or breakdown secondary to diarrhea or fecal incontinence.

Stool Characteristics

Nurses are responsible for observing and recording information about the patient's stool. Table 39-1 describes the

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

characteristics of a normal stool, along with special considerations used when observing a stool. Report and record anything unusual, including the passage of little or no gas or unusual amounts of gas.

Note and record, usually in the patient's health record, the frequency, amount, and characteristics of the patient's bowel movements. Describe any additional unusual observations, such as lightheadedness or straining. When assistive personnel or the patient assumes this responsibility, check with the patient and health record at regular intervals to see that the recording is accurate.

Ideally, populations at high risk for bowel elimination problems are identified before problems occur, and such problems are prevented or minimized through vigilant health care. For example, early colorectal cancer usually has no symptoms. Warning signs typically occur with more advanced disease. Refer to Box 39-1, Warning Signs of Colorectal Cancer. For this reason, encourage patients to schedule regular exams with their health care providers. Reinforce the importance of adhering to recommended screening for colorectal cancer, including sigmoidoscopy, colonoscopy, and fecal testing for blood. The American Cancer Society (www.cancer.org) provides guidelines for screening for patients at various risk levels for colorectal cancer.

Box 39-1 Warning Signs of Colorectal Cancer

- Rectal bleeding
- Persistent change in the bowel elimination pattern or consistence of the stool
- Blood in the stool
- Persistent cramping or pain in the lower abdomen or gas
- A feeling that the bowel doesn't empty completely after having a bowel movement
- Weakness or fatigue
- Losing weight without trying

Unfolding Patient Stories: Marvin Hayes • Part 1

Marvin Hayes, a 43-year-old male, is being seen at the clinic. He has a family history of colorectal cancer. What questions can the nurse ask to identify disturbances in bowel elimination? What are the signs and symptoms of colon and rectal cancer? What patient education would the nurse provide when orders are written to obtain a stool sample and schedule a colonoscopy? (Marvin Hayes' story continues in Chapter 42.)

Care for Marvin and other patients in a realistic virtual environment: *vSim for Nursing* (thepoint.lww.com/vSimFunds). Practice documenting these patients' care in DocuCare (thepoint.lww.com/DocuCareEHR).

Diagnostic Studies

The nurse is often responsible for caring for patients with elimination problems who are undergoing diagnostic testing. Specific guidelines for the nurse's role in stool collection and direct and indirect visualization studies follow.

STOOL COLLECTION

The nurse is responsible for obtaining the specimen according to facility procedure, labeling the specimen, and ensuring that the specimen is transported to the laboratory in a timely manner. The institution's policy and procedure manual or laboratory manual identifies specific information about the amount of stool needed, the time frame during which stool is to be collected, and the type of specimen container to use.

Always wear disposable gloves when any contact or handling of a stool specimen is likely. Hand hygiene before and after glove use is essential. Also, take care not to contaminate the outside of the specimen container with stool. Package, label, and transport specimens according to facility policy to ensure that no leakage of the specimen occurs. Patients may need specific instructions about collecting a stool specimen. It is important that health literacy is assessed, and the terms used regarding the bowel movement are familiar to the patient. For example, many patients may not understand the term "stool." Patients may be embarrassed to ask questions, so it is important the nurse

communicates the instructions in a manner which the patient understands (Cinar et al., 2014). Instructions may include the following:

Table 39-1 Normal Characteristics and Special Considerations for Observation of Stool

CHARACTERISTIC	NORMAL FINDING	SPECIAL CONSIDERATIONS FOR OBSERVATION
Volume	Variable	The volume of the stool depends on the amount the person eats and the nature of the diet. For example, a diet high in roughage produces more feces than a soft, bland diet. Consistently large diarrheal stools suggest a disorder in the small bowel or proximal colon; small, frequent stools with urgency to pass them suggest a disorder of the left colon or rectum.
Color	Infant: Yellow to brown Children and adult: Brown	The brown color of the stool is due to stercobilin, a bile pigment derivative. The rapid rate of peristalsis in the breastfed infant causes the stool to be yellow. Black stool can be as a result of intestinal bleeding. Melena, which is a thick, black, tarry stool, is caused by upper GI bleeding. The black color comes from the changes of hemoglobin during the digestive process. Bleeding low in the intestinal tract or from inflamed hemorrhoids or fissures can result in fresh blood in the stool. The color of the stool can also be influenced by diet. For example, the stool could be dark if the person eats red meat and dark-green vegetables, such as spinach. The stool will be light brown if the diet is high in milk and milk products and low in meat. The absence of bile may cause the stool to appear white or clay-colored. Certain drugs influence the color of the stool. For example, iron salts and bismuth subsalicylate can cause the stool to be black. Antacids cause it to be whitish. The stool darkens with standing.
Odor	Pungent; may be affected by foods ingested	The characteristic odor of the stool is due to indole and skatole, caused by putrefaction and fermentation in the lower intestinal tract. The odor of the stool is influenced by its pH value, which normally is neutral or slightly alkaline. Excessive putrefaction causes a strong odor. The presence of blood in the stool causes a unique odor.
Consistency	Soft, semisolid, and formed	The consistency of the stool is influenced by fluid and food intake and gastric motility. The less time stool spends in the intestine (or the shorter the intestine), the more liquid the stool. Many pathologic conditions influence consistency.
Shape	Formed stool is usually about 1 inch (2.5 cm) in diameter and has the tubular shape of the colon, but may be larger or smaller, depending on the condition of the colon	A GI obstruction may result in a narrow, pencil-shaped stool. Rapid peristalsis thins the stool. Increased time spent in the large intestine may result in a hard, marble-like fecal mass.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

Constituents	Waste residues of digestion: bile, intestinal secretions, shed epithelial cells, bacteria, and inorganic material (chiefly calcium and phosphates); seeds, meat fibers, and fat may be present in small amounts	Internal bleeding, infection, inflammation, and other pathologic conditions may result in abnormal constituents. These include blood, pus, excessive fat, parasites, ova, and mucus. Foreign bodies also may be found in the stool.

- Void first, because the laboratory study may be inaccurate if the stool contains urine (Fischbach & Fischbach, 2018).
- Defecate into the required container, such as clean or sterile bedpan or the bedside commode (depending on the specimen required), rather than the toilet, because the water in the toilet bowl may affect the analysis results (Fischbach & Fischbach, 2018).
- Do not place toilet tissue in the bedpan or specimen container because contents in the paper may influence laboratory results (Fischbach & Fischbach, 2018).
- Avoid contact with soaps, detergents, and disinfectants as these may affect test results (Fischbach & Fischbach, 2018).
- Notify the nurse when the specimen is available, so that it may be collected and transported to the laboratory as required.

When placing a specimen in a laboratory container, put on gloves and use two clean tongue blades. Usually, 1 inch (2.5 cm) of formed stool or 30 mL of liquid stool is sufficient (Fischbach & Fischbach, 2018). If portions of the stool include visible blood, mucus, or pus, include these with the specimen (Fischbach & Fischbach, 2018). Also, be sure that the specimen is free of any barium or enema solution. Because a fresh specimen produces the most accurate results, send the specimen to the laboratory immediately. If this is not possible, the specimen should be either refrigerated or kept warm; contact the laboratory for instructions based on the type of testing (Fischbach & Fischbach, 2018). Do not refrigerate specimens for ova and parasites (Fischbach & Fischbach, 2018).

Stool Culture

Culture of stool is indicated when there is suspected infection from bacteria, virus, fungi, or parasites. Obtain stool cultures before initiation of antiinfective therapy. If antibiotic or antifungal therapy has already begun, identify the specific medication in the laboratory request (Boruchoff & Weinstein, 2019).

Occult Blood

Certain conditions, such as ulcer disease, inflammatory bowel disorders, and colon cancer, place the patient at high risk for intestinal bleeding. The color of the stool may reflect the source of the bleeding. Black, tarry stools may indicate upper GI bleeding, such as from a peptic ulcer, due to a reaction between hemoglobin and gastric acid. Lower GI bleeding, such as from hemorrhoids or a polyp, may produce bright-red blood in the stool. Certain foods and medications can also cause a black or reddish stool. **Occult blood** in the stool (blood that is hidden in the specimen or cannot be seen on gross examination) can be detected with screening tests.

Fecal occult blood testing (FOBT) may be used to detect occult blood in the stool. It is used for initial/early screening for disorders such as cancer and for GI bleeding in conditions such as ulcer disease, inflammatory bowel disorders, and intestinal polyps (MedlinePlus, 2020). Consecutive stool samples (three to six) should be collected from different stool samples to increase accuracy (Fischbach & Fischbach, 2018). FOBT may be performed within an institution, collected at the bedside, and sent to the laboratory for analysis. The sample may also be collected by the patient at home and delivered or mailed to the health care provider's office or to the laboratory for analysis.

The *guaiac fecal occult blood test* (gFOBT) is a chemical test that detects the enzyme peroxidase in hemoglobin molecules when blood is present in the stool sample. A positive gFOBT result indicates that abnormal bleeding is occurring somewhere in the digestive tract. Certain medications, such as a salicylate intake of more than 325 mg daily, other nonsteroidal antiinflammatory drugs, steroids, iron preparations, and anticoagulants, also may lead to *false-positive* readings (Fischbach & Fischbach, 2018). The evidence for practice is conflicting regarding the impact of ingestion of certain foods and supplements before specimen collection on the accuracy of the test results (Doubeni, 2020, MedlinePlus, 2020). Foods and supplements that are suggested to have a possible effect on test results include red meat, cantaloupe, turnips, radishes, parsnips, horseradish, mushrooms, broccoli, cauliflower, apples, bananas, cantaloupe, and vitamin C–enriched foods and juices as well as vitamin C in excess of 250 mg/day (American Cancer Society, 2020; Colorectal Cancer Alliance, 2019a; Fischbach & Fischbach, 2018; MedlinePlus, 2020). Patients should consult with their health care providers and follow directions provided for the collection test kit provided.

The *fecal immunochemical test* (*FIT*) uses antibodies directed against human hemoglobin to detect blood in the

stool. A positive FIT is more specific for bleeding in the lower GI tract (Fischbach & Fischbach, 2018). No drug or dietary restrictions are required for the FIT (American Cancer Society, 2020; Colorectal Cancer Alliance, 2019b).

The following are recommendations for the patient preparing for a fecal occult blood test (Fischbach & Fischbach, 2018):

- Avoid barium enemas for 72 hours before and during stool specimen collection.
- Do not collect samples during or until 3 days after menstrual period.
- Do not collect samples while the patient has bleeding hemorrhoids or hematuria.

In clinical settings, these restrictions are usually not practical. Be sure to note the presence of any of the previously mentioned conditions in the clinical setting.

Figure 39-5 demonstrates the procedure for a gFOBT test. A positive result from either the gFOBT or the FIT requires follow-up testing, such as a sigmoidoscopy or colonoscopy (American Cancer Society, 2020).

Timed Specimens

Consider the first stool passed by the patient as the start of the collection period. Depending on the test, it may require saving the entire stool passed or only a sample. Collect the required volume of every stool passed within the designated period. Follow laboratory instructions for sending stools to the laboratory.

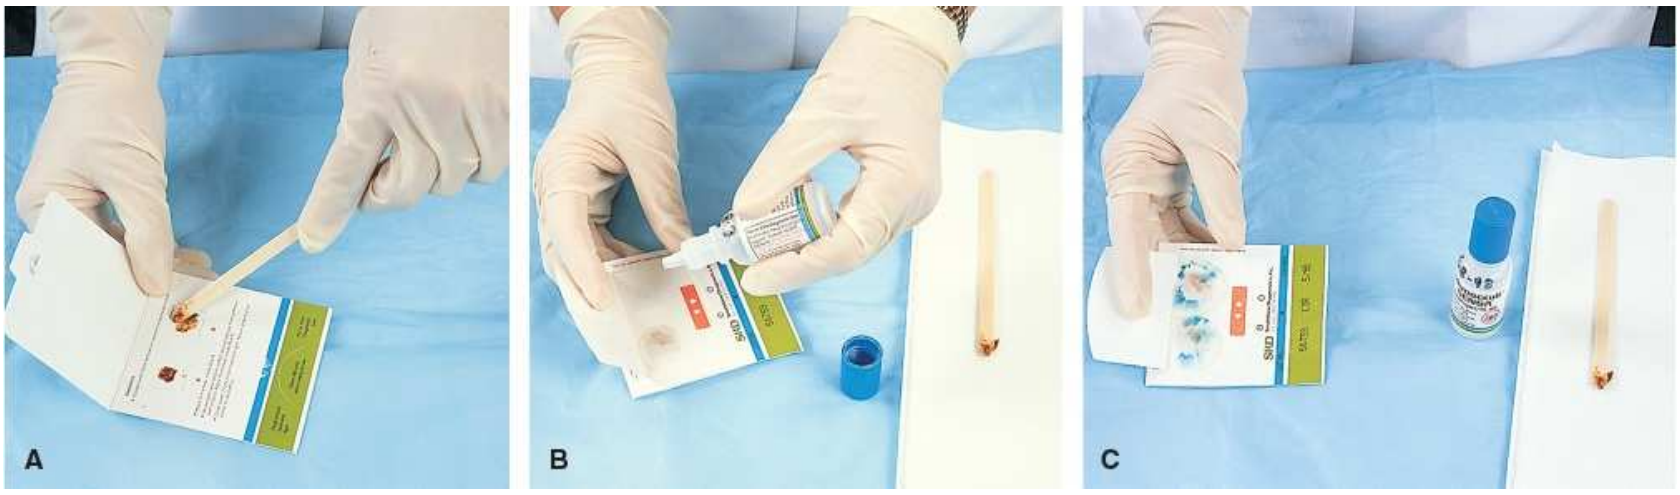

FIGURE 39-5. Testing a stool specimen for occult blood. **A.** Applying a stool specimen to the test paper. **B.** Adding developing solution to the back side of the paper according to directions. **C.** Blue coloration indicating positive results. (*Source:* Used with permission from Shutterstock. *Photos by B. Proud.*)

Specimens for Pinworms

Adult pinworms, parasitic intestinal worms, live in the cecum. Pinworms migrate to the anal area during the night to deposit eggs and retreat into the anal canal during the day. The most common symptom of a pinworm infection is perianal itching. Collect this specimen in the morning, immediately after the patient awakens and before the patient urinates, has a bowel movement, or a bath. Use clear cellophane tape to collect a specimen for pinworms; do not use micropore or adhesive-type tape (Fischbach & Fischbach, 2018). Apply gloves and press the tape against the anal opening, remove it immediately, and then place it on a slide. Pinworm eggs can usually be detected on the tape under a microscope. This test may need to be repeated on 4 to 6 consecutive days before ruling out the presence of pinworms (Fischbach & Fischbach, 2018).

DIRECT VISUALIZATION STUDIES

Endoscopy is the direct visual examination of body organs or cavities. Most commonly, this is done using a fiberoptic endoscope, a long, flexible tube containing glass fibers that transmit light into the organ and return an image that can be viewed. Pincers may be inserted through the tube to obtain a tissue sample for biopsy. An endoscope enables the health care provider to view the integrity of the mucosa, blood vessels, and specific organ parts and is helpful for diagnosing inflammatory, ulcerative, and infectious diseases; benign and malignant neoplasms; and other lesions of the esophageal, gastric, and intestinal mucosa. Endoscopic studies include the following:

- *Esophagogastroduodenoscopy (EGD):* visual examination of the esophagus, the stomach, and the duodenum
- *Colonoscopy:* visual examination of the large intestine from the anus to the ileocecal valve
- *Sigmoidoscopy:* visual examination of the sigmoid colon, the rectum, and the anal canal

Nursing responsibilities before and after these studies are described in Box 39-2.

Virtual enteroscopy (wireless video capsule endoscopy) is a minimally invasive technology that provides diagnostic imaging of the small intestine (American Society for Gastrointestinal Endoscopy, 2020). In this procedure, the patient swallows a capsule, about the size of a vitamin, which contains a small camera that emits a radio signal. The capsule is propelled through the small intestine via peristalsis, taking two pictures per second. Several sensors are attached to the patient's abdomen and pick up the radio signal from the capsule, and the data are recorded on a small

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

recording device worn on a belt. The system captures about 55,000 images in an 8-hour exam. The patient returns to the facility after 8 hours, and the external sensors and data recorder are removed. The information is downloaded from the recorder to a computer and can be transferred to a videotape for easy viewing by the health care provider. The capsule is excreted during the process of normal defecation in 24 to 48 hours and is intended for one-time use only (Cave, 2021).

The patient is normally NPO (fasting) for 10 to 12 hours the evening before capsule ingestion. A bowel prep is usually not needed, but it may be used in some patients (American Society for Gastrointestinal Endoscopy, 2020). During the first 2 hours of the study, the patient is not allowed to eat or drink anything. After the first 2 hours, the patient may consume small amounts of liquids. After 4 hours, the patient may have a small meal (American Society for Gastrointestinal Endoscopy, 2020). The patient should avoid vigorous physical activity such as running or jumping during the study (American Society for Gastrointestinal Endoscopy, 2020). Patients should not be near an MRI device or schedule an MRI examination after ingesting the capsule and until the capsule is excreted (American Society for Gastrointestinal Endoscopy, 2020). Because there is no sedation or discomfort and a relatively normal day can be planned, many patients prefer this method of endoscopy. In addition, no air is needed to expand the small intestine, as it is in traditional endoscopy; therefore, the patient does not feel uncomfortable and bloated. This method, however, does not allow for obtaining biopsies of any suspicious area, so additional endoscopic studies may be required, based on the results.

INDIRECT VISUALIZATION STUDIES

Indirect visualization of the GI tract is commonly performed through radiography. The passage of x-rays through the patient creates a radiograph or film depicting body structures. This technique is useful for detecting obstructions, strictures, inflammatory disease, tumors, ulcers, and other lesions, and for diagnosing a hiatal hernia and other structural changes in the GI tract.

Box 39-2 Common Diagnostic Studies for the Gastrointestinal Tract

Esophagogastroduodenoscopy (EGD)

Allows visual examination of the esophagus, stomach, and upper duodenum by means of a long, flexible, fiberoptic-lighted scope.

Preparation

- A signed consent form is required for this procedure.
- Fasting is required 6 to 8 hours before the test (check facility policy).
- Dentures need to be removed before the test.
- Remind patients that they will be awake but sedated and that a local anesthetic will be sprayed into the mouth and throat to depress the gag reflex.

Aftercare

- Withhold food and fluids until the gag reflex returns.
- Check vital signs according to the protocol.
- Observe for signs of perforation: pain, persistent difficulty swallowing, vomiting blood, or black, tarry stools.
- Explain to the patient that it is normal to sense throat soreness and hoarseness for several days; saline gargles and lozenges may be helpful.

Colonoscopy

Allows visual examination of the rectum, colon, and distal small bowel using a long, flexible, fiberoptic-lighted scope.

Preparation

- Ensure that an informed consent is signed.
- Preparation prior to test may involve:
- If possible, a low-residue diet (low fiber) should be followed several days before the procedure. A clear liquid diet is usually ordered for 48 to 72 hours before the procedure (Fischbach & Fischbach, 2018). There are multiple types of bowel preps for this procedure. The provider performing the procedure will decide which is best for the individual patient.
- The prep is usually given as a split dose, with half being given the night before and rest the morning of the procedure. It is recommended the second dose be given at least 5 hours and completed at least 2 hours before the study. There are some who may receive the prep the same day as the procedure,

especially if the procedure is scheduled for later in the day.

- The prep may be better tolerated if a straw is used, and the liquid is chilled. Some prep solutions may come with a flavor pack, which may improve the flavor as well.
- Those who cannot tolerate the oral prep or have a contraindication to large volumes of fluid may have an enema prep.
- May be NPO for at least 6 to 8 hours before the study with small sips of water for meds, and nothing for 2 hours before the study.
- Explain to the patient they will be sedated during the test.

Aftercare

- The patient may experience flatulence or gas pains because air was used to distend the intestines for better visibility.
- Usual diet may be resumed once patient recovers from the sedation.
- Check vital signs according to facility protocol.
- Observe for signs of bowel perforation: rectal bleeding, abdominal pain and distention, fever, malaise.

Sigmoidoscopy

Allows visual examination of the distal sigmoid colon, the rectum, and the anal canal through a flexible or rigid sigmoidoscope.

Preparation

- Ensure that an informed consent is signed.
- Preparation may include light meal the night before and two commercially prepared enemas (Fleet). In older adults where these enemas would be contraindicated, an oral preparation could be used. Sedation is not usually required but may be ordered.

Aftercare

- Patient may experience flatulence or gas pains because air was used to distend the intestines for better visibility.
- Observe for signs of bowel perforation.
- If biopsy was performed, patient should be informed that slight rectal bleeding may occur.

Upper Gastrointestinal (UGI) and Small-Bowel Series

Involves fluoroscopic examination of the esophagus, stomach, and small intestine after ingestion of barium sulfate.

Preparation

- Ensure that an informed consent is signed.
- Keep patient NPO after midnight the day of the test.
- Inform patient that a chalky-tasting barium contrast mixture will be given to drink before the test.
- If the patient has diabetes, alert the radiology department, and schedule the exam for early morning. If the patient is taking metformin, special considerations may be necessary. Consult with the health care team to determine if the metformin should be suspended for the day of and several days after the study (Fischbach & Fischbach, 2018).

Aftercare

- A post-test laxative (e.g., milk of magnesia) is usually prescribed to prevent fecal impaction from barium sulfate that has hardened. Notify the health care provider if barium is not passed, usually within 2 days.
- Explain that the barium may lighten the color of stools for the next several days. After the barium is expelled, the stool color will return to normal.

Barium Enema

Involves a series of radiographs that examine the large intestine after rectal instillation of barium sulfate.

Preparation

- An informed consent must be signed.
- Preparation may consist of dietary modifications and a bowel prep.
- Review the patient's history for any history of ulcerative colitis or active GI bleeding that would prohibit the use of the standard bowel preparation.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

Aftercare

- Encourage fluids to prevent dehydration.
- Inform the patient that the barium may lighten the color of the stools. A laxative may be prescribed. Notify the health care team if barium is not passed, usually within 2 days.
- Encourage rest because the bowel preparation and the test exhaust many patients.

Abdominal Ultrasound

Uses ultrasound waves to visualize organs via a small transducer placed against the skin.

Preparation

- Assure the patient that no radiation is employed and that the test is painless.
- Patient must be NPO for a minimum of 8 hours before the examination.
- Explain that gel will be applied to the skin and that a sensation of warmth or wetness may be felt. The gel does not stain but avoid wearing nonwashable clothing.
- Abdominal ultrasound must be performed before studies involving barium, as retained barium may compromise the study. If this scheduling is not possible, at least 24 hours must elapse between the barium procedure and the ultrasound.

Aftercare

- Ensure that any residual gel is removed from the skin.
- Normal diet and fluids may be resumed, unless contraindicated by the test results.

Magnetic Resonance Imaging (MRI)

Provides physiologic information and detailed anatomic views of tissues using a superconducting magnet and radiofrequency signals.

Preparation

- Evaluate the patient for need for sedation. Patients who are claustrophobic or unable to lie still during study may benefit from sedation.
- Patients with implanted surgical clips or other metallic structures and those with implanted electromechanical devices, such as cardiac pacemakers, drug infusion pumps, and cochlear implants, cannot be exposed to MRI procedures.
- An informed consent is required.
- Pregnant patients are not routinely scanned because an increase in amniotic fluid/fetal temperature may be harmful.

Aftercare

- If intravenous contrast is used during the study, monitor for sensitivity and adverse reactions.
- Monitor contrast injection site for signs of irritation, infection, and bruising.
- If prestudy sedation was given, monitor patient closely until sedation wears off to prevent injury.

Abdominal CT Scan

Thin beams of x-rays are directed at and moved around the abdomen, resulting in computer-manipulated pictures that are not obscured by overlying anatomy.

Preparation

- An oral contrast is consumed before the study
- Intravenous iodine contrast may be administered.
- Assess for patient allergies to iodine, IV contrast, and/or shellfish. Prestudy preparation may be required if allergies are present.
- Assess for renal impairment; check laboratory values for elevated BUN and creatinine levels.
- Patient should not eat solid foods on the day of the study; clear liquids may be consumed up to 2 hours before the study.
- CT scan is contraindicated for pregnant patients.
- An informed consent is required.
- If the patient has diabetes, alert the radiology department, and schedule the exam for early morning. If the patient is taking metformin, special considerations may be necessary. Consult with the health care team to determine if the metformin should be suspended for the day of and several days after the study (Fischbach & Fischbach, 2018).

Aftercare

- If intravenous contrast is used during study, monitor for sensitivity and adverse reactions.
- Monitor contrast injection site for signs of irritation, infection, and bruising.
- If prestudy sedation was given, monitor patient closely until sedation wears off to prevent injury.

Source: Adapted from A-Rahim, Y. I., & Falchuk, M. (2021). UpToDate. Bowel preparation before colonoscopy in adults. Wolters Kluwer. https://www.uptodate.com/contents/bowel-preparation-before-colonoscopy-in-adults; Centers for Disease Control and Prevention (CDC). (2021). Colorectal cancer screening continuing education. CRC screening and surveillance: Optimizing quality. Section 3: The role of primary care providers in the delivery of high-quality colonoscopy. https://www.cdc.gov/cancer/colorectal/quality/CRC_Screening_Optimizing_Quality_Primary_Care3.pdf; and Fischbach, F. T., & Fischbach, M. A. (2018). A manual of laboratory and diagnostic tests (10th ed.). Wolters Kluwer.

Use of a radiopaque contrast medium, such as barium sulfate, accentuates the body structures being visualized. In the upper GI examination and small-bowel series, the patient drinks the barium sulfate like a milkshake. The barium coats the esophagus, stomach, and small intestine to enhance visualization. In the barium enema or lower GI examination, barium sulfate is instilled into the large intestine through a rectal tube inserted through the anus.

Fluoroscopy projects consecutive x-ray images onto a screen for continuous observation of the flow of the barium. During a computerized tomography (CT) scan, thin beams of x-rays are directed at and move around the abdomen, resulting in computer-manipulated pictures that are not obscured by overlying anatomy. Contrast may be given orally or intravenously to enhance the images. Magnetic resonance imaging (MRI) provides physiologic information and detailed anatomic views of tissues using a superconducting magnet and radiofrequency signals. Computers use the signals to construct detailed sectional images of the abdomen. Intravenous contrast can be given to enhance the images. Abdominal ultrasound visualizes all solid upper abdominal organs, including the liver, bile ducts, gallbladder, appendix, pancreas, kidneys, adrenals, spleen, and the abdominal aorta and vena cava. The specific nursing responsibilities related to these studies are included in Box 39-2.

Examples of Actual or Potential Health Problems and Needs

BOWEL ELIMINATION

Actual or Potential Health Problems and Needs	Possible Etiologic Factors	Potential Signs and Symptoms
Diarrhea	Adverse effects of pharmaceutical agents Abuse of laxatives Emotional stress Intestinal infection Colon disease and other diseases Radiation	• At least three loose, liquid stools per day, increased frequency • Urgency • Reports of abdominal pain and/or cramping • Hyperactive bowel sounds
Bowel Incontinence	Dietary habits General decline in muscle tone Laxative abuse Rectal sphincter abnormality Cognitive impairment	• Involuntary passage of stool (stool characteristics vary) • *"I'm sorry, I couldn't get into the bathroom (or onto the bedpan) quickly enough."* • *"It came so fast I couldn't hold it back."* • Constant dribbling of soft stool
Constipation Risk	Insufficient fluid intake Insufficient fiber intake Inactivity Delaying defecation when urge is present Misuse of laxatives	—

SCHEDULING FOR DIAGNOSTIC STUDIES

Nurses may be involved in scheduling diagnostic studies when a patient is to undergo multiple studies. Use the following guidelines for scheduling studies of the GI tract:

1. Follow a logical sequence when more than one test is required for accurate diagnosis:
   - Fecal occult blood tests: to detect GI bleeding
   - Barium studies: to visualize GI structures and reveal any inflammation, ulcers, tumors, strictures, or other lesions
   - Endoscopic examinations: to visualize an abnormality, locate a source of bleeding, and if necessary, provide biopsy tissue samples
2. A barium enema and routine radiography should precede an upper GI series because retained barium from an upper GI series could take several days to pass through the GI tract and cloud anatomic detail on the barium enema studies.
3. Noninvasive procedures usually take precedence over invasive procedures, such as endoscopic studies, when sufficient diagnostic data can be obtained from them. In some instances, endoscopic studies may be done before barium studies to ensure visualization.
4. It is important to consider any comorbidities, such as diabetes mellitus, that the patient may have in scheduling diagnostic studies that require the patient to have an altered diet or to have nothing by mouth.

Diagnosing Actual or Potential Health Problems and Needs

An assessment of a patient's bowel status may lead to the identification of one or more actual or potential health problems and needs related to bowel elimination. Following the formulation of the actual or potential health problems and needs, the nurse communicates findings to other nursing and health care professionals through the use of written and spoken word. The written actual or potential health problem or need becomes a permanent part of the patient's health record. Examples of health problems and needs with related etiology and signs and symptoms can be found in the Examples of Actual or Potential Health Problems and Needs: Bowel Elimination.

Outcome Identification and Planning

Expected outcomes are derived from the actual or potential bowel elimination problems or needs identified. The goal is to maintain or restore optimum function related to bowel elimination, alleviate symptoms or side effects of disease or treatment, and to prevent complications. General patient outcomes are listed here. Actual patient outcomes should list specific behaviors and criteria individualized for the patient situation. The patient will:

- Have a soft, formed bowel movement without discomfort
- Explain the relationship between bowel elimination and dietary fiber, fluid intake, and exercise
- Relate the importance of seeking medical evaluation if changes in stool color or consistency persist
- Maintain skin integrity

Implementing

Nursing care related to bowel elimination includes interventions to promote regular bowel habits, prevent and treat constipation, prevent and treat diarrhea, decrease flatulence, promote elimination of feces, manage bowel incontinence, and implement bowel-training programs. Nursing care related to caring for a patient with a nasogastric (NG) tube for gastric decompression is also discussed in the following sections.

Promoting Regular Bowel Habits

Promote regular bowel habits in well and ill patients by attention to timing, positioning, privacy, nutrition, and exercise.

TIMING

Encourage toileting at the patient's usual time during the day. Ask the patient to explain what measures are most successful in maintaining regular bowel function. Offer whatever assistance is needed to help the patient to the bathroom, commode, or bedpan at the time that a patient usually experiences the urge to defecate. This is often about an hour after meals, when mass colonic peristalsis occurs. Because many patients feel uncomfortable about requesting time for elimination, educate all patients about the importance of heeding this natural urge, as postponing it could result in constipation and other problems.

POSITIONING

Sitting upright on a toilet or commode promotes defecation. Most patients who are able to use the bedside commode or bathroom toilet have little difficulty assuming this position, although they may need support. An elevated toilet seat may be ordered for patients with orthopedic problems who cannot lower themselves to a toilet seat. Sitting upright

promotes a sense of normalcy and the effects of gravity help to promote regular bowel movements. Sitting with the knees higher than the hips (using a small step stool if necessary) instead of resting the feet on the floor may improve defecation by straightening the anorectal junction and easing the evacuation of stool (Mounsey et al., 2015; Queensland Health, 2019).

It is best to avoid bedpan use; encourage use of the toilet or bedside commode, as discussed previously. Patients who need to use a bedpan often benefit from having the head of the bed elevated to as close to a sitting position as possible, at least 30 degrees, unless this is contraindicated. An overhead trapeze may be helpful for patients with weak lower extremities. Offer the patient moistened hand wipes at the bedside to substitute for handwashing after toileting. Always empty, clean, and return the bedpan to the patient's bedside stand or store according to facility policy.

PRIVACY

Many adults and children cannot defecate in the presence of another person. Unless the patient is extremely weak and requires assistance, provide privacy in the health care facility and in the home. Always respect the patient's need to be alone while defecating, unless the patient's condition makes this impossible. Pull the bedside drapes around a patient who is using a bedside commode or bedpan. If any visitors are present, ask them to step outside for a few minutes. When assisting patients to the bathroom, step out of the bathroom as long as it is safe to do so. For well patients who cannot defecate in a public restroom (with multiple toilets) or strange environment, suggest that they use a private restroom with only one toilet.

Hygiene

Patients who are confined to bed or who use a bedside commode find it difficult to perform their usual genital hygiene. Careful cleansing of the perineal and genital areas is needed for patient comfort and to prevent potential alterations in skin integrity. This is easily accomplished for patients by using warmed, moistened disposable washcloths and skin cleanser. Because people customarily wash their hands after toileting and hand hygiene prevents transmission of microorganisms, offer patients a moistened towelette or soap and water to wipe their hands after removing the bedpan or using the bedside commode.

NUTRITION

Patients with bowel elimination problems may need a dietary analysis to determine which foods and fluids are contributing to their problem and which may help in its treatment. General dietary recommendations to promote regular defecation include a fluid intake of 2,000 to 3,000 mL/day (average 2,600 mL) and high-fiber intake (Dudek, 2022; Medline Plus, 2021). It is important to be aware of those patients, particularly older adults with cardiac and renal problems, for whom increased fluid intake may be contraindicated. Increasing fiber intake without sufficient fluid intake can result in severe GI problems, including fecal impaction. Specific recommendations for treating constipation, diarrhea, and excessive flatulence follow.

EXERCISE

Although there is conflicting evidence on the role exercise plays in eliminating constipation, it is known that regular exercise improves GI motility and aids in defecation (Mounsey et al., 2015; Pinto et al., 2020). Encourage those patients who are able to exercise regularly for 2½ hours or more a week (USDHHS, 2018). It is important to get patients out of bed and walking as soon as they are able, instructing them that inactivity can lead to constipation, distention, and impaction. Bedside exercises may be helpful for patients who are immobile. Pelvic floor muscle training exercises (Kegel exercises) strengthen pelvic and rectal muscle tone and may be helpful for weakened patients (Medline Plus, 2021). Refer to Chapter 38 (p. 1465) for details related to use of PFMT exercises.

Providing Comfort Measures

Comfort measures related to defecation include working with the patient to develop a bowel elimination routine that results in the easy passage of a soft, formed stool; being attentive to perineal hygiene and the maintenance of skin integrity; and using warm, moist heat (sitz bath or tub bath) to soothe the perineal area. Additional interventions include the following:

- Encouraging recommended diet (if pertinent) and exercise
- Using medications, such as laxatives and antidiarrheals, only as needed if nonpharmacologic interventions are not effective
- Applying ointments or astringents (witch hazel) to inflamed and irritated tissue around the anal opening

PREVENTING AND TREATING CONSTIPATION

Constipation is dry, hard stool; infrequent difficult passage of stool; and/or the incomplete passage of stool (Bauldoff et al., 2020; Mitchell, 2019a). Decreased gastric motility slows the passage of feces through the large intestine, resulting in increased fluid absorption from the fecal mass and causing dry, hard stool. Straining often accompanies

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

defecation. Some people may be constipated and yet have a daily bowel movement, whereas others who regularly defecate no more than three times a week are not constipated. People at high risk for constipation include patients on bedrest or with decreased mobility (Bauldoff et al., 2020). In addition, those taking medications that cause constipation (e.g., opioids, anticholinergics); patients with reduced fluids, bulk, or fiber in their diet; people who are depressed; and patients with central nervous system disease or local lesions that cause pain while defecating are also at risk (Bauldoff et al., 2020; Mitchell, 2019a; Pont et al., 2019; Touhy & Jett, 2018).

TEACHING ABOUT NUTRITION

Promoting healthy behaviors can assist the patient and family/caregivers to achieve mutually desirable outcomes for preventing constipation. A combination of high-fiber foods (20 to 35 g of fiber), fluid intake of 2,000 to 3,000 mL/day, and exercise has been shown to be effective in controlling constipation in patients with deficiencies in dietary intake of fiber and/or fluid and reduced amounts of exercise (Dudek, 2022; Medline Plus, 2021). It is important to gradually increase the amount of fiber in the diet to avoid bloating and flatulence. It can be trial and error in determining the proper amount of fiber a person needs to maintain regular bowel movements while limiting adverse effects (Dudek, 2022). Caution the patient to avoid increasing fiber intake without drinking enough fluids. Foods that contain high amounts of fiber include bran, fruits, vegetables, and whole grains. Fiber supplements may be necessary if adequate fiber cannot be consumed through food (Dudek, 2022).

Think back to **Leroy Cobbs**, the patient who developed constipation while using opioid analgesics. The nurse should list in the teaching plan foods that stimulate peristalsis to prevent future episodes of constipation. If the patient knows to include these foods in their diet, they will be less worried about future problems and may be more amenable to using the medication to control their pain.

TEACHING ABOUT LAXATIVES

Laxatives are drugs that induce emptying of the intestinal tract. Bulk-forming laxatives such as psyllium work by absorbing water into the intestine to soften the stool and increasing stool bulk. Osmotic laxatives are not absorbable and work by bringing water into the intestine. Polyethylene glycol is a commonly used, well-tolerated osmotic laxative. Stimulant laxatives, such as bisacodyl and senna, improve defecation by increasing motility through irritation of the intestinal mucosa and increased water in the stool. Other frequently used laxatives are the saline-osmotics, such as magnesium hydroxide or magnesium citrate. Saline-osmotic laxatives act by drawing water into the intestines, stimulating peristalsis, and are effective but should be used in caution in those patients with renal disease. Magnesium hydroxide has antacid properties in small dosages and laxative properties in larger doses. Table 39-2 summarizes the types of laxatives.

Laxatives are sometimes necessary for people with limited activity or poor food intake. They are also used to empty the intestinal tract in preparation for surgery or diagnostic tests. Stool softeners such as docusate sodium may be used in conjunction with some prescribed medications to counteract the medications' constipating properties. Occasional use of laxatives is not harmful for most people, but people should not become dependent on them to induce regular bowel movements. The only laxatives that are appropriate and safe for long-term use are bulking agents, such as psyllium (Bauldoff et al., 2020). Because many laxatives are available as nonprescription drugs, and advertising promotes their use, many people take them frequently on their own initiative, whether they need them or not. Patient education is important in the safe use of over-the-counter medications.

Because of their chemical action, laxatives should not be taken when a patient is experiencing abdominal pain. Increased peristalsis caused by laxative use in the presence of an intestinal pathologic condition such as a bowel obstruction could result in patient harm (Bauldoff et al., 2020). Although many people take laxatives because they believe they are constipated, most are unaware that habitual use of laxatives may be the cause of chronic constipation (Bauldoff et al., 2020).

Nurses play a key role in helping patients who misuse laxatives. Breaking the physical and psychological habit of using laxatives is not easy for a person who has come to depend on them; it often requires much patience, support, and teaching. The person also frequently needs assistance with diet, fluid intake, activity, and regularity of habits (Shen et al., 2018). Overuse of laxatives because of chronic constipation may often be a sign of other disease processes such an eating disorder and requires further investigation (National Eating Disorder Association, 2018).

Preventing and Treating Diarrhea

Diarrhea is an increase in frequency (passage of three or more stools a day) and/or a change in consistency of stools (Dunlap & Patterson, 2020; Kyle & Carman, 2021). It is important to determine the consistency of the stool, as frequent bowel movements alone are not always indicative of diarrhea, but patients with diarrhea usually pass stools more frequently. Diarrhea is often associated with intestinal cramps. Nausea and vomiting may occur, and blood may also be noted. Diarrhea can be a protective response when the cause is an irritant in the intestinal tract. Regardless of the cause, however, large amounts of fluids and electrolytes may be lost relatively quickly through diarrhea, especially in infants, young children, and older adults (Bauldoff et al., 2020). If diarrhea is untreated, this loss of fluids and electrolytes places the person at high risk for life-threatening complications, such as vascular collapse and hypovolemic shock, hypokalemia and hypomagnesemia, and metabolic acidosis (Bauldoff et al., 2020). It is particularly important to maintain fluid balance in infants, children, and older adults because of their increased risk for dehydration, fluid overload, and electrolyte imbalances.

Table 39-2 Classification of Laxatives

TYPE	ACTION	ADVANTAGES	CAUTION
Bulk forming Psyllium, methylcellulose	Causes stool to absorb water. Increases stool weight, increases colonic distention, which stimulates peristalsis. Food supplement can take several days to weeks to see changes. Supplements will act within 12–72 hours.	Effects can also be achieved by increasing fiber in the diet to 25–35 g daily.	Can cause bloating and gas. Titrate dose to limit side effects. Not to be used in obstruction. Used cautiously with other swallowing disorders and in those who are immobile. Need to be able to increase water intake as well.
Osmotic Polyethylene glycol (PEG) Lactulose Sorbitol Magnesium citrate Sodium phosphate	Promote secretion of water into the colon. Stimulates bowel movement. Action usually in 12–96 hours.	Products such as polyethylene glycol dissolve completely in any fluid and are well tolerated.	Certain saline osmotic laxatives can lead to fluid and electrolyte imbalances and should not be used in older adults or those with kidney or cardiac disease.
Stimulant Bisacodyl Senna	Increase intestinal motility and colonic secretions Time to action: Oral 6–10 hours Rectal 15–60 minutes	Quick to work	Can cause severe cramping Frequently abused but generally safe Wait 1 hour after ingesting milk and antacids before using
Stool softeners	Agents with surfactant activity that decrease the tension between water and fat and lubricate the stool	Evidence is lacking to demonstrate effectiveness as a laxative. However, still may be seen in combination with use of other products.	Does not stimulate peristalsis, so can make stool soft and mushy but does not assist in evacuation
Lubricants Mineral oil	Lubricates the intestinal tract and slows down absorption of water in the colon, softening the stool and making it easier to pass	Often used in facilitating impaction removal	Serious complications in lungs can occur if aspirated, so avoid oral form in those at risk. Can interfere with absorption of vitamins especially ADEK Avoid use in those taking

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

vitamin D analogs such as calcipotriene

NURSING CARE CONSIDERATIONS FOR PATIENTS WITH DIARRHEA

The focus of nursing care is on eliminating the cause of the diarrhea and replacing lost fluids as well as treating the symptoms. Treatment for diarrhea typically depends on whether the problem is acute or chronic. Acute diarrhea may result from a viral or bacterial infection, a reaction to medication, or alterations in diet. It is characterized by its sudden onset and lasts several hours to several days. Rehydration is essential with acute diarrhea. Oral liquids may be used if the patient can tolerate them; otherwise, intravenous fluid replacement may be necessary. Refer to the Teaching about Nutrition discussion below. Stress the importance of hand hygiene with the patient and family/caregivers. Avoid antidiarrheal agents in acute diarrhea until a bacterial causative agent has been ruled out (Bauldoff et al., 2020).

Chronic (persistent) diarrhea typically lasts for more than 2 to 4 weeks (CDC, 2016). A thorough workup is needed in the patient with chronic diarrhea to determine the underlying cause. Chronic diarrhea has many possible causes, such as inflammatory bowel disease (e.g., Crohn disease, ulcerative colitis), irritable bowel syndrome, malabsorption syndromes, bowel tumor, metabolic disease (diabetes, hyperthyroidism), parasitic infection, side effects of drugs, laxative abuse, surgery, alcohol abuse, and radiation and chemotherapeutic agents (Bauldoff et al., 2020; MFMER, 2020c). Chronic diarrhea requires fluid and electrolyte replacement and, if severe and prolonged, may require pharmacologic intervention. Before treatment begins, it is important to make every effort to identify and eliminate the underlying cause (CDC, 2016).

Additional nursing measures for the patient with diarrhea include the following:

- Answer the patient's call bell immediately or ensure that a bedpan or commode is within easy reach. Diarrhea can be embarrassing, and the patient needs to know that the nurse is there to help. This also will decrease the risk of falls if the patient attempts to get out of bed on their own to quickly get to the bathroom to prevent incontinence.
- Whenever possible, address/remove the cause of the diarrhea. For example, discontinuing medications that cause diarrhea usually results in a return to normal defecation within 1 to 3 days.
- Sometimes there can be seepage or leakage of liquid stool in a patient with a fecal impaction. If there is any indication of a fecal impaction, further evaluation is necessary before using antidiarrheal medications.
- Give special care to the region around the anus, where skin irritation is common. Keep the area clean and dry. Use skin creams, moisture barriers, and ointments, as necessary to protect the skin.

Skin care measures would be important to include in the care plan for **Jeremy Green**, the young boy experiencing episodes of diarrhea. Doing so reduces Jeremy's risk for perianal excoriation and breakdown, which could further impair his body image and cause additional discomfort and pain.

TEACHING ABOUT NUTRITION

Supportive nutritional interventions depend on the severity of diarrhea and the underlying cause (Dudek, 2022). Encourage liberal fluid intake to replace losses, but clear liquids with high sugar content (high osmolality related to sugar content) should be avoided (Bauldoff et al., 2020; Dudek, 2022). On a short-term basis, a low-fiber, low lactose/sucrose/fructose diet may help decrease bowel stimulation (Dudek, 2022). Teach patients to avoid milk and milk products, raw fruits, gas-producing foods (bran, beans, corn, broccoli, cabbage), coffee, and alcoholic beverages (Bauldoff et al., 2020; Borum & Baumgartner, 2020, as cited in Dunlap and Patterson, 2020, p. 391; Dudek, 2022). Intravenous fluids should be utilized in the presence of severe dehydration and/or intolerance of oral rehydration (Borum & Baumgartner, 2021, as cited in Dunlap and Patterson, 2020, p. 391).

Alterations in fluid and electrolyte balance occur faster and more often in infants and children compared to adults. Therefore, infants and children experiencing diarrhea require more fluid and electrolyte replacement compared to adults. Encourage fluids, especially oral rehydration solutions containing sodium chloride, potassium, and glucose (Pedialyte® and Enfalyte®) and make them accessible for the child. Breast feeding should continue through the diarrhea. Children should resume an age-appropriate diet when tolerated. The diet should be high in complex carbohydrates, meats, fruits, and vegetables. Simple sugars such as fruit juices should be avoided. Special diets such as the BRAT diet (bananas, rice cereal, applesauce, and toast) are no longer recommended because of the lack of nutritional value (O'Ryan, 2020).

The use of probiotics (live microorganisms that are similar to beneficial microorganisms found in the human GI tract) to prevent, limit, and control diarrhea has been suggested as an effective dietary intervention for diarrhea, particularly antibiotic-associated diarrhea and *C. difficile*–associated disease (Cleveland Clinic, 2020a; NIH, 2020). Examples of foods containing probiotics include cheese, yogurt, kefir, tempeh, miso, soymilk, and some commercial dairy drinks. Probiotics can also be ingested through the use of commercially prepared supplements (LaRocque & Harris, 2020). See the accompanying PICOT in Practice box.

TEACHING ABOUT ANTIDIARRHEALS

Antidiarrheal medications should be used sparingly or not at all until the cause of the diarrhea has been identified (Bauldoff et al., 2020). Several types of antidiarrheal medications are available. Antimotility medications such as loperamide and diphenoxylate hydrochloride act directly on the smooth muscle of the GI tract. Bismuth subsalicylate has an antimicrobial action and an antisecretory effect. Refer to the following section on traveler's diarrhea for contraindications to the use of antimotility agents and bismuth subsalicylate. Table 39-3 highlights the major antidiarrheal agents.

TEACHING ABOUT FOOD SAFETY

Ensuring that food is safe for consumption and prepared and stored properly is a priority. Food poisoning, and the diarrhea that frequently accompanies it, can be prevented. The CDC (2020c; CDC, 2020d) recommends these measures related to promoting food safety:

- Take items that require refrigeration home immediately. Refrigerate perishable foods and leftovers within 2 hours (1 hour if it's hotter than 90°F outside). Refrigerator temperatures should be set to 40°F or below. Freezer temperatures should be 0°F or below.
- Wash hands and surfaces often. Wash surfaces and utensils after each use to prevent the spread of microorganisms.
- Use separate cutting boards and plates for produce and for meat, poultry, seafood, and eggs.
- Thoroughly wash all vegetables and fruit before preparing or eating.
- Do not wash meat, poultry, or eggs to prevent spreading microorganisms to the sink, countertops, and other kitchen surfaces.
- Never use raw eggs in any form because of the danger of infection with *Salmonella bacillus*. When cooking eggs, use only fresh ones that have been purchased within 3 to 5 weeks and kept in the refrigerator.
- Do not eat seafood raw or undercooked. Do not eat seafood if it has a strong, unpleasant odor.
- Use a food thermometer to ensure cooking food to the safe internal temperature. Cook whole meats to 145°F, ground meats to 160°F, and poultry to 165°F. Microwave food thoroughly; cook to the safe temperature of 165°F or above.

PICOT in Practice

ASKING CLINICAL QUESTIONS: PROBIOTICS

Scenario: You are a nurse who works in a new gastroenterology clinic. Ulcerative colitis (UC) is an inflammatory condition affecting the colon that cycles from period of exacerbation to remission. The majority of people with UC can be put into remission, leaving a group who do not respond to first or secondline therapies. You read an article that described the benefits of probiotics in the care of patient with inflammatory bowel disease. You discuss this with the nurse educator who is not familiar with the findings. You both decide to evaluate the literature to see the benefits of probiotics in patients with UC.

- **Population:** Patients with ulcerative colitis
- **Intervention:** Efficacy of probiotics
- **Comparison:** 5Aminosalicylic acid (5ASA)
- **Outcome:** Inducing or maintaining of remission
- **Time:** 12 months

PICOT Question: What is the efficacy of probiotics compared to 5aminosalicylic acid (5ASA) in inducing or maintaining remission for patient with ulcerative colitis during a 12-month period?

Finding

Two pertinent resources were located:

1. Kaur, L., Gordon, M., Baines, P. A., Iheozor-Ejiofor, Z., Sinopoulou, V., & Akobeng, A. K. (2020). Probiotics for induction of remission in ulcerative colitis. *Cochrane Database of Systematic Reviews, 3*(3), CD005573. https://doi.org/10.1002/14651858.CD005573.pub3

2. Iheozor-Ejiofor, Z., Kaur, L., Gordon, M., Baines, P. A., Sinopoulou, V., & Akobeng, A. K. (2020). Probiotics

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

for maintenance of remission in ulcerative colitis. *Cochrane Database of Systematic Reviews, 3*(3), CD007443. https://doi.org/10.1002/14651858.CD007443.pub3

When comparing efficacy of probiotics in the induction of remission 14 studies with 865 randomized participants were included. Twelve of the studies looked at adult participants, and two studies looked at pediatric participants with mild to moderate ulcerative colitis; the average age was between 12.5 and 47.7 years. When comparing efficacy of probiotics in the maintenance of remission, 12 studies with 1,473 randomized participants that met the inclusion criteria were included. Participants were mostly adults. Lowcertainty evidence suggests that probiotics may induce clinical remission in active ulcerative colitis (UC) when compared to placebo. There may be little or no difference in clinical remission with probiotics alone compared to 5ASA. The effectiveness of probiotics for the maintenance of remission in UC remains unclear. Maintenance of remission is low to very lowcertainty evidence from poorly conducted studies, which contribute limited amounts of data from a small number of participants.
Strength of Evidence: Level I: Systematic review
Recommendations: After conducting an assessment of the current literature you note that probiotics may be better at inducing remission than placebo (dummy treatment). It is unclear whether probiotics are better than 5aminosalicylic acid (5ASA), an antiinflammatory agent used to treat inflammatory bowel disease; however, there is limited evidence that when both treatments are used as combined therapy, they may be better than 5ASA alone in inducing remission. It is uncertain as to whether probiotics can maintain remission in people with UC once an exacerbation has subsided. You discussed the findings with the nurse educator and decide to present your findings to the unit during an educational in-service.

- Keep food hot after cooking; maintain the safe temperature of 140°F or above.
- Give only pasteurized fruit juices to young children (age <5 years) and other people who are at higher risk for food poisoning, such as adults older than age 65, people who are immunocompromised, pregnant women.

PREVENTING AND MANAGING TRAVELER'S DIARRHEA

Traveler's diarrhea (TD) is the most predictable travel-related illness (Connor, 2019). Risk increases when a person travels to a place where the climate or sanitary practices are different from those of their home (MFMER, 2019a). TD is caused by bacterial enteropathogens, viruses, or parasites, acquired from eating contaminated food or drinking contaminated water (MFMER, 2019a). Symptoms usually begin suddenly and may appear during the time of travel or shortly after the person returns home (MFMER, 2019a), and include more than three loose stools in a 24-hour period, fever, nausea, vomiting, and abdominal cramps and/or pain. Diarrhea caused by certain pathogens may also include bloody stools.

Management includes education about prevention and self-treatment strategies. Frequent handwashing with soap and water where available is important. Small containers of alcohol-based hand sanitizer containing ≥60% alcohol should be used when handwashing is not possible (Connor, 2019). Advise patients to peel fruits and vegetables and consume dry foods and foods that are piping hot and cooked thoroughly. Tell travelers to avoid tap water, ice cubes, fruit juice, unpeeled raw fruits and vegetables, unpasteurized dairy products, open buffets, and undercooked or reheated foods. Safe beverages include those that are commercially bottled and factory-sealed (Griffin & Hill, 2019). Boiled beverages and those appropriately chemically treated and disinfected are also safe to drink (Griffin & Hill, 2019).

Bismuth subsalicylate has been shown to reduce the incidence of TD by 50% and is recommended as a prophylaxis for traveler's diarrhea (Connor, 2019). Travelers with aspirin allergy; renal insufficiency and gout; and those taking anticoagulants, probenecid, or methotrexate should not take bismuth subsalicylate (Connor, 2019). It is not recommended for children younger than age 12 years or for pregnant women (Connor, 2019) and should not be taken for longer than 3 weeks (MFMER, 2019a). Use involves four times/day dosing; this inconvenient dosing contributes to decrease practicality of use (Connor, 2019). Prophylactic antibiotics are not recommended for most travelers (Connor, 2019).

Table 39-3 Classification of Antidiarrheal Medications

CATEGORY	NAME	ACTION	ADVANTAGES	CAUTIONS
Opioid-receptor agonists	Diphenoxylate and atropine	Slows gastric motility through local effect on GI wall	Effective	Should not be used if antibiotic-associated diarrhea such as *C. difficile* is suspected The anticholinergic effects can lead to changes in the patient's level of

				consciousness, increasing the risk for confusion and falls. For this reason, best to avoid in older adults There are also many drug interactions with anticholinergic medications, which can lead to CNS changes Avoid in patients taking opioids as it can increase constipation and urinary retention
	Loperamide	Inhibits peristalsis via direct effect on GI wall muscles; may also have an antisecretory property	Longer duration than diphenoxylate and atropine	Should not be used if antibiotic-related diarrhea such as *C. difficile* is suspected May be used in the older adult Higher-than-recommended doses have been shown to increase serious cardiac events such as prolonged QT, leading to life-threatening arrhythmias May cause drowsiness Should be discontinued if no improvement in 48 hours with acute illness
Antisecretory/antimicrobial	Bismuth subsalicylate	Decreases GI tract secretion Has antimicrobial action against bacterial and viral pathogens	No drowsiness	Requires frequent dosing Contains salicylates. Not to be given to children under 12 years. Check with health care provider in adolescents or when administering to patients using aspirin or other products that contain aspirin. Contraindicated for pregnant women May decrease absorption of some medications Will turn stool black

Treatment strategies include maintaining hydration with bottled beverages or treated with chlorine, boiled, or otherwise known to be purified and/or oral rehydration solutions; antimotility agents, such as loperamide and

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

diphenoxylate; and antibiotics (Connor, 2019). The use of antibiotics and/or antimicrobials should be based on severity of illness and etiologic agent (Brewer, 2018; Connor, 2019). Antimotility agents should be avoided in those with bloody diarrhea or who have diarrhea and fever.

Adult patients should see a health care professional if the patient (MFMER, 2019a):

- Has diarrhea persisting beyond 2 days
- Becomes dehydrated
- Has bloody or black stools
- Has a fever above 102°F

Children should see a health care professional if the patient has (MFMER, 2019a):

- Persistent vomiting
- Fever of 102°F or more
- Bloody stools or severe diarrhea
- Dry mouth or crying without tears
- Signs of being unusually sleepy, drowsy, or unresponsive
- Decreased volume of urine, including fewer wet diapers in infants

Encourage patients considering travel to underdeveloped countries to discuss their personal risks and the provision of prescription medication with their health care provider before beginning their travels.

Decreasing Flatulence

Formation of gases in the stomach or intestines is a result of normal breakdown of certain undigested foods in the large intestine or from swallowing of air when eating and drinking (Cleveland Clinic, 2020b). Burping or belching is the way most swallowed air leaves the stomach. Some gas moves into the small intestine where it is partially absorbed, and a small amount travels into the large intestine for release through the rectum **flatulence** (Cleveland Clinic, 2020b). Additional gas is produced when undigested carbohydrates move into the large intestine, where harmless and normal bacteria break down the food, producing hydrogen, carbon dioxide and, in about one third of all people, methane (Cleveland Clinic, 2020b). Eventually, these gases exit through the rectum. When the gas is not expelled but accumulates in the intestinal tract, the condition is referred to as intestinal distention. Gas-producing foods include most foods that contain carbohydrates; fats and proteins cause little gas (Cleveland Clinic, 2020b). Foods that often predispose a person to flatulence and distention include beans; vegetables, including broccoli, Brussels sprouts, artichokes, cabbage, onions, asparagus, and cauliflower; fruits, such as pears, apples, and peaches; whole grains, including whole wheat and bran; carbonated drinks and beer; milk and milk products, including cheese and ice cream; and foods containing sorbitol, such as dietetic foods and sugar-free candy and gum (Cleveland Clinic, 2020b; MFMER, 2020d). Foods that produce symptomatic gas in one person may not cause symptoms in another. Continued flatulence associated with unintended weight loss, fever, loss of appetite or feeling full quickly, chest discomfort, or change in bowel habits should be evaluated by the patient's health care provider for the presence of an underlying digestive disorder (MFMER, 2020d).

Teach patients about dietary adjustments through trial and error to avoid foods that cause increased flatulence. Several over-the-counter medications are available to help reduce flatulence. Antacids with simethicone or activated charcoal and supplements with digestive enzymes can help reduce symptoms (Cleveland Clinic, 2020b). Other possible interventions include the use of bismuth subsalicylate for short-term use to reduce odor; probiotics in yogurt and commercial supplements; and exercise to peristalsis and the escape of flatus.

Recall **Alberta Franklin**, the patient described in the Reflective Practice display. The nurse should include information about eliminating gas-producing foods in this patient's teaching plan to avoid excess gas formation and accumulation, which could cause the colostomy bag to overfill and possibly lead to detachment and leakage.

Emptying the Colon of Feces

Several methods are used to help promote elimination of feces: enemas, suppositories, oral intestinal lavage, and digital removal of stool. Discussion of each of these methods follows.

ENEMAS

An **enema** is the introduction of a solution into the large intestine, usually to remove feces. The instilled solution distends the intestine and irritates the intestinal mucosa, thus increasing peristalsis. An enema can also be used to administer certain medications. Enemas are generally classified as cleansing or retention enemas and should only be used occasionally (Mitchell, 2019b). Rectal agents should be avoided in patients at risk of thrombocytopenia, leukopenia, and/or mucositis and manipulation of the rectum and anus, including administration of enemas, should be avoided in immunocompromised patients and/or patients at risk for myelosuppression and mucositis (NCI, 2020). These actions can lead to development of anal fissures or abscesses, which are portals for infection (NCI, 2020). Enemas are also contraindicated for patients with bowel obstruction or paralytic ileus (Mitchell, 2019b) and in situations where administration could cause circulatory overload, mucosal damage, necrosis, perforation, or hemorrhage or following any GI or gynecological surgery in which sutures may be ruptured (Doughery & Lister, 2015, as cited in Mitchell, 2019b, p. 154).

Cleansing (Evacuant) Enemas

Cleansing enemas are given to remove feces from the colon, commonly to:

- Relieve constipation or fecal impaction
- Evacuate the bowel before surgery to prevent involuntary escape of fecal material during surgical procedures
- Promote visualization of the intestinal tract by radiographic or endoscopic examination

The most common types of solutions used for cleansing enemas are tap water, normal saline solution, soap solution, and hypertonic solution. Commonly used enema solutions are described in Table 39-4.

Hypotonic (tap water) and isotonic (normal saline solution) enemas are large-volume enemas that result in rapid colonic emptying. However, using such large volumes of solution (adults, 500 to 1,000 mL; infants, less than 250 mL [Kyle & Carman, 2021]) may be dangerous for patients with weakened intestinal walls, such as those with bowel inflammation or bowel infection.

Hypertonic solution preparations (phosphate and sodium citrate enemas) are available commercially and are administered in smaller volumes (adult, 118 to 197 mL). These solutions draw water into the colon, which stimulates the defecation reflex. They may be contraindicated in patients for whom sodium and/or water retention is a problem (NICE, 2017, as cited in Mitchell, 2019b, p. 154). Phosphate enemas should not be used in older adults (Toughy & Jett, 2018). Hypertonic solution enemas are also contraindicated for patients with renal impairment or reduced renal clearance because such patients have compromised ability to excrete phosphate adequately, with resulting hyperphosphatemia (Dougherty & Lister, 2015, as cited in Mitchell, 2019b, p. 154).

Retention Enemas

Retention enemas are retained in the bowel for a prolonged period for different reasons:

- Oil-retention enemas: soften the stool and lubricate the intestinal mucosa, making defecation easier (Bauldoff et al., 2020). About 150 to 200 mL of solution is administered to adults.

Table 39-4 Commonly Used Enema Solutions

SOLUTION	AMOUNT	ACTION	TIME TO TAKE EFFECT (MINUTES)	ADVERSE EFFECTS
Tap water (hypotonic)	500–1,000 mL	Distends intestine, increases peristalsis, softens stool	15	Can lead to fluid and electrolyte imbalance, water intoxication Should not be used in children
Normal saline (isotonic)	500–1,000 mL	Distends intestine, increases peristalsis, softens stool	15	
Soap	500–1,000 mL (concentrate at 3–5 mL/1,000 mL)	Distends intestine, irritates intestinal, which stimulates peristalsis mucosa, softens stool	10–15	Must only use castile soap, other soaps will cause significant rectal mucosa irritation or damage
Phosphate	70–130 mL	Draw fluids out of the	5–10	Avoid in patients who are

(hypertonic)		interstitial space into the colon, leading to distention, which stimulates peristalsis. Commonly used, commercially prepared		dehydrated or where phosphate retention could be a concern Can be irritating to rectum
Oil (mineral, olive, or cottonseed oil)	150–200 mL	Lubricates stool and intestinal mucosa; often used as a retention enema If able, patient may need to hold solution for 30–60 minutes	30	

- Carminative enemas: help to expel flatus from the rectum and provide relief from gaseous distention. Common solutions include the milk and molasses enema (equal parts) (Wanfui-Verry et al., 2019) and the soap-solution enema (Bauldoff et al., 2020).
- Medicated enemas: provide medications that are absorbed through the rectal mucosa.

Equipment

Commercially prepared enema kits include a flexible bottle containing hypertonic solution with an attached, prelubricated firm tip about 5 to 7.5 cm (2 to 3 inches) long. Its ease of use makes it particularly convenient in the home. In many instances, patients can administer their own enema.

Tap water, saline solution, and soap solution enemas are administered using a container, rubber or plastic tubing with side openings near its distal end, a tubing clamp, lubricant, and the prescribed solution. Regardless of the type of enema to be given, clean technique is used. Always wear or have the caregiver wear disposable gloves to protect from exposure to blood, body fluids, and microorganisms.

Patient Preparation

Some patients already know why enemas are used and how they are administered. Reinforce this information and correct any misconceptions that they may have. For patients who have not previously had an enema, explain the purpose, what they can expect, and how they can participate. In all cases, administration of medications using the rectal route can be embarrassing for the patient; it is essential to provide for patient privacy (Mitchell, 2019b). The procedure offers an excellent opportunity for health teaching because many people are unfamiliar with or uncomfortable talking about the functioning of the intestinal tract. Failure to provide explanations and protect privacy may result in an uncomfortable and disagreeable situation for the patient.

A reclining position is recommended for enema administration—specifically left side–lying with the knees flexed and the upper thigh pulled toward the abdomen if possible (Mitchell, 2019b), but if the patient has a respiratory disorder or is having difficulty breathing, elevate the head of the bed slightly. Avoid Fowler position because the solution will remain in the rectum, and expulsion will occur rapidly, resulting in minimal cleansing. Some patients think the solution should be expelled as soon as possible. Reinforce the need to retain the solution to enhance the evacuant effect (Dougherty & Lister, 2015, as cited in Mitchell, 2019b, p. 156).

Administration Using a Hypotonic or Isotonic (Large-Volume) Solution

The procedure for administering a cleansing enema using a large volume of solution is described in Skill 39-1 (on pp. 1555–1560).

Administration Using a Hypertonic (Small-Volume) Solution

Administering a cleansing enema using a hypertonic solution differs from the procedure described in Skill 39-1 (on pp. 1555–1560) in the following ways:

- The equipment is included in the commercially prepared set. The only additional equipment needed is a bedpan for a bedridden patient; an easily accessible commode in case the patient has an urgent need to expel the enema; and a disposable waterproof pad to protect bed linens (Mitchell 2019b).
- Place the patient in the left side–lying position lying with their knees flexed and the upper thigh pulled toward the abdomen if possible (Mitchell, 2019b). Additional lubrication of the rectal tip is recommended, even though it is prelubricated.
- Slowly insert the nozzle to the depth of 4 to 5 inches (10 to 12.5 cm) (Mitchell, 2019b). Instill the solution into the rectum by applying gentle pressure on the collapsible solution container, squeezing from the bottom to the nozzle (Fig. 39-6). It should take 1 to 2 minutes to administer the enema. Withdraw the nozzle slowly.
- Administer the hypertonic enema solution cautiously to a patient with hemorrhoids. The rigid tip may tear fragile

rectal mucosa that is enlarged and inflamed, causing pain, torn rectal tissue, and necrosis. Generous lubrication is recommended before inserting the enema tip.

Administration of an Oil-Retention Enema

The procedure for giving an oil-retention enema differs from that for giving a cleansing enema in the following respects:

- A small nozzle is used. The small size helps to reduce intestinal contractions so that the patient can retain the oil more easily. Oil enemas are available in commercial kits similar to those for hypertonic-solution enemas.
- Administer the oil-retention enema at body temperature to minimize muscle contractions caused by a warmer or cooler solution.
- Instruct the patient to retain the oil for at least 30 minutes for best cleansing results.
- A cleansing enema may be prescribed after an oil-retention enema to facilitate emptying of the bowel.

FIGURE 39-6. Technique for compressing a small-volume enema container.

RECTAL SUPPOSITORIES

A **suppository** is a conical or oval solid substance shaped for easy insertion into a body cavity and designed to melt at body temperature. Various rectal suppositories are available. Suppositories can be used to stimulate the bowel in a constipated patient. Suppositories can also be used to deliver drug therapy and can be used to deliver medications such as antipyretics when the patient is unable to take them orally (Mitchell, 2019c). Refer to Chapter 30 for Guidelines for Nursing Care 30-6.

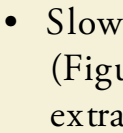
ORAL INTESTINAL LAVAGE

Oral polyethylene glycol solutions (PEG) can be used to cleanse the intestine of feces. This solution is prescribed by the health care provider and can be administered before visual examination of the GI tract, such as with a colonoscopy or sigmoidoscopy, or as a preparation (emptying) of the bowel before intestinal surgery (Karch, 2020). Evacuation of feces may begin within 1 hour after the first glass and is completed within 3 to 6 hours (Karch, 2020). As with an enema, a clear return indicates that the bowel preparation is complete. A clear diet for 24 hours before taking this solution lessens the time needed for completion of the bowel prep, but potassium replacement may be required before surgery because of the limited potassium in a clear diet. The solution has a slightly salty taste and is easier to tolerate if it is cold and consumed quickly. Carefully assess older adults using oral intestinal lavage because they are more prone to electrolyte imbalances (Toughy & Jett, 2018).

DIGITAL REMOVAL OF STOOL

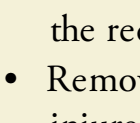
Fecal impaction, most often caused by constipation, prevents the passage of normal stools. Small amounts of fluid may pass around the impacted mass; liquid fecal seepage with no passage of normal feces is a sign of an impaction. Older adults who are hospitalized or under institutional care, patients who are immobile, and patients who have scleroderma, chronic renal failure, spinal cord injury, or other health conditions that damage the nerves that innervate the muscles of the intestines are at high risk for fecal impaction (Falcón et al., 2016; MedlinePlus, 2022a; Setya et al., 2021).

Digital (manual) removal of feces is an invasive procedure that involves the manual removal of feces from the rectum using a gloved finger (Dougherty & Lister, 2015, as cited in Mitchell, 2019d, p. 430). Include dietary interventions, adequate fluids, and adjustment of medication in the patient's care plan before considering digital removal of feces (Mitchell, 2019d). If a patient with a fecal impaction cannot expel the fecal mass voluntarily and oil-retention and cleansing enemas fail to break up the mass, the impaction may need to be removed manually. Digital removal of stool is a prescribed intervention. This procedure is embarrassing and very uncomfortable and may cause



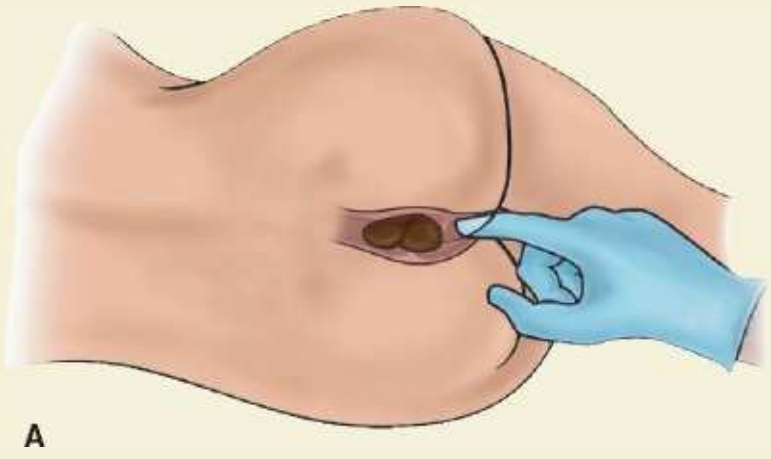
for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

great discomfort and pain to the patient as well as irritation of the rectal mucosa and bleeding (Mitchell, 2019d). Digital removal of a fecal mass can stimulate the vagus nerve, resulting in a slowed heart rate (Mitchell, 2019d). If this occurs, stop the procedure immediately, monitor the patient's heart rate and blood pressure, and notify the health care team. Many patients find that a sitz bath or tub bath after this procedure soothes the irritated perineal area. The health care team may order an oil-retention enema to be given before the procedure to soften stool. The procedure for digital (manual) removal of a fecal impaction is outlined in the Guidelines for Nursing Care 39-1.

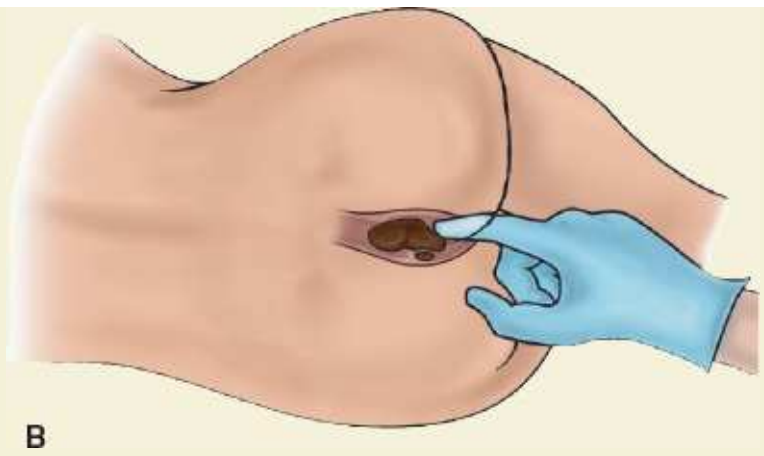


Guidelines for Nursing Care 39-1

Digital Removal of Fecal Impaction



To manually remove a fecal impaction, the following technique is recommended:



- Perform hand hygiene and put on PPE, if indicated.

- Identify the patient.
- Close the door to the room and pull the privacy curtain.
- Explain what you are going to do, and why you are going to do it to the patient.
- Have a second person assist with the procedure. The second person can reassure and comfort the patient while the first person works to break up the mass.
- Encourage/assist the patient to empty their bladder.
- Place the patient in a left side-lying position. Drape the patient to preserve privacy yet provide easy access. Place a protective pad under the patient. Remove the patient's clothing from the waist down.
- Place a bedpan on the bed for depositing removed feces. Have toilet paper and personal cleaning supplies on hand for use after the procedure is completed.
- Put on gloves.
- Assess the anal area for evidence of skin soreness, swelling, bleeding, discharge, prolapse, excoriation, and hemorrhoids. If any abnormalities are present, do not continue with the procedure (Mitchell, 2019d). Confer with the health care team.
- Lubricate the index finger generously to reduce irritating the rectum and insert the finger gently into the anal canal (Figure A). The presence of the finger added to the mass tends to cause discomfort for the patient if the work is not done slowly and gently.
- Slowly and gently, work the finger around in circular movements and into the hardened mass to break it up (Figures B and C), then remove pieces of it (Figure D). Instruct the patient to bear down, if possible, while extracting feces to ease in removal. Avoid using a hooked finger to remove feces, as this may cause damage to the rectal mucosa and anal sphincter (Mitchell, 2019d).
- Remove the impaction at intervals if it is severe. This helps to avoid discomfort as well as irritation, which can injure intestinal mucosa.
- Use an oil-retention enema, if necessary. The enema may be given before attempts are made to break up and remove the impaction digitally, or it may be ordered after digital attempts fail. A cleansing enema is often ordered after an oil-retention enema.
- Wash and dry the patient's buttocks and anal area. Assist the patient to a comfortable position.

A Inserting gloved, lubricated finger into fecal mass.

B Slowly and gently using finger to break up some of the hardened mass.

C Breaking off a section of the impaction.

D Removing a section of the impaction.

Managing Bowel Incontinence

Bowel incontinence or fecal incontinence is the loss of voluntary control of defecation (Bauldoff et al., 2020), the inability of the anal sphincter to control the discharge of fecal and gaseous material. The cause of incontinence may be related to loss of sphincter tone, such as changes in the function of the rectum and anal sphincter related to aging; neurologic injury or disease; local trauma, such as obstetric tears; inflammation as a result of infection or radiation; and the presence of tumors (Bauldoff et al., 2020; Palmer, 2019; Yates, 2019). The patient may not be able to perceive the urge to move the bowels or completely empty the rectum after a bowel movement, which can also result in incontinence. Alternations in mental health may also cause a patient to be indifferent to the passage of stool. Although bowel incontinence is seldom life threatening, it can be a distressing and undignified experience (Palmer, 2019). Patients with bowel incontinence suffer embarrassment, may become depressed, and may pose a challenge for nurses because of the risk for alterations in skin integrity (Bauldoff et al., 2020; Fisher & Himan, 2020; Voegeli, 2018). (Refer to the discussion regarding incontinence-associated dermatitis in the next section.)

The following nursing interventions are helpful for a patient who experiences bowel incontinence:

- Note when incontinence is most likely to occur and assist the patient to the bathroom or commode at those times. If there is no pattern, offer toileting at regular intervals, such as every few hours (Francis, 2018).
- Keep the skin clean and dry by using proper hygienic measures. Apply a protective skin barrier after cleaning the skin, according to the manufacturer's directions. Impaired skin integrity may develop when such measures are overlooked. Refer to the following discussion regarding incontinence-associated dermatitis.
- Change bed linens and clothing as necessary to avoid odor, skin irritation, and embarrassment. Disposable bed pads and moisture-proof undergarments can be considered but should not be used until other measures have been tried. These materials often worsen any skin irritation or breakdown present as a result of skin contact with stool by retaining moisture against the skin, raising the pH of the skin, and prolonging contact of the stool against the skin, increasing damage from digestive enzymes present in the stool (Gump & Schmelzer, 2016; Voegeli, 2018).

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

- Bowel-training programs may also be helpful. Bowel-training programs are discussed later in the chapter.

INCONTINENCE-ASSOCIATED DERMATITIS

Prolonged contact of the skin with urine or feces leads to a form of moisture-associated skin damage (MASD) known as **incontinence-associated dermatitis (IAD)** (Fisher & Himan, 2020). Erythema, maceration, denuding, and inflammation occur as a result of exposure to urine or stool and may affect the skin of the perineum, perianal area, buttocks, inner thighs, sacrum, and coccyx (Jacobson & Wright, 2015; Voegeli, 2018). Incontinence and resulting excessive moisture also contribute to pressure injury formation, particularly pressure injury of the sacral area (Gray & Giuliano, 2018; Jacobson & Wright, 2015; Lachenbruch et al., 2016). Symptoms of IAD include erythema with poorly defined edges located in patches on the skin or continuously over large areas and the skin may feel warmer and firmer than the surrounding unaffected skin (Beeckman et al., 2015; Francis, 2018; Voegeli, 2018) (Fig. 39-7). In patients with darker skin tones, skin may appear paler, darker, purple, dark red, or yellow when compared with the surrounding area (Beeckman et al., 2015; Fisher, 2020). Edema and lesions may be present, including vesicles, bullae, papules, or pustules. The epidermis may be damaged to varying depths, with patients reporting discomfort, pain, burning, itching, or tingling (Beeckman et al., 2015; Francis, 2018; Jacobson & Wright, 2015). In addition to discomfort and pain, patients may experience loss of independence, alterations in activities and sleep, reduced quality of life, and secondary skin infections (bacterial and fungal) (Beeckman et al., 2015; Fisher, 2020; Voegeli, 2018).

FIGURE 39-7. Incontinence-associated dermatitis (IAD). (*Source:* Wound, Ostomy and Continence Nurses Society®. *Core Curriculum: Continence Management*, 2nd ed.)

Skin care and use of nonocclusive absorbent products designed for incontinence to wick moisture away from the skin are critical pieces of evidence-based nursing care to prevent and treat IAD (Beeckman et al., 2015; Jacobson & Wright, 2015; Voegeli, 2018). Appropriate skin care involves a structured skin care regimen that includes regular skin assessment, skin cleansing, moisturizers or emollients to replenish and restore lipids in the skin, and the use of skin barrier protectants to proactively protect the skin from stool-associated irritation, maceration (overhydration), and breakdown (Southgate & Bradbury, 2016; Voegeli, 2018; Yates, 2018b).

Cleansing of the skin should be provided daily and after each episode of incontinence, using skin cleansers that are specially designed for at risk or compromised skin, are pH balanced and may be no-rinse (Beeckman et al., 2015; Southgate & Bradbury, 2016; Voegeli, 2018; Yates, 2018b). Avoid using soap and water as these can be irritating, drying, and alter the skin's pH, contributing to irritation (Yates, 2018b). Avoid excessive friction on the skin, such as through scrubbing, as this can damage the skin (Jacobson & Wright, 2015; Southgate & Bradbury, 2016). Limit the use of disposable briefs; incontinence products that wick moisture away from the skin may be used as necessary (Jacobson & Wright, 2015). A skin barrier/protectant should be applied to all skin that comes into contact or potentially comes into contact with stool after cleansing to prevent direct contact with stool and to promote resolution

of IAD if present (Beeckman et al., 2015; Voegeli, 2018). Products are available that are "all-in-one," ensuring all steps of skin care are implemented and include a disposable soft cloth that contains cleanser, moisturizer, and barrier, for example (Francis, 2018). Patients with complicated IAD that does not respond to treatment with 2 weeks should be referred to an advanced practice wound specialist, such as a wound ostomy continence nurse or dermatologist (Francis, 2018).

Additional information and discussion related to incontinence and skin care can be found in Chapters 32 and 33.

INDWELLING RECTAL TUBE

A fecal management system (or bowel management systems with an indwelling rectal catheter) may be used for patients with uncontrollable diarrhea who are very ill, receiving palliative care at the end of life, or confined to bed (Palmer, 2019). A tube inserted into the rectum directs loose stool into a collection bag (Palmer, 2019). However, relatively little research supports the safety of these systems, and they should be used with caution (Whiteley & Sinclair, 2014). Disadvantages of indwelling rectal tubes include leakage and perirectal skin damage, injury to the rectal mucosa, and injury of the anal sphincter (Continence Product Advisor, 2021). The fecal incontinence device, discussed in the next section, may be a safer alternative.

EXTERNAL ANAL POUCH

Use of an external anal pouch provides the means to protect perianal skin from repeated episodes of fecal incontinence of very loose stool (Powers & Zimmaro Bliss, 2012). This pouch has a flexible wafer with an opening at its center. One side of the wafer adheres to the skin around the anus and the other side is connected to a collection bag (Palmer, 2019). The bag has a port to empty stool without removing the wafer from the skin and the port can be attached to gravity drainage, allowing liquid stool to accumulate in a collection bag (Palmer, 2019) (Fig. 39-8). It is best applied before the perianal area becomes excoriated. If excoriation is already present, application of a skin barrier prior to applying the pouch may be helpful. Disadvantages of these devices include the risk of skin damage from the adhesive on the perianal skin (Continence Product Advisor, 2021).

Removing paper backing from adhesive of rectal pouch.

Applying pouch over anal opening.

Attaching connector of fecal pouch to tubing of drainage bag.

FIGURE 39-8. Applying a fecal incontinence device.

Nursing responsibilities include careful regular assessment and documentation of the perianal skin condition and attentive management of the drainage system. Change the pouch if it is not intact or leakage has occurred. Provide explanations and support to the patient and family/caregivers so that they understand the use of this system.

Implementing Bowel-Training Programs

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

Patients with a history of chronic constipation and impaction and those who are incontinent of stool may benefit from a **bowel-training program**. The purpose of this program is to manipulate factors within the person's control (food and fluid intake, exercise, time for defecation) to produce the elimination of a soft, formed stool at regular intervals without a laxative. Kegel exercises (refer to p. 1465 in Chapter 38) and biofeedback may also be used to strengthen pelvic and rectal muscle tone (Phillips, 2020). This effort to regain bowel control may be initiated in the health care setting or the patient's home. When the patient has established a regular pattern of defecation, continue to offer assistance with toileting. A bowel-training program may include the following interventions:

- Plan bowel program with patient and appropriate family members/caregivers.
- Set a regular time for daily bowel movements that is convenient for the patient; consider timing of 20 to 40 minutes after a meal, as eating stimulates bowel activity (Phillips, 2020).
- Monitor bowel movements including frequency, consistency, shape, volume, and color, as appropriate.
- Some patients may benefit from stimulating bowel movements by using a suppository or small enema; drinking warm prune juice or fruit nectar may also be helpful (Phillips, 2020).
- Ensure privacy.
- Use digital stimulation to trigger a bowel movement: Insert a gloved, lubricated finger into the anus and make a circular motion until the sphincter relaxes. Try to contract the muscles of the abdomen and bear down; bending forward on the toilet may be helpful. If the patient does not have a bowel movement within 20 minutes, they should repeat the process (National Association for Continence, n.d.; Phillips, 2020). The patient should perform digital stimulation every day until a pattern of regular bowel movements is established (National Association for Continence, n.d.; Phillips, 2020).
- Encourage adequate fluid intake 2,000 to 3,000 mL/day (Phillips, 2020).
- Teach about foods that promote bowel regularity.

Maintaining a Nasogastric Tube

A **nasogastric (NG) tube** is a pliable single- or double-lumen (inner open space) plastic tube that is hollow, allowing for the removal of gastric secretions and instillation of solutions such as medications or feedings into the stomach. Use of NG tubes for nutritional support is discussed in Chapter 37. Instillation of medications using an NG tube is discussed in Chapter 30.

NG tubes may be inserted to decompress or drain the stomach of fluid or unwanted stomach contents such as poison or medication and air (Burns & Delgado, 2019), and may be used when conditions are present in which peristalsis is absent. Examples include paralytic ileus and intestinal obstruction by tumor or hernia, and adhesive small bowel obstruction (ten Broek et al., 2018). NG tubes may also be used to allow the GI tract to rest before or after abdominal surgery to promote healing (Bauldoff et al., 2020). Historically, an NG tube was often used postoperatively as a routine part of care after major abdominal surgery, to rest the intestinal tract and promote healing. Research now shows the routine use of NG tubes after abdominal surgery may serve no beneficial purpose and may actually delay the patient's progress, increasing the time required for flatus to occur and increasing pulmonary complications (Hodin & Bordeianou, 2020; Kantrancha & George, 2014; Sigmon & An, 2020; Venara et al., 2020). Decompression should be reserved for patients with conditions such as a prolonged postoperative ileus or a small bowel obstruction (Hodin & Bordeianou, 2020).

The NG tube is passed through the nasopharynx into the stomach. Tubes for decompression typically are attached to suction. Suction can be applied intermittently or continuously. When the underlying condition has been resolved and/or the NG tube is no longer indicated, the tube is removed. Skill 39-2 (on pp. 1560–1565) describes the procedure for NG tube insertion. Skill 39-3 (on pp. 1566–1568) outlines for the procedure for removal of an NG tube.

Double-lumen tubes are used for gastric decompression (Sigmon & An, 2020) (Fig. 39-9). One larger lumen empties the stomach via suction, and the other provides for a continuous flow of air (acting as a sump) (Sigmon & An, 2020). The airflow lumen controls suction by preventing the drainage lumen from pulling stomach mucosa into the tube's openings and irritating the stomach lining. A one-way antireflux valve may be used in the airflow lumen to prevent reflux of gastric contents through the airflow lumen (see Fig. 39-9). When pressure from gastric contents enters the airflow tubing, the valve closes to prevent secretions from exiting the tube.

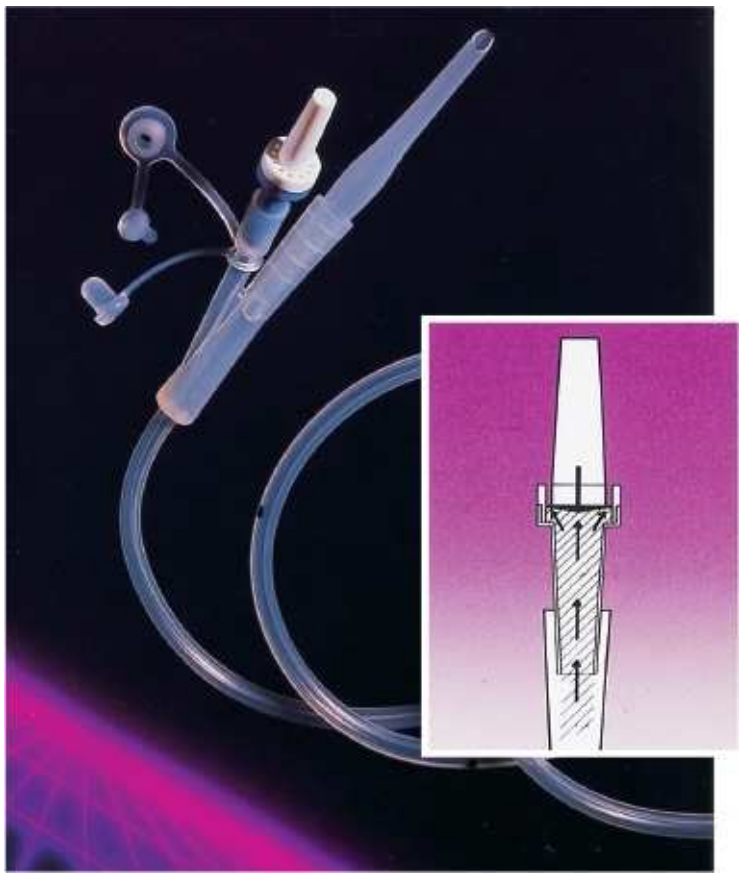


FIGURE 39-9. Double-lumen nasogastric tube. Insert on right shows close up of a one-way antireflux valve.

NG tubes used for decompression require irrigation with 30 to 60 mL of normal saline solution every 4 to 8 hours to maintain patency. Skill 38-4 (on pp. 1568–1572) describes the procedure for irrigating an NG tube connected to suction.

PROMOTING PATIENT SAFETY

Nasogastric tube placement must be verified before administration of any fluids or medications to promote patient safety (Judd, 2020). This decreases the risk that the tip of the tube is situated in the stomach or intestine, preventing inadvertent administration of substances into the wrong place. Radiographic examination, measurement of tube length, measurement of tube marking, measurement of aspirate pH, and monitoring of carbon dioxide have been suggested to confirm feeding tube placement. The use of two or more of these techniques in conjunction increases the likelihood of correct tube placement (AACN, 2020; Anderson, 2019; Anderson, 2018; Dias et al., 2019; Rahimi et al., 2015). Recommendations for use of visual inspection of gastric aspirate are conflicting; this method should be used cautiously if part of policy and procedure guidelines and with consideration to the potential for inaccuracy (AACN, 2020; Dias et al., 2019; Mak & Tam, 2020; Metheny et al., 2019). When bedside methods to check placement suggest the tube has been displaced, a radiograph should be requested to determine the tube's location (AACN, 2020). An old technique of auscultation of air injected into a feeding tube has been proved unreliable and should not be used (AACN, 2020; Anderson, 2018; Boeykens et al., 2014; Boullata et al., 2017; Irving et al., 2018; Metheny et al., 2019).

A detailed discussion of each of these methods to confirm placement is provided in Chapter 37. Radiographic examination (x-ray) to confirm placement is the standard method for checking if the NG tube is in the stomach, but often it is only ordered on initial placement, and many times is not prescribed for NG tubes inserted for decompression. Placement must be checked frequently while the tube is in place, and repeated, frequent radiographs are not practical (Boullata et al., 2017).

Another way to verify tube placement is to mark the tube with an indelible marker at the nostril and measure the length of the exposed tube after insertion. Document this measurement (AACN, 2020; Dias et al., 2019). Check and compare tube length with this initial measurement, in conjunction with the previous two methods for checking tube placement. Observe for a change in the external tube length at regular intervals and before use (AACN, 2020). Any change in the length of the exposed tube may indicate dislodgement (AACN, 2020; Boullata et al., 2017).

Testing of the pH of gastric secretions aspirated from the tube is recommended to verify gastric tube placement (AACN, 2020; Dias et al., 2019; Irving et al., 2018; Metheny et al., 2019). Guidelines for Nursing Care 37-1 outlines the procedure for assessing gastric aspirate pH.

Monitoring for carbon dioxide to determine NG tube position and/or dislodgement has been evaluated (Hess et al., 2021). This involves the use of a colorimetric end-tidal CO_2 detector to detect the presence of carbon dioxide, which would indicate tube positioning in the patient's airway (Hess et al., 2021). However, a carbon dioxide sensor cannot determine where an NG tube's tip ends in the GI tract (esophagus, stomach, or small bowel) (Hodin & Bordeianou, 2020).

Refer to Chapter 37, pages 1417–1421, for a detailed discussion of each of these methods to confirm placement.

PROVIDING COMFORT MEASURES

Patients with NG tubes often experience discomfort related to irritation to nasal and throat mucosa and drying of the

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

oral mucous membranes. Administer oral hygiene frequently, as often as every 2 to 4 hours, to prevent drying of tissues and to relieve thirst. Frequently offer the patient the opportunity to rinse the mouth with warm water and mouthwash solution. Lubricate the lips generously. Keep the nares clean, especially around the tube, where secretions tend to accumulate. Use a lubricant after cleaning the nares. Help control local irritation from the tube in the throat by offering analgesic throat lozenges or anesthetic sprays, as prescribed. Ensure that the tube is secured to patient's nose and cheek, based on facility policy, to prevent tension and tugging on the tube, causing trauma to the nares, and potential inadvertent displacement or dislodgement (Morton & Fontaine, 2018). Displacement or dislodgement of a tube can lead to aspiration, pneumonia, and sepsis (Powers, 2019). Use of a commercial securement device is recommended (Schroeder & Sitzer, 2019). Refer to Box 37-8 in Chapter 37 (p. 1424) for methods to secure an NGT.

Meeting the Needs of Patients With Bowel Diversions

Patients sometimes undergo surgical procedures to create an opening into the abdominal wall for fecal elimination. The word **ostomy** is a term for a surgically formed opening in an organ of the body. In the case of the GI tract, the intestinal mucosa is brought out to the abdominal wall, and a **stoma**, the part of the ostomy that is attached to the skin, is formed by suturing the mucosa to the skin. An **ileostomy** allows liquid fecal content from the ileum of the small intestine to be eliminated through the stoma. A **colostomy** permits formed feces in the colon to exit through the stoma. Colostomies are further classified by the part of the colon from which they originate. Figure 39-10 shows the location of an ileostomy and various colostomies. In many institutions, if the ostomy surgery is not emergent, patients meet with a specially trained registered nurse called a wound, ostomy, and continence nurse (WOCN). Together, they determine the ideal location for the stoma. Stoma site marking is also completed by colorectal surgeons and other clinicians to select an effective stoma site (Salvadalena et al., 2015). Preoperative stoma site marking is associated with reduced occurrence of stoma and perisomal complications and should be considered part of preoperative care (Hsu et al., 2020; Roveron et al., 2016; Salvadalena et al., 2015).

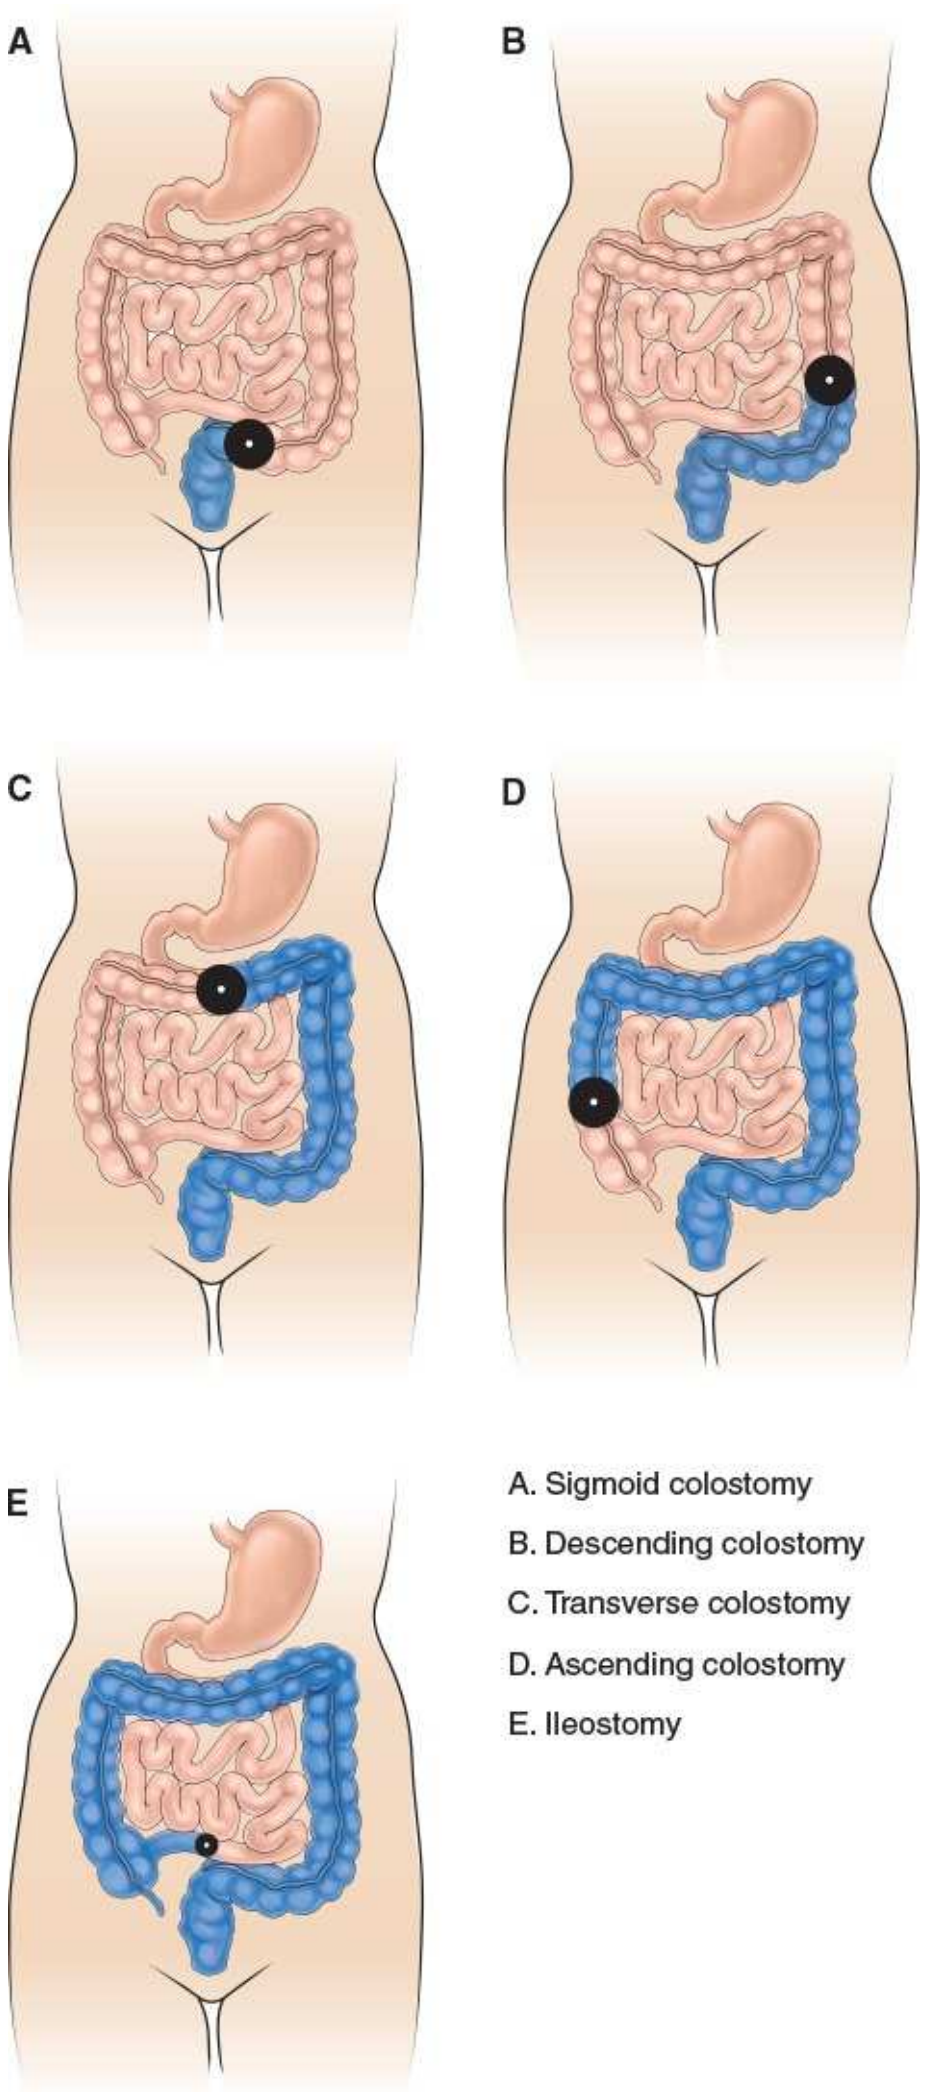

FIGURE 39-10. A–E. Location of various colostomies, and location of an ileostomy. The shaded portions represent the sections of the bowel that have been removed or are currently inactive.

An ileostomy or colostomy may be either temporary or permanent. Temporary ostomies are performed to allow the intestine to repair itself after inflammatory disease, some types of intestinal surgery, or injury. The patient returns for a second surgery in several weeks, and the intestine is reconnected. Permanent ostomies are performed for debilitating intestinal diseases or cancer of the colon or rectum. Patients will have these ostomies for the rest of their lives.

A surgical intervention that does not involve an external stoma is the restorative proctocolectomy ileal pouch–anal anastomosis (IPAA), also called a J pouch or an ileoanal anastomosis. This procedure is an option for use in those patients with inflammatory bowel disease, particularly ulcerative colitis, and patients with hereditary nonpolyposis colorectal cancer and familial adenomatous polyposis (Fichera, 2021). IPAA involves removal of the colon and rectum but leaves the anus sphincter intact. The small intestine is sutured directly to the anus, a colon-like pouch or reservoir is created from the last several inches of the small intestine, and the patient is able to control expulsion of feces through the intact internal and external anal sphincter (Fig. 39-11). The patient often receives a temporary ileostomy, and an adjustment period lasting several months is needed for the newly formed ileoanal reservoir to

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

stretch and adjust to its new function (NIDDK, 2014).

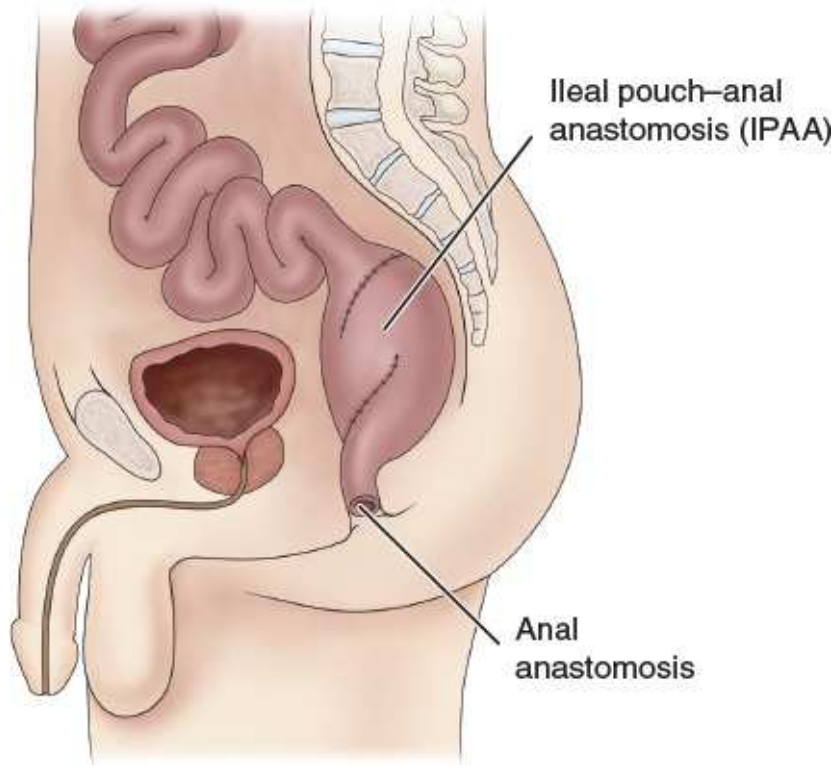

FIGURE 39-11. Ileal pouch–anal anastomosis (IPAA).

COLOSTOMY AND ILEOSTOMY CARE

The patient with an ostomy needs physical and psychological support both preoperatively and postoperatively (Wasserman & McGee, 2017). Support can come from the patient's family/caregivers, members of the health care team, and from people who have had similar experiences. Evidence shows patients who receive consultation preoperatively and care postoperatively from an enterostomal therapy nurse or a WOCN experience better long-term outcomes (Salvadalena et al., 2015). The following guidelines help to promote the ostomy patient's physical and psychological comfort:

- Keep the patient as free of odors as possible. Empty an ostomy appliance before it is half-full to reduce the risk of separation from the skin and leakage (Blevins, 2019; WOCN, 2018).
- Inspect the patient's stoma regularly. Note the size of the stoma, which usually stabilizes within 6 to 8 weeks (Stelton, 2019). It should ideally protrude about 1 to 3 cm above skin level and be dark pink to red in color and moist (Stelton, 2019) (Fig. 39-12). A pale stoma may indicate anemia (Fig. 39-13A), and a dark or purple-blue stoma may reflect compromised circulation or ischemia and may initially appear swollen and edematous. After 6 weeks, the edema has usually subsided. Bleeding around the stoma and its stem should be minimal. The edges of the stoma should appear secure to the surrounding skin (Stelton, 2019). The pulling away of the stoma from the peristomal skin is called mucocutaneous separation or stoma dehiscence (Stelton, 2019) and occurs more often in patients who are at risk for impaired healing, including patients with diabetes, poor nutritional status or who received high-dose steroid therapy or chemotherapy before surgery (Butler, 2009). Notify the health care team promptly if bleeding persists or is excessive, or if color changes occur in the stoma or if it appears the stoma is separating from the peristomal skin (Stelton, 2019).

FIGURE 39-12. Stoma should be dark pink to red and moist. (*Source:* Reprinted with permission from Hill, R., Hall, H., & Glew, P. [2022]. Fundamentals of nursing and midwifery [4th ed.]. Wolters Kluwer; Fig. 44-33.)

- Depending on the surgical technique, the final stoma may be flush with the skin. Erosion of skin around the stoma area can also lead to a flush stoma (Fig. 39-13B). If an abdominal dressing is in place at the surgical incision, check it frequently for drainage and bleeding. The dressing is usually removed after 24 hours.
- Keep the skin around the stoma site (peristomal area) clean and dry. If care is not taken to protect the skin around the stoma, irritation or infection may occur. Assess the peristomal (around the stoma) skin; peristomal skin should be intact and appear consistent with that of the rest of the abdomen, without pain or discomfort (Burch, 2018). In patients with light skin tones, the peristomal skin should not be reddened; in patients with darker skin tones, the skin should not have darker discolorations (Stelton, 2019). A leaking or ill-fitted stoma appliance will cause moisture-associated skin damage (Berti-Hearn & Elliott, 2019) (refer to the discussion earlier in the chapter). Candida or yeast infections can also occur around the stoma if the area is not kept dry.
- Measure the patient's fluid intake and output. Check the ostomy appliance for the quality and quantity of discharge. Initially after surgery, peristalsis may be inhibited. As peristalsis returns, stool will be eliminated from the stoma.
- Explain each aspect of care to the patient and explain what the patient's role will be when beginning self-care. Patient teaching is one of the most important aspects of colostomy and ileostomy care and should include family members, caregivers and/or people identified by the patient to include in care, when appropriate. Teaching can begin before surgery so that the patient has adequate time to absorb information.
- Encourage the patient to participate in care and to look at the ostomy. Patients normally experience emotional depression during the early postoperative period. Help the patient cope by listening, explaining, and being available and supportive. A visit from a representative of the local ostomy support group may be helpful. Patients usually begin to accept their altered body image when they are willing to look at the stoma, make neutral or positive statements concerning the ostomy, and express interest in learning self-care.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

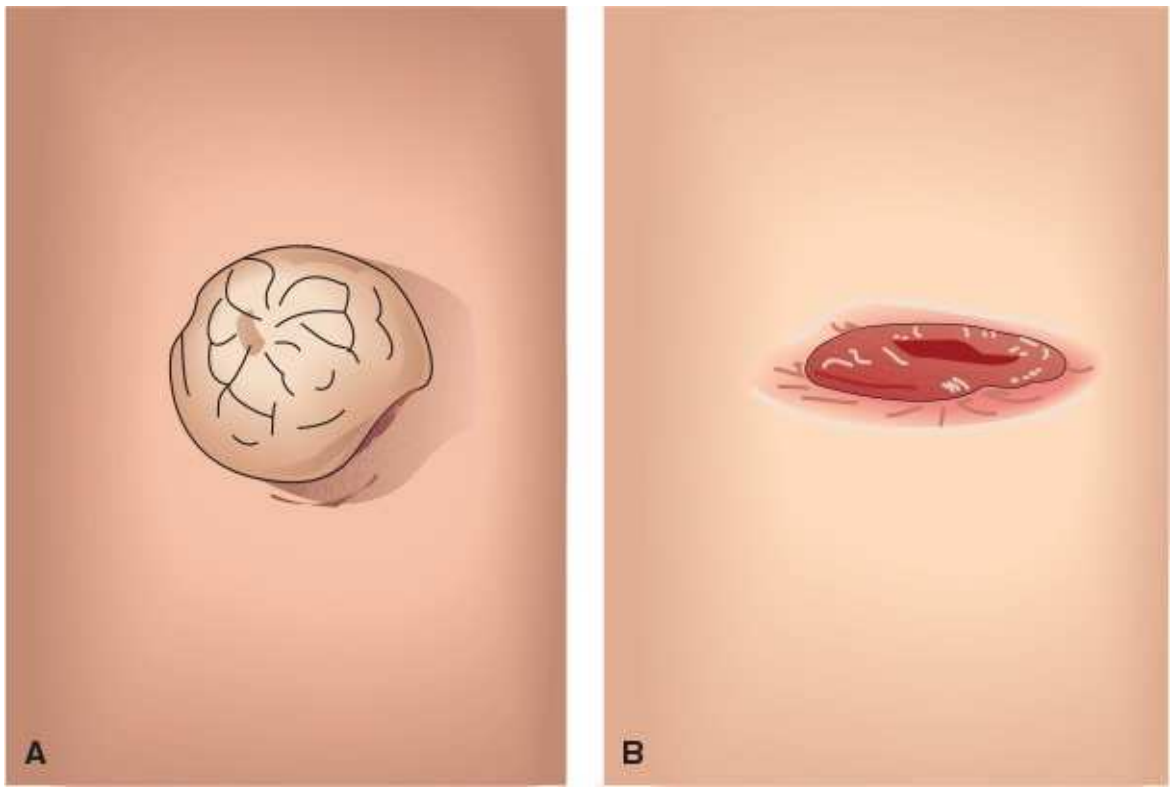

FIGURE 39-13. A. A pale stoma may indicate anemia. **B.** Eroded skin around the area may lead to a flush stoma.

- Provide support for the patient's physical, psychological, and social activities. Coping strategies need to address body image concerns, permanent body changes, and underlying health issue(s) that resulted in the surgery (Berti-Hearn & Elliott, 2019; Díaz et al., 2018).
- Encourage patients and their partner/family/caregiver to discuss concerns and to seek help and support (Berti-Hearn & Elliott, 2019; Chandler, 2020; Hill, 2020).

QSEN INFORMATICS AND PATIENT-CENTERED CARE

Nurses must continually evaluate sources of information to ensure health care decisions based on high-quality resources. Provision of individualized teaching plans that assist patients to select and evaluate appropriate technology and information resources related to bowel elimination support achievement of optimal health care outcomes.

Changing the Ostomy Appliance

The ostomy appliance should protect the skin, collect the fecal discharge, and control odor. Typically, a colostomy does not produce drainage until normal peristalsis returns, usually within 2 to 5 days. An ileostomy drains within 24 to 48 hours because of the liquid contents in the small intestine.

Appliances are either one-piece (barrier backing already attached to the pouch) or two-piece (separate pouch that fastens to the barrier backing). A transparent one-piece appliance is used in the initial postoperative period to allow for visualization of the stoma. For the first few days after surgery, most patients wear an open-ended appliance that allows for drainage of fecal material without removing the appliance. The barrier backing has an adhesive barrier that protects the surrounding skin from the stoma output. Appliances can be either drainable or closed. How frequently a drainable appliance should be changed depends on the type being used and specific patient circumstances, but usually every 3 to 7 days (American Cancer Society, 2019; Berti-Hearn & Elliott, 2019; O'Flynn, 2018; Stelton, 2019). Remove and change nondrainable pouches when they are half-full. Types of ostomy equipment are illustrated in Figure 39-14 and include various types of one-piece and two-piece pouches.

Recall **Alberta Franklin**, the patient with the new colostomy requiring a change of appliance. The nurse needs to demonstrate competence and dexterity when changing this patient's bag by being adequately prepared and organized. In addition, the nurse can use the time during bag changes to teach the patient about self-care measures and to assess the patient's acceptance of the colostomy.

If an appliance is leaking from underneath the barrier backing, ring, or wafer, remove the pouch, cleanse the skin, and apply a new appliance. The procedure to change or empty an ostomy appliance is outlined in Skill 39-5 (on pp. 1572–1577). The act of removing an appliance from the skin can result in mechanical damage to the skin or skin stripping, abrasions, or injury cause by the removal of the outer, loosely bound, epidermal cell layers (peristomal medical adhesive–related skin injury (PMARSI) (Berti-Hearn & Elliott, 2019; Burch, 2019a; LeBlanc et al., 2019). This can be uncomfortable or even very painful for the patient. The cumulative effects of skin stripping over time can result in peristomal skin breakdown. The use of a silicone-based adhesive remover allows for the easy, rapid, and painless removal of a stoma pouch without the associated problems of PMARSI (Berti-Hearn & Elliott, 2019; Chandler, 2015; LeBlanc et al., 2019; Stelton, 2019). A skin barrier film or sealant may be used to protect the skin under the skin wafer or barrier (Goldberg et al., 2018; Landmann & Cashman, 2020; WOCN, 2018).

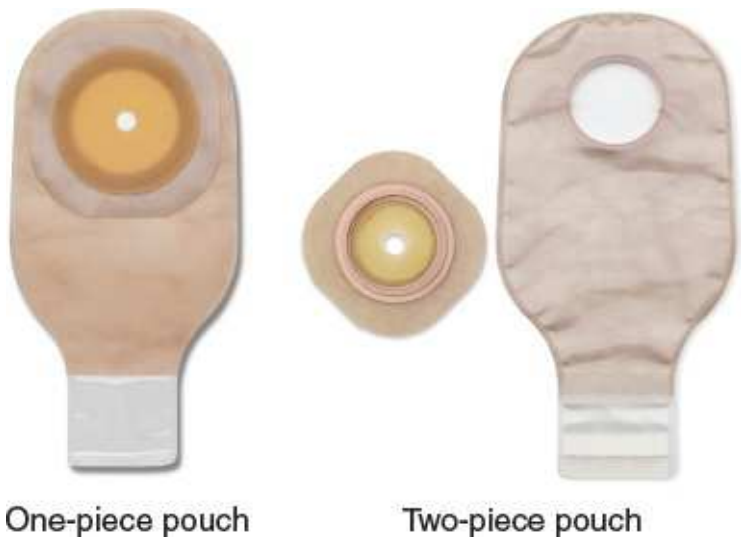

FIGURE 39-14. Examples of ostomy pouches and closures. This equipment comes in various models and sizes. Convex pouches, belts, and other devices to prevent leaks and irritation (not shown) are also available. (*Source:* Courtesy of Hollister Incorporated, Libertyville, Illinois.)

Irrigating a Colostomy

Colostomy irrigation is a way of achieving fecal continence and control (Kent et al., 2015). Irrigations are used to stimulate the colon to empty to promote regular evacuation of stool (up to 24 to 48 hours) from distal colostomies, resulting in reduction or elimination of the need for the patient to use a pouch to collect stool (Cleveland Clinic, 2016; Kent et al., 2015). Colostomy irrigation may be indicated in patients who have a left-sided end colostomy in the descending or sigmoid colon, are mentally alert, have adequate vision, and have adequate manual dexterity needed to perform the procedure (Goldberg et al., 2018; Kent et al., 2015). Contraindications include irritable bowel syndrome (IBS), peristomal hernia, postradiation damage to the bowel, diverticulitis, and Crohn disease (Kent et al., 2015). Ileostomies are not irrigated because the fecal content of the ileum is liquid and cannot be controlled.

Water is inserted into the colostomy, and the water and feces are expelled from the colostomy into the irrigation sleeve and then the toilet. The patient establishes a routine by repeating this process regularly, once a day or once every second day, the colon can be trained to empty with minimal spillage of stool in between irrigations (Cleveland Clinic, 2016). Once the patient has established bowel continence, a small appliance can be worn over the stoma. These "stoma caps" are small-capacity coverings with a pad to soak up discharge and a flatus filter (Kent et al., 2015; Palmer, 2020). If a colostomy irrigation is to be implemented, consult facility policy regarding the accepted procedure and, ideally, consult the WOCN for patient education and support.

Patient Education

The patient can return to an active and full life with an ostomy and may have an improved quality of life as the symptoms of the conditions requiring the ostomy are often eliminated. Make the patient aware of community resources available for assistance, such as home health care nurses, special clinics, wound ostomy and continence nurses, and ostomy support groups. Encourage the patient to seek follow-up health care on a regular basis.

Patient education is essential for independence in self-care. As the patient assumes responsibility for self-care, teach the patient how to make the necessary observations, to be aware of indications of problems, and to recognize when to seek assistance. For these goals to be met, the patient and/or family member/caregiver needs to be able to do the following:

- Explain the reason for bowel diversion and the rationale for treatment.
- Demonstrate self-care behaviors that effectively manage the ostomy.
- Describe follow-up care and existing support resources.
- Report where supplies may be obtained in the community.
- Verbalize related fears and concerns.
- Demonstrate a positive body image.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

During the first 6 to 8 weeks after surgery, encourage the patient with an ostomy to consume low-fiber foods, avoiding foods high in fiber to reduce stool output (Palmer, 2020). Urge patients to drink at least 2.5 quarts of fluids, preferably water, daily. Ileostomy output is high in potassium and sodium, so if the patient is experiencing increased output, it is very important that electrolytes are monitored closely.

Box 39-3 Dietary Considerations for Patients With an Ileostomy or Colostomy

Foods That May Cause Gas and/or Produce Odor

Apples
Asparagus
Beer
Cucumbers
Dairy products
Dried peas, beans, and lentils
Eggs
Fatty foods
Fish
Garlic
Melons
Nuts
Onions
Pickles
Radish
Vegetables from the cabbage family.
The carbohydrate raffinose in these foods is poorly digested and leads to gas.
This includes foods such as broccoli, Brussels sprouts, cabbage, cauliflower, and turnips.

Foods That May Cause Stomal Blockage

Bean sprouts
Cabbage
Celery
Coconut
Corn
Dried fruit
Mushrooms
Nuts
Peas
Pineapple
Popcorn
Seeds
Skins from fruits and vegetables

Foods That May Help to Thicken Stool

Applesauce
Bananas
Cheese
Creamy peanut butter
Pasta
Potatoes
Rice
Tapioca
Yogurt

Foods That May Decrease Odor

Buttermilk
Kefir

Parsley
Yogurt

Source: Burgess-Stocks, J. (2020). Eating with an ostomy A comprehensive nutrition guide for those living with an ostomy. United Ostomy Associations of America. https://www.ostomy.org/wp-content/uploads/2020/07/Eating_with_an_Ostomy_2020-07.pdf

Patients with ileostomies also need to be aware they may experience a tendency to develop food blockages, especially when high-fiber foods are consumed. This is because scar tissue from the place where the intestine passes through the abdominal muscle tightens the inside diameter of the ileum and can narrow it to much less than its normal diameter. Fiber blockages can cause cessation of gas and/or bowel movements, watery stools with bad odor, abdominal cramping and pain, and distention, along with nausea and vomiting (Burgess-Stocks, 2020; Memorial Sloan Kettering Cancer Center, 2019). Foods that commonly cause blockage to occur include nuts, corn, popcorn, coconuts, mushrooms, stringy vegetables, and foods with skins and casings (Landmann & Cashman, 2020; Memorial Sloan Kettering Cancer Center, 2019).

Additional dietary considerations for patients with an ileostomy or colostomy are outlined in Box 39-3.

Health teaching about medication use is an important intervention for patients with ostomies. The transit time for substances to move through the intestine might change and could affect the absorption of medications (Burgess-Stocks, 2020). Some medications may discolor the stool and cause unusual odors, some may cause constipation, and some may not dissolve or be absorbed completely because the small bowel is where most absorption occurs. Tablets, capsules, or particles of medication found in the appliance pouch when the patient empties it indicate the patient might not be getting the full dose of medication (Burgess-Stocks, 2020). Reinforce with the patient the importance of contacting the health care team if this occurs (Burgess-Stocks, 2020). Long-acting, enteric-coated, or sustained-release medications are designed to be released in the colon. These extended-release medications should be avoided in patients without a colon, and the use of liquid, chewable, or uncoated tablets or injectable forms of medication may be needed (Burgess-Stocks, 2020). Laxatives and enemas should not be used in patients with an ileostomy or transverse colostomy, as use can cause severe fluid and electrolyte imbalance or severe dehydration (Burgess-Stocks, 2020). Laxatives may sometimes be used by patients with a colostomy who experience constipation, but patients should only do so under the guidance of their health care provider, as effects will vary depending on the type of surgery the patient had (Burgess-Stocks, 2020). The preferred treatment for constipation is an increase in fluid intake and/or dietary fiber as opposed to using laxatives (Palmer, 2020).

Research in Nursing

Bridging the Gap to Evidence-Based Practice

Living with an Ostomy

A stoma operation causes major changes in a patient's life because of the resulting physical damage, disfigurement, loss of bodily function, and change in personal hygiene. Such changes are a cause of major concern for patients and raise important issues for the provision of quality care. Individuals participating in support groups benefit from the social support and information obtained from the group interaction (MFMER, 2020e; MFMER, 2020f). How do support groups impact the life of a person with a stoma?

Related Research

Byfield, D. (2020). The lived experiences of persons with ostomies attending a support group. A qualitative study. *Journal of Wound, Ostomy & Continence Nursing*, *47*(5), 489–495. https://doi.org/10.1097/WON.0000000000000696

This study explored how a support groups affect coping and adaptation in those with an ostomy. The purpose of the study was to describe the lived experiences of patients with ostomies participating in a support group. Fifteen adults with different types of ostomies attending an ostomy support group responded to the invitation to participate in the study; data saturation was reached with the final sample of 10 participants. Individual semistructured interviews were conducted by the principal investigator in the classroom where the monthly support group meetings were held. The main open-ended interview question asked participants, "What is your experience of participating in a support group for patients with an ostomy in Georgia?", followed by additional supporting questions. Interviews were recorded, and handwritten field notes were completed that included nonverbal moments, body movements, and facial expressions. Interview recordings were transcribed verbatim. Thematic analysis was performed, and member checking occurred, with individual participants reviewing notes corresponding to their interview. Double coding of the transcripts was done by an independent researcher. Four themes and 10 subthemes emerged regarding the lived experiences of individuals attending an ostomy support group:

Theme 1: support group gives hope and changes lives, with two subthemes of increased knowledge and provided new knowledge and allows open communication.

Theme 2: changes in body image, with two subthemes of some things are different and everyone is the same.

Theme 3: I am not alone, with four subthemes of feeling of belonging, willingness to be helped, being supported, and

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

developing lifelong relationships.
Theme 4: being independent, with two subthemes of confidence in rejoining society and building confidence and decreased shame.

The researchers concluded that participation in an ostomy support group allowed individuals with ostomies to function at more advance levels than they were before participating in the support group. The lived experiences were characterized by hope, willingness to live fully again, participating in different activities, and making new friends. The researchers suggested these findings add to and support the body of knowledge related to the interactions between nurses and individuals with ostomies as well as the care needed to ensure a safe discharge from the acute care facility and may help in the improvement of education provided during hospitalization. Providing this information will equip patients and families with a better understanding of and methods to care for their new ostomies and adjust to their new health status.

Relevance to Nursing Practice

Patients experiencing life-altering surgeries resulting in a stoma require both knowledge and support to adapt and achieve an improved quality of life after surgery. Nurses have a unique opportunity to not only provide the education and support to these patients but to their social support systems as well. This study supports the nurse's role in not only providing hands-on ostomy care but also in helping the patient developing social support systems either through friends, families/caregivers, or outside resources such as a support group or engaging with others who have a colostomy. In addition to assisting patients to learn the physical care needs related to a stoma, nurses must address the psychosocial concerns of patients with ostomies as part of their nursing interventions. Assisting patients to adjust and encouraging social interactions should be part of the care routinely given to stoma patients.

Many times, patients are embarrassed when they have to use public restrooms to empty their bag. Teach patients with ostomies about the various methods of odor control. Remind them that if the bag is clean and sealed well, odor usually is not a problem during normal activity. Consuming probiotics, such as yogurt, aids in digestion and can help control odor (Burgess-Stocks, 2020). There are odor eliminators that contain chlorophyll that may be taken orally; reinforce the need for the patient to consult with their healthcare provider prior to use and warn the patient these products may turn the stool green and interfere with absorption of medication (Burgess-Stocks, 2020). There is some evidence that bismuth subsalicylate can also assist in reducing odors in patients if use is not contraindicated. Use of bismuth can turn the stool black and may also interfere with absorption of medication (Burgess-Stocks, 2020). Patients should consult with their healthcare provider before taking bismuth (Burgess-Stocks, 2020). Commercial odor-control products also are available for purchase. The WOCN can help with the selection of odor-control strategies.

The patient with an ostomy can resume normal activity after healing is completed and their strength returns, including work, swimming, and sexual relations (MFMER, 2020e; Palmer, 2020). However, the patient may need to restrict strenuous activities, such as heavy lifting, during the first 2 to 3 weeks after surgery to avoid increasing the risk of a stoma hernia (MFMER, 2020e; NIDDK, 2014). Physical contact sports such as football or karate and should be avoided (NIDDK, 2014). Patients with an ostomy should talk with their health care provider about timing for resuming their normal activities and possible need for stoma protection devices when participating in sports/activities (Goldberg et al., 2018; MFMER, 2020e; NIDDK, 2014). When traveling, the patient should carry a 1- to 2-day supply of equipment in a carry-on bag in case checked luggage is lost. Nurses play a significant role in providing physical, emotional, and psychological support to help patients, their families, and caregivers others adjust to this major life change. The Research in Nursing display provides insight into the lived experiences of patients with ostomies.

Evaluating

Evaluation is an ongoing and deliberate part of the nursing process, comparing the patient's health status with previously defined expected outcomes. The nurse reflects on the effectiveness of the plan of care to promote healthy bowel functioning by evaluating whether the patient has met the individualized patient goals specified in the plan. Adjustments in the plan of care are made accordingly. Nursing care is considered effective if the patient expresses satisfaction with the bowel elimination measures and is able to (as appropriate, based on specific behaviors and criteria individualized for the patient situation):

- Verbalize the relationships among bowel elimination and nutrition, fluid intake, exercise, and stress management.
- Develop a plan to modify any factors that contribute to current bowel problems or that might adversely affect bowel functioning in the future.
- Promote bowel functioning as appropriate for the person.
- Provide care for bowel diversion and know when to notify the health care team.
- See the accompanying Nursing Care Plan 39-1 for Jeremy Green.

REFLECTIVE PRACTICE LEADING TO PERSONAL LEARNING

Remember that the goal of reflective practice is to look at an experience, understand it, and learn from it. As you begin to develop expertise in implementing measures related to bowel elimination, reflect on your experiences—successes and failures—in order to improve your practice. How can you do it better next time? What did you learn today that can help you tomorrow? Begin your reflection by paying close attention to the following while performing interventions and providing nursing care related to bowel elimination:

- Did your preparation and practice related to performing assessment related to bowel elimination result in your feeling confident in your ability to gather reliable, accurate, and complete data? Did your competence and confidence inspire the patient's and the family/caregiver's trust?
- How did you prioritize the data you collected? What patterns in the data did you identify? What knowledge from your learning, personal experience and intuition did you use to make decisions and develop your plan of care?
- Did your commitment to engage your patients and families/caregivers and to collaborate with your fellow students, instructor, and other members of the health care team as you implemented the care plan result in successful partnerships?
- Were you aware of any cultural and/or ethnic beliefs or practices that may have influenced the patient's personal bowel elimination practices? Were you aware of any stereotypes or prejudices that might have negatively influenced the clinical encounter? If so, how did you address these?
- Was patient/family/caregiver participation in the process at an optimal level? How might you have better engaged the patient and family/caregivers? Did the care plan accurately reflect patient priorities and preferences?
- Did you need to modify the care plan as a result of ongoing assessments? Did you think of better interventions to produce the expected outcomes?

Perhaps the most important questions to reflect on are: Are your patients and their families/caregivers better for having had *you* share in the critical responsibility of partnering with them to address their bowel elimination needs? Are your patients now receiving thoughtful, person-centered, prioritized, holistic, evidence-based treatment and care because of your efforts?

Nursing Care Plan for Jeremy Green 39-1

Jeremy Green, age 4 years, was placed in day care when their mother returned to work 6 months ago. Jeremy presents at the hospital with a diagnosis of viral gastroenteritis. A comprehensive nursing assessment included the following notations:

- Admitted with report of diarrhea beginning 3 days ago.
- Seen today by pediatrician, who recommended admission and workup to exclude causes other than viral.
- Mother reports liquid stools (no observable blood, pus, or mucus) six to seven times daily beginning 3 days ago with amounts of "one to two cups."
- Urgency results in soiling of pants.
- Child has sipped boiled skim milk and cola and eaten a small amount of broth and a few pretzels but has no appetite.
- Reports nausea and vomited twice 3 days ago.
- Child is pale and eyes are sunken.
- Skin is warm and dry, with decreased turgor and dry mucous membranes.
- Hyperactive bowel sounds (52/min)
- Height, 45 inches; weight, 36 lb; temperature, 99.8°F (rectally); pulse, 88 beats/min; respiratory rate, 18 breaths/min
- Mother reported several other children in same day care center are out sick with diarrhea.

ACTUAL OR POTENTIAL HEALTH PROBLEMS AND NEED

Diarrhea

Etiology: unknown cause (possibly viral, rule out malabsorption of lactose and other causes)

Signs and Symptoms: passage of liquid stools (1 to 2 cups) for 3 days; urgency with fecal soiling, decreased appetite, transient nausea and vomiting.

EXPECTED OUTCOME

By 5/5/25 the patient will:

- Demonstrate improved fluid and electrolyte balance by maintenance of present weight (36 lb), presence of moist mucous membranes, positive skin turgor, pulse and respiratory rate within normal limits, urine output equal to fluid intake.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

EXPECTED OUTCOME

At the time of discharge, the patient will:

- Voluntarily pass a formed stool of usual consistency (experience less or no diarrhea)

NURSING INTERVENTIONS	RATIONALE	EVALUATIVE STATEMENT
Assess and chart frequency and amount of diarrhea, stool characteristics, precipitating factors, and accompanying manifestations (GI symptoms, hyperactive bowel sounds).	This assists in identifying the cause of the diarrhea.	5/8/25 Outcome partially met. No recurrence of liquid stools for 24 hours. Revision: Continue to monitor for return of usual stool *D. Lentsky, RN*

EXPECTED OUTCOME

At the time of discharge, the patient will:

- Exhibit normoactive bowel sounds (occurring every 5 to 15 seconds)

NURSING INTERVENTIONS	RATIONALE	EVALUATIVE STATEMENT
Work collaboratively with the health care provider to identify the cause of the diarrhea. Obtain stool specimens and send to laboratory.	Correct treatment depends on identification of the cause of the diarrhea. Viral diarrhea is usually self-limiting and lasts 24 to 72 hours. Prolonged diarrhea after acute viral illness may be from temporary malabsorption of lactose or other simple sugars.	5/8/25 Bowel sounds are normoactive. *D. Lentsky, RN*
Instruct Jeremy and their parents (if they want to participate in care) on correct infection control precautions for handling stool.	Proper precautions prevent transmissions of infectious diarrhea to others.	
Increase the frequency and length of rest periods and discourage strenuous activity.	Exercise and activity stimulate peristalsis.	
Assess for the ability to take sips of water and tolerate small servings of food without vomiting or increasing diarrhea.	Antidiarrheal medications are generally not indicated in the care of children with viral gastroenteritis. Therefore, care is symptomatic. The ability to drink sips of water aids in decreasing the risk of dehydration, and if tolerated demonstrates the resolving of the symptoms of the viral gastroenteritis.	

SAMPLE DOCUMENTATION

5/7/25 Nursing

Liquid stools have decreased to two in the past 24 hours. Negative report on stool culture; Dr. Simpson notified of results. Patient denies pain, nausea, and cramping. Patient is playing with toys in bed. Normoactive bowel sounds auscultated in four quadrants.

D. Lentsky, RN

Skill 39-1 Administering a Large-Volume Cleansing Enema

DELEGATION CONSIDERATIONS

The administration of some types of enemas may be delegated to assistive personnel (AP) who have received appropriate training. The administration of a large-volume cleansing enema may be delegated to licensed practical/vocational nurses (LPN/LVNs). The decision to delegate must be based on careful analysis of the patient's needs and circumstances as well as the qualifications of the person to whom the task is being delegated. Refer to the Delegation Guidelines in Appendix A.

EQUIPMENT

- Enema solution as prescribed at or just above body temperature (Dougherty & Lister, 2015, as cited in Mitchell, 2019b, p. 155) in the prescribed amount (amount will vary depending on the type of solution, patient's age, and patient's ability to retain the solution; average cleansing enema for an adult may range from 500 to 1,000 mL)
- Disposable enema set, which includes a solution container and tubing
- Water-soluble lubricant
- IV pole
- Necessary additives, as prescribed
- Waterproof pad
- Bath thermometer (if available)
- Bath blanket
- Bedpan or commode and toilet tissue
- Disposable gloves
- Additional PPE, as indicated
- Paper towel
- Washcloth, skin cleanser, and towel

Implementation

ACTION	RATIONALE
1. Review the patient's health record for any limitations in physical activity. Verify the prescribed intervention for the enema. Gather equipment.	Physical limitations may require adaptations in performing the skill. Verifying the prescribed intervention ensures that the correct intervention is administered to the right patient. Assembling equipment provides for an organized approach to the task.
 2. Perform hand hygiene and put on PPE, if indicated.	Hand hygiene and PPE prevent the spread of microorganisms. PPE is required based on transmission precautions.
 3. Identify the patient.	Identifying the patient ensures the right patient receives the intervention and helps prevent errors.
4. Explain the procedure to the patient and provide the rationale as to why the enema is needed. Discuss the associated discomforts that may be experienced and possible interventions that may allay this discomfort. Answer any questions, as needed.	Explanation facilitates patient engagement and reduces anxiety.
5. Assemble equipment on the overbed table or other surface within reach.	Arranging items nearby is convenient, saves time, and avoids unnecessary stretching and twisting of muscles on the part of the nurse.
6. Close the curtains around the bed and close the door	This ensures the patient's privacy. Explanation relieves

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

to the room, if possible. Discuss where the patient will defecate. Have a bedpan, commode, or nearby bathroom ready for use.	anxiety and facilitates patient engagement. The patient is better able to relax and participate if they are familiar with the procedure and know everything is in readiness when the urge to defecate is felt. Defecation usually occurs within 5 to 15 minutes.
7. Warm the enema solution to at or just above body temperature by placing the container with the enema solution in the amount prescribed in a container of warm water, and check the temperature with a thermometer, if available. If a thermometer is not available, warm and test on your inner wrist. If tap water is used, adjust the temperature as it flows from the faucet.	Enema solution should be at or just above body temperature and warmed, if necessary, by placing the container with the enema solution in a container of warm water (Dougherty & Lister, 2015, as cited in Mitchell, 2019b, p. 155). Warming the solution prevents chilling the patient, adding to the discomfort of the procedure. A cold solution could cause cramping; a too-warm solution could cause trauma to intestinal mucosa.
8. Add the enema solution to the enema set solution container. Release the clamp and allow fluid to progress through the tube before reclamping.	This causes any air to be expelled from the tubing. Although allowing air to enter the intestine is not harmful, it may further distend the intestine.
9. Adjust the bed to a comfortable working height (VHACEOSH, 2016). Position the patient on their left side (Sims' position), with the upper thigh pulled toward the abdomen, if possible, or the knee–chest position, as dictated by patient comfort and condition. Fold the top linen back just enough to allow access to the patient's rectal area. Drape the patient with the bath blanket, as necessary, to maintain privacy and warmth. Place a waterproof pad under the patient's hip.	Having the bed at the proper height prevents back and muscle strain. The Sims' or knee–chest position facilitates flow of solution via gravity into the rectum and colon, optimizing solution retention. Folding back the linen in this manner minimizes unnecessary exposure and promotes the patient's comfort and warmth. The waterproof pad will protect the bed.
10. Put on gloves.	Gloves prevent contact with contaminants and body fluids.
11. Elevate the solution so that it is no higher than 18 inches (45 cm) above the level of the anus (Figure 1). Plan to give the solution slowly over a period of 5 to 10 minutes. Hang the container on an IV pole or hold it at the proper height.	Gravity forces the solution to enter the intestine. The amount of pressure determines the rate of flow and pressure exerted on the intestinal wall. Giving the solution too quickly causes rapid distention and pressure, poor defecation, or damage to the mucous membrane.
12. Generously lubricate the end of the rectal tube 2 to 3 inches (5 to 7 cm). A disposable enema set may have a prelubricated rectal tube.	Lubrication facilitates passage of the rectal tube through the anal sphincter and prevents injury to the mucosa.
13. Lift a buttock to expose the anus. Ask the patient to take several deep breaths. Slowly and gently insert the enema tube 4 to 5 inches (10 to 12.5 cm) for an adult. Direct it at an angle pointing toward the umbilicus, not the bladder (Figure 2).	Good visualization of the anus helps prevent injury to tissues. Deep breathing helps relax the anal sphincters. The anal canal is about 1 to 2 inches (2.5 to 5 cm) long. Insertion 4 to 5 inches (10 to 12.5 cm) ensures the tube is inserted past the external and internal anal sphincters (Dougherty & Lister, 2015, as cited in Mitchell, 2019b, p. 155); further insertion may damage the intestinal mucous membrane. The suggested angle follows the normal intestinal contour and thus will help to prevent perforation of the bowel. Slow insertion of the tube minimizes spasms of the intestinal wall and sphincters.

FIGURE 1. Adjusting height of solution container.

FIGURE 2. Inserting enema tip into anus, directing tip toward umbilicus.

14. If resistance is met while inserting the tube, permit a small amount of solution to enter, withdraw the tube slightly, and then continue to insert it. **Do not force entry of the tube.** Ask the patient to take several deep breaths.

Resistance may be due to spasms of the intestine or failure of the internal sphincter to open. The solution may help to reduce spasms and relax the sphincter, thus making continued insertion of the tube safe. Forcing a tube may injure the intestinal mucosa wall. Taking deep breaths helps relax the anal sphincter.

15. Introduce the solution slowly over a period of 5 to 10 minutes. Hold the tubing all the time that solution is being instilled. Assess for dizziness, lightheadedness, nausea, diaphoresis, and clammy skin during administration. **If the patient experiences any of these symptoms, stop the procedure immediately, monitor the patient's heart rate and blood pressure, and notify the health care team.**

Introducing the solution slowly helps prevent rapid distention of the intestine and a desire to defecate. Assessment allows for detection of a vagal response. The enema may stimulate a vagal response, which increases parasympathetic stimulation, causing a decrease in heart rate.

16. Clamp the tubing or lower the container if the patient has the urge to defecate or cramping occurs (Figure 3). Instruct the patient to take small, fast breaths or to pant.

These techniques help relax muscles and prevent premature expulsion of the solution.

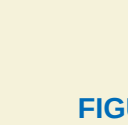
17. After the solution has been given, clamp the tubing (Figure 4) and remove the tube. Have a paper towel ready to receive the tube as it is withdrawn.

Wrapping the tube in a paper towel prevents dripping of the solution.

FIGURE 3. Holding bag lower to slow flow of enema solution.

FIGURE 4. Clamping tubing before removing.

18. Return the patient to a comfortable position. Encourage the patient to hold the solution until the urge to defecate is strong, usually in about 10 to 15 minutes. Make sure the linens under the



This amount of time usually allows muscle contractions to become sufficient to produce good results. Dry linens promote patient comfort. Removing contaminated gloves and performing hand hygiene prevent the spread of microorganisms.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

patient are dry. Remove your gloves and ensure that the patient is covered. Perform hand hygiene.

19. Raise the side rail. Lower the bed height and adjust the head of the bed to a comfortable position.

Positioning promotes comfort and safety.

20. Remove additional PPE, if used. Perform hand hygiene.

Proper removal of PPE reduces the risk for infection transmission and contamination of other items. Hand hygiene prevents the spread of microorganisms.

21. When the patient has a strong urge to defecate, place them in a sitting position on a bedpan or assist them to a commode or a nearby bathroom. Offer toilet tissues, if not in the patient's reach (Figure 5). Stay with the patient or have the call bell readily accessible.

The sitting position is most natural and facilitates defecation. Fall prevention is a high priority due to the urgency of reaching the commode.

FIGURE 5. Offering toilet tissue to patient on bedside commode.

22. Remind the patient not to flush the commode before you inspect the results of the enema.

The results need to be observed and recorded. Additional enemas may be necessary if the health care provider has prescribed enemas "until clear." Refer to "Special Considerations" below.

23. Put on gloves and assist the patient, if necessary, with cleaning the anal area. Offer washcloths, skin cleanser, and water for handwashing. Remove gloves. Perform hand hygiene.

Cleaning the anal area and proper hygiene deter the spread of microorganisms. Gloves prevent contact with contaminants and body fluids. Hand hygiene deters the spread of microorganisms.

24. Leave the patient clean and comfortable. Care for equipment properly.

Bacteria that grow in the intestine can be spread to others if equipment is not properly cleaned.

Hand hygiene deters the spread of microorganisms.

25. Perform hand hygiene.

DOCUMENTATION

Guidelines

Document the amount and type of enema solution used; amount, consistency, and color of stool; pain assessment rating; assessment of the perineal area for any irritation, tears, or bleeding; and the patient's reaction to the procedure.

Sample Documentation

7/22/25 1310 800-mL tap water enema given via rectum. Large amount of soft, brown stool returned. No

irritation, tears, or bleeding noted in perineal area. Patient reported "stomach cramping," which was relieved when enema was released. Rates pain as 0 after evacuation of enema.

—K. Sanders, RN

DEVELOPING CLINICAL REASONING AND CLINICAL JUDGMENT

UNEXPECTED SITUATIONS AND ASSOCIATED INTERVENTIONS

- *Solution does not flow into rectum:* Reposition the rectal tube. If solution will still not flow, remove the tube, and check for any fecal contents clogging the tube.
- *Patient cannot retain enema solution for adequate amount of time:* The patient may need to be placed on a bedpan in the supine position while receiving the enema. The head of the bed may be elevated 30 degrees for the patient's comfort.
- *Patient cannot tolerate large amount of enema solution:* Amount and length of administration may have to be modified if the patient begins to report pain.
- *Patient reports severe cramping with introduction of enema solution:* Lower the solution container and check the temperature and flow rate. If the solution is too cold or the flow rate too fast, severe cramping may occur.

SPECIAL CONSIDERATIONS

General Considerations

- Rectal agents should be avoided in patients at risk of thrombocytopenia, leukopenia, and/or mucositis, and manipulation of the rectum and anus, including administration of enemas, should be avoided in immunocompromised patients and/or patients at risk for myelosuppression and mucositis (NCI, 2020). These actions can lead to development of anal fissures or abscesses, which are portals for infection (NCI, 2020).
- If the patient experiences fullness or pain, or if fluid escapes around the tube, stop administration. Wait 30 seconds to a minute and then restart the flow at a slower rate. If symptoms persist, stop administration, and contact the health care team.
- If the order states the enema is to be given "until clear," check with the health care team before administering more than three enemas. Severe fluid and electrolyte imbalances may occur if the patient receives more than three cleansing enemas. Results are considered clear whenever there are no more pieces of stool in the enema return. The solution may be colored but still considered a clear return.

Infant and Child Considerations

- When administering an enema to a child, use isotonic solutions. Plain water is not used because it is hypotonic and can cause rapid fluid shift and fluid overload (Silbert-Flagg & Pillitteri, 2018).
- Appropriate fluid volume for an enema (Silbert-Flagg & Pillitteri, 2018):
- Infant: 250 mL or less
- Toddler or preschooler: 250 to 350 mL
- School-aged child: 300 to 500 mL
- Adolescent: 500 mL
- Position the infant or toddler on their abdomen with knees bent. Position the child or adolescent on their left side with the right leg flexed toward the chest (Cincinnati Children's, 2018).
- Insert the tubing into the rectum 2 to 3 inches (5 to 7.5 cm) for children (ages 2 to 10 years); 1 to 1.5 inches (2.5 to 4 cm) for infants (Cincinnati Children's, 2018).

Older Adult Considerations

- If the older adult cannot retain the enema solution, administer the enema with the patient on the bedpan in the supine position. For comfort, elevate the head of the bed 30 degrees, if necessary, and use pillows appropriately.

Skill 39-2 Inserting a Nasogastric Tube

DELEGATION CONSIDERATIONS

The insertion of an NG tube is not delegated to assistive personnel (AP). Depending on the state's nurse practice act and the organization's policies and procedures, insertion of an NG tube may be delegated to licensed

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

practical/vocational nurses (LPN/LVNs). The decision to delegate must be based on careful analysis of the patient's needs and circumstances as well as the qualifications of the person to whom the task is being delegated. Refer to the Delegation Guidelines in Appendix A.

EQUIPMENT

- NG tube of appropriate size (8F to 18F)
- Stethoscope
- Water-soluble lubricant
- Normal saline solution or sterile water, for irrigation, depending on facility policy
- Tongue blade
- Irrigations set, including a large syringe (20 to 50 mL)
- Flashlight
- Nonallergenic tape (1 inch wide)
- Tissues
- Glass of water with straw
- Topical anesthetic—lidocaine spray or gel (optional)
- Clamp
- Suction apparatus (if prescribed)
- Bath towel or disposable pad
- Emesis basin
- Safety pin and rubber band
- Nonsterile, disposable gloves
- Additional PPE, as indicated
- Tape measure, or other measuring device
- Skin barrier
- pH test strip (calibrated in units of 0.5 and approved for use with human secretions)

IMPLEMENTATION

ACTION	RATIONALE
1. Verify the prescribed intervention for insertion of an NG tube. Gather equipment, including selection of the appropriate NG tube.	This ensures the patient receives the correct treatment. Assembling equipment provides for an organized approach to the task. NG tubes should be radiopaque, contain clearly visible markings for measurement, and may have multiple ports for aspiration.
 2. Perform hand hygiene and put on PPE, if indicated.	Hand hygiene and PPE prevent the spread of microorganisms. PPE is required based on transmission precautions.
 3. Identify the patient.	Identifying the patient ensures the right patient receives the intervention and helps prevent errors.
4. Explain the procedure to the patient, including the rationale for why the tube is needed. Discuss the associated discomforts that may be experienced and possible interventions that may allay this discomfort. Answer any questions, as needed.	Explanation facilitates patient engagement and reduces anxiety.
5. Assemble equipment on the overbed table or other surface within reach.	Arranging items nearby is convenient, saves time, and avoids unnecessary stretching and twisting of muscles on the part of the nurse.
6. Close the patient's bedside curtain or door. Raise the bed to a comfortable working position (VHACEOSH, 2016). Assist the patient to high-Fowler position or elevate the head of the bed 45	Closing the curtains or the door provides for patient privacy. Having the bed at the proper height prevents back and muscle strain. The upright position is more natural for swallowing and reduces the risk for

degrees if the patient is unable to maintain an upright position. Drape their chest with a bath towel or disposable pad. Have an emesis basin and tissues within reach.	aspiration if the patient should vomit. Passage of the tube may stimulate gagging and tearing of the eyes.
7. **Refer to facility policy regarding method(s) to determine insertion length.** Measure the distance to insert the tube by placing the tube tip at the patient's nostril and extending it to the tip of the earlobe and then to the point midway between the xiphoid process and umbilicus. Alternatively, measure from the xiphisternum (xiphoid process) to the earlobe, to the nose and add 10 cm (Fan et al., 2019). **Refer to facility policy. Mark the tube with an indelible marker.**	The NEMU (nose-ear-mid-umbilicus) has been suggested as an accurate method of measurement in infants and children (Ellett et al., 2012; Irving et al., 2018). Another method, the xiphisternum-earlobe-nose + 10 cm, has been suggested as the best estimate for the length of NG tube required (Fan et al., 2019). Correct positioning results in tip positioning between 3 and 10 cm under the lower esophageal sphincter (Torsy et al., 2018). Determination of NG tube insertion length is controversial, and recommendations are conflicting; most evidence for practice identifies the need for more research to determine more accurate and reliable ways to determine tube insertion depth (Boeykens, 2018; Fan et al., 2019; Mak & Tam, 2020; Parker et al., 2018; Taylor, 2020; Torsy et al., 2018).
8. Put on gloves. Lubricate the tip of the tube (at least 2 to 4 inches) with water-soluble lubricant. Apply topical anesthetic to the nostril and oropharynx, as appropriate.	Lubrication reduces friction and facilitates passage of the tube into the stomach. Water-soluble lubricant will not cause pneumonia if the tube accidentally enters the lungs. Topical anesthetics act as local anesthetics, reducing discomfort. Consult the health care team for an order for a topical anesthetic, such as lidocaine gel or spray, if needed.
9. After selecting the appropriate nostril, ask the patient to flex their head slightly back against the pillow. Gently insert the tube into the nostril while directing the tube upward and backward along the floor of the nose (Figure 1). The patient may gag when the tube reaches the pharynx. Provide tissues for tearing or watering of the eyes. Offer comfort and reassurance to the patient.	Following the normal contour of the nasal passage while inserting the tube reduces irritation and the likelihood of mucosal injury. The tube stimulates the gag reflex readily. Tears are a natural response as the tube passes into the nasopharynx. Many patients report that gagging and throat discomfort can be more painful than the tube passing through the nostrils.

FIGURE 1. Beginning insertion with patient positioned with head slightly flexed back.

10. When the pharynx is reached, instruct the patient to touch their chin to their chest. Encourage the patient to sip water through a straw or swallow (Figure 2). Advance the tube in a downward and backward direction when the patient swallows. Stop when the patient breathes. **If gagging and coughing persist,**	Bringing the head forward helps close the trachea and open the esophagus. Swallowing helps advance the tube, causes the epiglottis to cover the opening of the trachea, and helps to eliminate gagging and coughing. Excessive coughing and gagging may occur if the tube has curled in the back of the throat.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

stop advancing the tube and check placement of the tube with a tongue blade and flashlight. If the tube is curled, straighten the tube and attempt to advance it again. Keep advancing the tube until the pen marking is reached. **Do not use force.** Rotate the tube if it meets resistance.	Forcing the tube may injure mucous membranes.
11. **Discontinue the procedure and remove the tube if there are signs of distress, such as gasping, coughing, cyanosis, and inability to speak or hum.**	The tube is in the airway if the patient shows signs of distress and cannot speak or hum. If, after three attempts, NG insertion is unsuccessful, another nurse may try, or the patient should be referred to another health care professional.
12. Secure the tube loosely to the nose or cheek with tape until placement is verified. Confirm placement of the NG tube in the patient's stomach using at least two methods.	Verify correct placement of the NG tube after the initial insertion, before beginning a feeding or instilling medications or liquids, and at regular intervals during continuous feedings (Metheny et al., 2019). A misplaced tube in the lungs or pulmonary tissue places the patient at risk for aspiration, pneumonia, and even death (Lamont et al., 2011, as cited in Anderson, 2018). With the exception of radiographic examination, which is usually done immediately after insertion to verify initial tube placement, the use of two or more techniques in conjunction with each other increases the likelihood of correct tube placement (AACN, 2020; Anderson, 2019; Anderson, 2018; Dias et al., 2019; Rahimi et al., 2015).
13. After confirmation of tube placement, secure the tube. Apply a skin barrier to the tip and end of the nose and allow it to dry. Remove gloves and secure the tube with a commercially prepared securement device (Figure 3) (follow the manufacturer's directions) or tape it to the patient's nose. To secure with tape:	Securing the tube prevents migration of the tube inward and outward. The skin barrier improves adhesion and protects skin. Constant pressure of the tube against the skin and mucous membranes may cause pressure injury (Powers, 2019).

FIGURE 2. Advancing tube after patient drops chin to chest and while swallowing.

FIGURE 3. Example of a commercially prepared securement device. (*Source:* Courtesy of Hollister, Incorporated, Libertyville, Illinois.)

a. Cut a 4-inch piece of tape and split the bottom 2 inches (Figure 4) or use packaged nose tape for NG tubes.

b. Place the unsplit end over the bridge of the patient's nose (Figure 5).

c. Wrap the split ends under and around the NG tube (Figure 6). **Be careful not to pull the tube too tightly against the nose** (Powers, 2019).

FIGURE 4. Making a 2-inch cut into a 4-inch strip of tape.

FIGURE 5. Applying tape to patient's nose.

FIGURE 6. Wrapping split ends around NG tube.

14. Put on gloves. Clamp the tube and remove the syringe. Cap or attach the tube to suction (Figure 7), according to the prescribed interventions. Remove gloves. Perform hand hygiene.

Gloves prevent contact with blood and body fluids and transfer of microorganisms. Suction provides for decompression of the stomach and drainage of gastric contents. Removing gloves properly and using hand hygiene reduces the risk for infection transmission and contamination of other items.

FIGURE 7. NG tube attached to wall suction.

15. Measure the length of the exposed tube. Reinforce the marking on the tube at the nostril with indelible ink. Ask the patient to turn their head to the side opposite the nostril in which the tube is inserted. Secure the tube to the patient's gown by using rubber band or tape and a safety pin. For additional support, tape the tube onto the patient's cheek using a piece of tape. **Secure the vent of the double-lumen tube**

The tube should be marked with an indelible marker at the nostril. This marking should be assessed each time the tube is used to ensure the tube has not become displaced. Tube length should be checked and compared with this initial measurement, in conjunction with pH measurement and visual assessment of aspirate, at regular intervals. An increase in the length of the exposed tube may

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

above stomach level. Attach the vent at shoulder level (Figure 8).

indicate dislodgement (AACN, 2020; Boullata et al., 2017). Securing prevents tension and tugging on the tube. Turning the head ensures adequate slack in the tubing to prevent tension when the patient turns the head. Securing the double-lumen tube above stomach level prevents seepage of gastric contents and keeps the lumen clear for venting air.

FIGURE 8. Patient with Salem sump tube (NG) secured. Note blue vent at patient's shoulder.

16. Put on gloves. Assist with or provide oral hygiene at 2- to 4-hour intervals. Lubricate the lips generously and clean nares and lubricate, as needed. Offer analgesic throat lozenges or anesthetic spray for throat irritation, if needed.

Gloves prevent contact with blood and body fluids and transfer of microorganisms. Oral hygiene keeps the mouth clean and moist, promotes comfort, and reduces thirst.

17. Remove and reapply the NG tube securement device every 24 hours; assess, clean, and apply a skin barrier to the skin beneath or in contact with the NG tube prior to replacement. Reposition the tube to alleviate pressure. Provide nares hygiene as needed (Schroeder & Sitzer, 2019).

Pressure from the tube can create pressure damage; these actions help prevent development of pressure injury (Baranoski & Ayello, 2020; EPUAP, NPIAP, & PPPIA, 2019a; Schroeder & Sitzer, 2019).

18. Remove equipment and return the patient to a position of comfort. Remove gloves. Perform hand hygiene. Raise the side rail and lower the bed.

Positioning promotes patient comfort and safety. Removing gloves properly and using hand hygiene reduces the risk for infection transmission and contamination of other items.

19. Remove additional PPE, if used. Perform hand hygiene.

Proper removal of PPE reduces the risk for infection transmission and contamination of other items. Hand hygiene prevents transmission of microorganisms.

DOCUMENTATION

Guidelines

Document the size and type of the NG tube that was inserted and the postinsertion measurement of the length of the tube from the tip of the nose to the end of the exposed tube. Also, document the results of the x-ray that was taken to confirm the tube position, if applicable. Record the pH of the aspirated gastric contents. Document the naris where the tube was placed and the patient's response to the procedure. Include assessment data related to the abdomen. Record the patient teaching that was discussed.

Sample Documentation

DocuCare Practice documenting NG tube insertion in *Lippincott DocuCare*.

10/4/25 0945 Abdomen slightly distended and taut; hypoactive bowel sounds. Patient reports transient nausea. 14F double-lumen nasogastric tube inserted via right naris, 20 cm of tube from naris to end of tube post insertion; aspirate pH 4; patient tolerated without incident.

—S. Essner, RN

DEVELOPING CLINICAL REASONING AND CLINICAL JUDGMENT

UNEXPECTED SITUATIONS AND ASSOCIATED INTERVENTIONS

- *As tube is passing through the pharynx, patient begins to retch and gag:* This is common during placement of an NG tube. Ask the patient if they want to stop the procedure, which will allow the patient to gain composure from the gagging episode. Continue to advance the tube when the patient relates that they are ready. Have the emesis basin nearby in case the patient begins to vomit.
- *You are unable to pass the tube after trying a second time down the one nostril:* If the patient's condition permits, inspect the other nostril and attempt to pass the NG tube down this nostril. If unable to pass down this nostril, consult with the health care team.
- *As the tube is passing through the pharynx, the patient begins to cough and shows signs of respiratory distress:* **Stop advancing the tube.** The tube is most likely entering the trachea. Pull the tube back into the nasal area. Support the patient as they regain normal breathing ability and composure. If the patient feels that they can tolerate another attempt, ask the patient to keep their chin on their chest and swallow as the tube is advanced to help prevent the tube from entering the trachea. Begin to advance the tube, watching for any signs of respiratory distress.
- *No gastric contents can be aspirated:* Reposition the patient and flush the tube with 30 mL of air in a large syringe. Slowly apply negative pressure to withdraw fluid.

SPECIAL CONSIDERATIONS

General Considerations

- A nasal bridle (Figure 9) is another type of commercial device that has been suggested to secure NG tubes (Stabler et al., 2018; Taylor et al., 2018).
- Check tube placement before administering any fluids, medications, or feeding, using multiple techniques: x-ray, external length, external verification marking, pH testing, and carbon dioxide monitoring (if available). Consistent inability to withdraw fluid from tube may indicate displacement of the tube from the stomach into the esophagus (AACN, 2020).
- Signs of respiratory distress may be absent in patients with an impaired level of consciousness when NG tubes are inadvertently positioned in the airway (AACN, 2020).
- Sterile water should be used for tube flushes in immunocompromised or critically ill patients (Allen, 2015; Boullata et al., 2017).
- Gastric pH ≥6 is of no benefit in predicting tube location in the GI tract or in ruling out tracheopulmonary placement (Boullata et al., 2017).

Infant and Child Considerations

- Infants are obligate nose breathers; tubes are usually inserted via the mouth (orogastric tube). Insertion through a nostril is usually more comfortable for older children (Silbert-Falgg & Pillitteri, 2018).

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

FIGURE 9. Example of a commercially prepared nasal bridle. (*Source:* Images courtesy of Applied Medical Technology, Inc. [AMT]. https://www.appliedmedical.net)

Skill 39-3 Removing a Nasogastric Tube

DELEGATION CONSIDERATIONS

The removal of an NG tube is not delegated to assistive personnel (AP). Depending on the state's nurse practice act and the organization's policies and procedures, removal of an NG tube may be delegated to licensed practical/vocational nurses (LPN/LVNs). The decision to delegate must be based on careful analysis of the patient's needs and circumstances as well as the qualifications of the person to whom the task is being delegated. Refer to the Delegation Guidelines in Appendix A.

EQUIPMENT

- Tissues
- 50-mL syringe
- Nonsterile gloves
- Additional PPE, as indicated
- Stethoscope
- Disposable plastic bag
- Bath towel or disposable pad
- Normal saline solution for irrigation (optional)
- Emesis basin

IMPLEMENTATION

ACTION	RATIONALE
1. Check the health record for the prescribed intervention for removal of the NG tube. Gather equipment.	This ensures the patient receives the correct treatment. Gathering equipment provides for an organized approach to the task.
 2. Perform hand hygiene and put on PPE, if indicated.	Hand hygiene and PPE prevent the spread of microorganisms. PPE is required based on transmission precautions.
 3. Identify the patient.	Identifying the patient ensures the right patient receives the intervention and helps prevent errors.
4. Explain the procedure to the patient and why this intervention is warranted. Describe that it will entail	Patient engagement is facilitated when explanations are provided. Due to potential changes in a patient's

a few moments of discomfort. Perform key abdominal assessments as described above.	condition, assessment is vital before initiating intervention.
5. Pull the patient's bedside curtain. Raise the bed to a comfortable working position (VHACEOSH, 2016). Assist the patient to a 30- to 45-degree position. Place a towel or disposable pad across the patient's chest (Figure 1). Give tissues and an emesis basin to the patient.	This provides for privacy. An appropriate working height facilitates comfort and proper body mechanics for the nurse. A towel or pad protects the patient from contact with gastric secretions. An emesis basin is helpful if the patient vomits or gags. Tissues are necessary if the patient wants to blow their nose when the tube is removed.
6. Put on gloves. Discontinue suction and separate the tube from suction. Detach the tube from any securement to patient's gown and/or face and carefully remove the securement device or adhesive tape from the patient's nose.	Gloves prevent contact with blood and body fluids. Disconnecting the tube from suction and the patient allows for its unrestricted removal.
7. Check placement (refer to Skill 38-2) and flush the tube with 10 mL of water or normal saline solution (optional) or clear with 30 to 50 mL of air (Figure 2).	Air or saline solution clears the tube of secretions or debris.

FIGURE 1. Placing towel or disposable pad across patient's chest.

FIGURE 2. Flushing NG tube with 10-mL water.

8. Clamp the tube with your fingers by doubling the tube on itself (Figure 3). **Instruct the patient to take a deep breath and hold it. Quickly and carefully remove the tube while the patient holds their breath.** Coil the tube in the disposable pad as you remove it from the patient.	Clamping prevents drainage of gastric contents into the pharynx and esophagus. The patient holds their breath to prevent accidental aspiration of gastric secretions in the tube. Careful removal minimizes trauma and discomfort for the patient. Containing the tube in a towel while removing it prevents leakage onto the patient.
9. Dispose of the tube per facility policy. Remove gloves. Perform hand hygiene.	This prevents contamination with microorganisms.
10. Offer mouth care to the patient and facial tissue to blow their nose. Assist the patient to a position of comfort, as needed.	These interventions promote patient comfort.
11. Remove equipment, raise the side rail, and lower the bed.	Positioning promotes patient comfort and safety.
12. Put on gloves and measure the amount of NG drainage in the collection device. Record the measurement on the output flow record, subtracting irrigant fluids if necessary (Figure 4). Add solidifying agent to the NG drainage and dispose of the drainage according to facility policy.	Irrigation fluids are considered intake. To obtain the true NG drainage, irrigant fluid amounts are subtracted from the total NG drainage. NG drainage is recorded as part of the output of fluids from the patient. Solidifying agents added to liquid NG drainage facilitate safe biohazard disposal.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

FIGURE 3. Doubling tube on itself.

FIGURE 4. Measuring the amount of nasogastric drainage in collection device.

13. Remove gloves and additional PPE, if used. Perform hand hygiene.

Proper removal of PPE reduces the risk for infection transmission and contamination of other items. Hand hygiene prevents transmission of microorganisms.

DOCUMENTATION

Guidelines

Document assessment of the abdomen. If an abdominal girth reading was obtained, record this measurement. Document the removal of the NG tube from the naris where it had been placed. Note if there is any irritation to the skin of the naris. Record the amount of NG drainage in the suction container on the patient's intake-and-output record as well as the color of the drainage. Record any pertinent teaching, such as instructions to the patient to notify the nurse if they experience any nausea, abdominal pain, or bloating.

Sample Documentation

10/29/25 1320 NG tube removed from L naris without incident. 300 mL of dark brown liquid emptied from NG tube. Patient's abdomen is 66 cm; abdomen is soft, nontender with hypoactive bowel sounds in all four quadrants.

—S. Essner, RN

Developing Clinical Reasoning and Clinical Judgment

UNEXPECTED SITUATIONS AND ASSOCIATED INTERVENTIONS

- Within 2 hours after NG tube removal, the patient's abdomen is showing signs of distention: Notify the health care team. Anticipate an order to reinsert the NG tube.
- Epistaxis occurs with removal of the NG tube: Occlude both nares until bleeding has subsided. Ensure that patient is in upright position. Document the epistaxis in the patient's health record.

Skill 39-4 Irrigating a Nasogastric Tube Connected to Suction

DELEGATION CONSIDERATIONS

The irrigation of an NG tube is not delegated to assistive personnel (AP). Depending on the state's nurse practice act and the organization's policies and procedures, irrigation of an NG tube may be delegated to licensed practical/vocational nurses (LPN/LVNs). The decision to delegate must be based on careful analysis of the patient's needs and circumstances as well as the qualifications of the person to whom the task is being delegated. Refer to the Delegation Guidelines in Appendix A.

EQUIPMENT

- Water, sterile water, or normal saline solution for irrigation (based on facility policy)
- Nonsterile gloves
- Additional PPE, as indicated
- Irrigation set, including a large syringe (20 to 50 mL)
- Clamp
- Disposable waterproof pad or bath towel
- Emesis basin
- Tape measure, or other measuring device
- pH test strip (calibrated in units of 0.5 and approved for use with human secretions)
- Stethoscope (for abdominal assessment)

IMPLEMENTATION

ACTION	RATIONALE
1. Gather equipment. Verify the prescribed intervention or facility policy and procedure regarding frequency of irrigation, solution type, and amount of irrigant. Check expiration dates on the irrigating solution and irrigation set.	Assembling equipment provides for an organized approach to the task. Verification ensures the patient receives the correct intervention. Facility policy dictates safe interval for reuse of equipment.
 2. Perform hand hygiene and put on PPE, if indicated.	Hand hygiene and PPE prevent the spread of microorganisms. PPE is required based on transmission precautions.
 3. Identify the patient.	Identifying the patient ensures the right patient receives the intervention and helps prevent errors.
4. Explain the procedure to the patient and why this intervention is needed. Answer any questions, as needed. Perform key assessments as described above.	Explanation facilitates patient engagement. Due to potential changes in a patient's condition, assessment is vital before initiating an intervention.
5. Assemble equipment on the overbed table or other surface within reach.	Organization facilitates performance of the task.
6. Pull the patient's bedside curtain. Raise the bed to a comfortable working position (VHACEOSH, 2016). Assist the patient to 30- to 45-degree position, unless this is contraindicated. Pour the irrigating solution into container.	This provides for privacy. An appropriate working height facilitates comfort and proper body mechanics for the nurse. This position minimizes risk for aspiration. Preparing the irrigation provides for an organized approach to the task.
7. Put on gloves. Place a waterproof pad on the patient's chest, under the connection of the NG tube and suction tubing. **Check placement of the NG tube.** Refer to Skill 39-2.	Gloves prevent contact with body fluids. The waterproof pad protects the patient's clothing and bed linens from accidental leakage of gastric fluid. Checking placement before the instillation of fluid is necessary to prevent accidental instillation into the respiratory tract if the tube has become dislodged.
8. Draw up 30 mL of irrigation solution (or amount indicated in the order or policy) into the irrigation syringe (Figure 1).	This delivers measured amount of irrigant through the tube. Flushing the tube prevents occlusion (Bischoff et al., 2020; Boullata et al., 2017; Drummond Hayes, 2018).
9. Clamp the NG tube near the connection site using a clamp, or double the tube on itself. Disconnect the tube from the suction apparatus (Figure 2) and lay it on a disposable pad or towel, or hold both tubes upright in your nondominant hand (Figure 3).	Clamping prevents leakage of gastric fluid.
10. Place tip of the syringe in the tube. **If a double-lumen tube is used, make sure that the syringe tip is placed in the drainage port and not in the blue**	Gentle insertion of saline solution (or gravity insertion) is less traumatic to gastric mucosa. The blue air vent acts to decrease pressure built up in the

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

air vent. Hold the syringe upright and gently insert the irrigant (Figure 4) (or allow solution to flow in by gravity if facility policy or prescribed intervention indicates). **Do not force solution into the tube.**

stomach when the Salem sump is attached to suction. It is not to be used for irrigation. Flushing the tube prevents occlusion (Bischoff et al., 2020; Boullata et al., 2017; Drummond Hayes, 2018).

FIGURE 1. Preparing syringe with 30 mL of irrigation solution.

FIGURE 2. Clamping nasogastric tube while disconnecting.

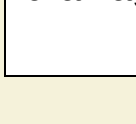


FIGURE 3. Keeping both tubes upright to prevent leakage of gastric fluid.

FIGURE 4. Gently instilling irrigation.

11. If you are unable to irrigate the tube, reposition the patient and attempt irrigation again. Inject 10 to 20 mL of air and aspirate again. **If repeated attempts to irrigate the tube fail, consult with the health care team or follow facility policy.**	The tube may be positioned against gastric mucosa, making it difficult to irrigate. Injection of air may reposition the end of the tube.
12. After irrigant has been instilled, hold the end of the NG tube over the irrigation tray or emesis basin. Observe for return flow of NG drainage into the container. Alternatively, you may reconnect the NG tube to suction and observe the return drainage as it drains into the suction container.	Return flow may be collected in an irrigating tray or other available container and measured. This amount will need to be subtracted from the irrigant to record the true NG drainage. A second method involves subtracting the total irrigant from the shift from the total NG drainage emptied over the entire shift to find the true NG drainage. Check facility policy for guidelines.
13. If not already done, reconnect the drainage port to suction, if prescribed.	This allows for continued removal of gastric contents, as prescribed.
14. Inject air into the blue air vent after irrigation is complete. Position the blue air vent above the patient's stomach.	Following irrigation, the blue air vent is injected with air to keep it clear. Positioning the blue air vent above the stomach prevents the stomach contents from leaking from the NG tube.
 15. Remove gloves. Perform hand hygiene. Lower the bed and raise the side rails, as necessary. Assist the patient to a position of comfort.	Proper removal of gloves and hand hygiene prevent transmission of microorganisms. Lowering the bed and assisting the patient to a comfortable position promote safety and comfort.

16. Put on gloves. Measure returned solution, if collected outside of the suction apparatus. Rinse equipment if it will be reused. Label equipment with the date, patient's name, room number, and purpose (for NG tube/irrigation).	Gloves prevent contact with blood and body fluids. The irrigant placed in the tube is considered intake; solution returned is recorded as output. Record on the intake and output record. Rinsing promotes cleanliness, infection control, and prepares equipment for the next irrigation.
 17. Remove gloves and additional PPE, if used. Perform hand hygiene.	Proper removal of PPE reduces the risk for infection transmission and contamination of other items. Hand hygiene prevents transmission of microorganisms.

DOCUMENTATION

Guidelines

Document assessment of the patient's abdomen. Record if the patient's NG tube is clamped or connected to suction, including the type of suction. Document the color and consistency of the NG drainage. Record the solution type and amount used to irrigate the NG tube as well as ease of irrigation or any difficulty related to the procedure. Record the amount of returned irrigant, if collected outside of the suction apparatus. Alternatively, record irrigant amount so it can be subtracted from the total NG drainage amount at the end of the shift. Record the patient's response to the procedure and any pertinent teaching points that were reviewed, such as instructions for the patient to contact the nurse for any feelings of nausea, bloating, or abdominal pain.

Sample Documentation

10/15/25 1100 Abdomen slightly distended but soft; absent bowel sounds, denies nausea. NG tube placement confirmed; aspirate pH 4; exposed NG tube 20 cm, consistent with documented length. NG tube irrigated with 30 mL of normal saline. NG tube reconnected to low intermittent suction. Clear drainage with brown flecks noted from tube. Patient tolerated irrigation without incident.

—S. Essner, RN

Developing Clinical Reasoning and Clinical Judgment

UNEXPECTED SITUATIONS AND ASSOCIATED INTERVENTIONS

- *Flush solution is meeting a lot of force when plunger is pushed:* Inject 20 to 30 mL of free air through the NG tube into the stomach in an attempt to reposition the tube and enable flushing of the tube.
- *Tube is connected to suction as prescribed, but nothing is draining from the tube:* First, check the suction canister to ensure that the suction is working appropriately. Disconnect the NG tube from suction and place your gloved thumb over the end of the suction tubing. If there is suction present, the problem lies in the tube itself. Next, attempt to flush the tube to ensure its patency.
- *After flushing the tube, the tube is not reconnected to suction as prescribed:* Reconnect the tube to suction as soon as the error is noticed. Assess the abdomen for distention and ask the patient if they are experiencing any nausea or any abdominal discomfort. Complete any paperwork per institutional policy, such as a variance report.

SPECIAL CONSIDERATIONS

General Considerations

- A one-way, antireflux valve may be used in the airflow lumen to prevent reflux of gastric contents through the airflow lumen (Figure 5). When pressure from gastric contents enters the airflow tubing, the valve closes to prevent secretions from exiting the tube. This valve is removed before flushing the lumen with air and then replaced.
- Check tube placement before administering any fluids, medications, or feeding, using multiple techniques: x-ray, external length, external verification marking, pH testing, and carbon dioxide monitoring (if available). Consistent inability to withdraw fluid from tube may indicate displacement of the tube from the stomach into the esophagus (AACN, 2020).

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

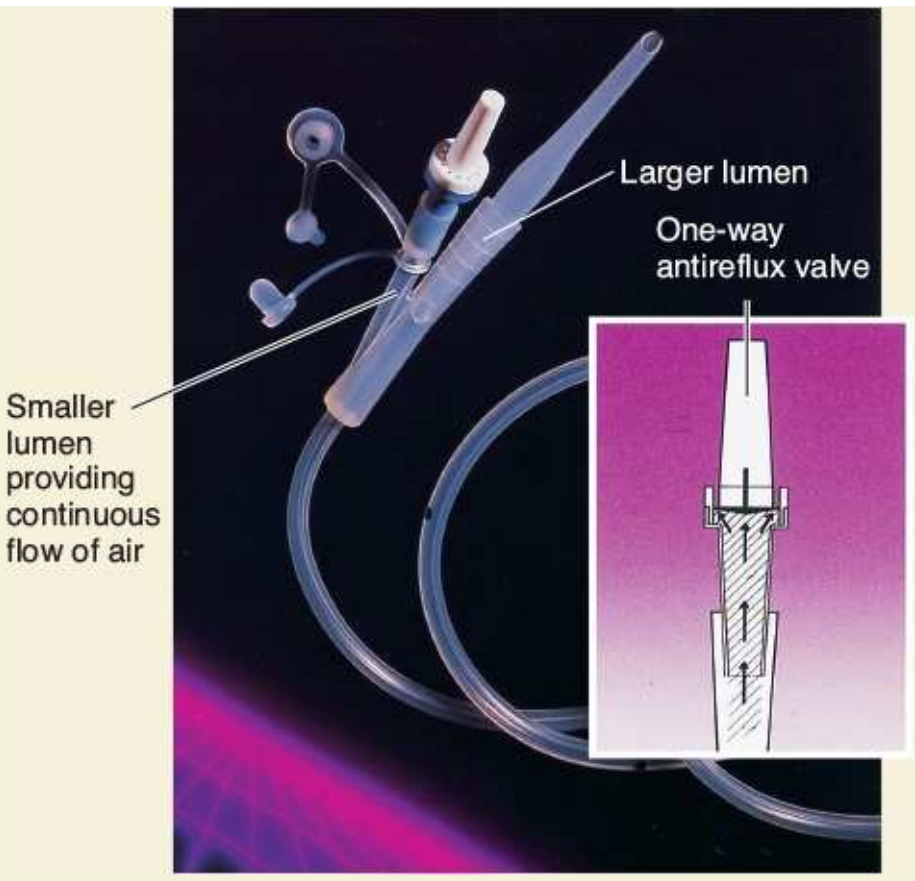

FIGURE 5. Double-lumen nasogastric tube with a one-way antireflux valve in the airflow lumen.

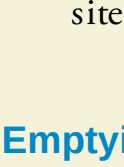
Signs of respiratory distress may be absent in patients with an impaired level of consciousness when NG tubes are inadvertently positioned in the airway (AACN, 2020).

- Sterile water should be used for tube flushes in immunocompromised or critically ill patients (Allen, 2015; Boullata et al., 2017).
- Gastric pH ≥6 is of no benefit in predicting tube location in the GI tract or in ruling out tracheopulmonary placement (Boullata et al., 2017).
- Monitoring for carbon dioxide to determine NG tube position and/or dislodgement has been investigated (Hess et al., 2021). This involves the use of a colorimetric end-tidal CO_2 detector to detect the presence of carbon dioxide, which would indicate tube positioning in the patient's airway (Hess et al., 2021). Monitoring for carbon dioxide may be helpful to detect placement of a feeding tube in the tracheobronchial tree (AACN, 2020; Boullata et al., 2017; Hess et al., 2021). However, this technique may be unreliable, as it cannot differentiate placement in the mouth, and carbon dioxide may not be detected when the tube is in the patient's airway if the ports in the tube are occluded (Gilbert & Burns, 2010, as cited in AACN, 2020).

Skill 39-5 Emptying and Changing an Ostomy Appliance

DELEGATION CONSIDERATIONS



Emptying a stoma appliance on an ostomy may be delegated to assistive personnel (AP) as well as to licensed practical/vocational nurses (LPN/LVNs). Changing a stoma appliance on an ostomy may be delegated to an LPN/LVN. The decision to delegate must be based on careful analysis of the patient's needs and circumstances as well as the qualifications of the person to whom the task is being delegated. Refer to the Delegation Guidelines in Appendix A.

EQUIPMENT

- Premoistened disposable washcloths or
  - Basin with warm water
  - Skin cleanser, towel, washcloth
- Toilet tissue or paper towel
- Silicone-based adhesive remover
- Gauze squares
- Skin protectant, such as Skin-Prep™
- One-piece ostomy appliance
- Closure clamp, if required, for appliance

- Stoma measuring guide
- Graduated container, toilet, or bedpan
- Ostomy belt (optional)
- Disposable gloves
- Additional PPE, as indicated
- Small plastic trash bag
- Waterproof disposable pad

IMPLEMENTATION

ACTION	RATIONALE
1. Gather equipment.	Assembling equipment provides for an organized approach to the task.
 2. Perform hand hygiene and put on PPE, if indicated.	Hand hygiene and PPE prevent the spread of microorganisms. PPE is required based on transmission precautions.
 3. Identify the patient.	Identifying the patient ensures the right patient receives the intervention and helps prevent errors.
4. Close the curtains around the bed and close the door to the room, if possible. Explain to the patient what you are going to do and why. Encourage the patient to observe or participate, if possible and as appropriate.	This ensures the patient's privacy. Explanation relieves anxiety and facilitates engagement. Having the patient observe or assist encourages self-acceptance and helps patient develop self-care skills.
5. Assemble equipment on the overbed table or other surface within reach.	Arranging items nearby is convenient, saves time, and avoids unnecessary stretching and twisting of muscles on the part of the nurse.
6. Assist the patient to a comfortable sitting or lying position in bed or a standing or sitting position in the bathroom. If the patient is in bed, adjust the bed to a comfortable working height (VHACEOSH, 2016). Place a waterproof pad under the patient at the stoma site.	Either position should allow the patient to view the procedure in preparation to learn to perform it independently. Lying flat or sitting upright facilitates smooth application of the appliance. Having the bed at the proper height prevents back and muscle strain. A waterproof pad protects linens and the patient from moisture.
Emptying an Appliance	
7. Put on gloves. Remove the clamp (Figure 1) and fold the end of the appliance or pouch upward like a cuff.	Gloves prevent contact with blood, body fluids, and microorganisms. Creating a cuff before emptying prevents additional soiling and odor.
8. Empty the contents into a bedpan, toilet, or measuring device (Figure 2).	Appliances do not need rinsing because rinsing may reduce the appliance's odor barrier.
9. Wipe the lower 2 inches of the appliance or pouch with toilet tissue or a paper towel (Figure 3).	Drying the lower section removes any additional fecal material, thus decreasing odor problems.
 10. Uncuff the edge of the appliance or pouch and apply a clip or clamp, or secure the Velcro closure. Ensure the curve of the clamp follows the curve of the patient's body. Remove gloves. Perform hand hygiene. Assist the patient to a comfortable position.	The edge of the appliance or pouch should remain clean. The clamp secures closure. Hand hygiene deters spread of microorganisms. Positioning ensures patient comfort.
11. If the appliance is not to be changed, place the bed in the lowest position. Remove additional PPE, if used.	Proper removal of PPE reduces the risk for infection transmission and contamination of other items. Hand

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

Perform hand hygiene. hygiene prevents the spread of microorganisms.

FIGURE 1. Removing clamp, getting ready to empty pouch.

FIGURE 2. Emptying contents of appliance into a measuring device.

FIGURE 3. Wiping lower 2 inch of pouch with paper towel.

Changing an Appliance

12. Place a disposable pad on the work surface. Open the premoistened disposable washcloths or set up the washbasin with warm water and the rest of the supplies. Place a trash bag within reach.
    The pad protects the work surface. Organization facilitates performance of the procedure.
13. Put on clean gloves. Place a waterproof pad under the patient at the stoma site. Empty the appliance as described in Steps 7–10.
    The pad protects linens and the patient from moisture. Emptying the contents before removal prevents accidental spillage of fecal material.
14. Put on gloves. Use two hands to gently remove the appliance faceplate, starting at the top and keeping the abdominal skin taut. Remove the appliance faceplate from the skin by pushing the skin from the appliance rather than pulling the appliance from the skin (Figure 4). Apply a silicone-based adhesive remover by spraying or wiping with the remover wipe, as indicated.
    Gloves prevent contact with blood and body fluids. The seal between the surface of the faceplate and the skin must be broken before the faceplate can be removed. Harsh handling of the appliance can damage the skin and impair the development of a secure seal in the future. A silicone-based adhesive remover loosens the adhesive bond to make removal easier and less likely to damage the skin and is particularly beneficial for patients with fragile skin and those at increased risk for medical adhesive–related skin injury/stripping (Collier, 2019; LeBlanc et al., 2019; Swift et al., 2020).

FIGURE 4. Gently removing appliance.

15. Place the appliance in the trash bag, if disposable. If reusable, set it aside to wash in lukewarm soap and water and allow it to air dry after the new appliance is in place.

    Thorough cleaning and airing of the appliance reduces odor and deterioration of the appliance. For aesthetic and infection control purposes, discard used appliances appropriately.

16. Use toilet tissue to remove any excess stool from the stoma (Figure 5). Cover the stoma with a gauze pad. Clean the skin around the stoma with skin cleanser and water or a cleansing agent and a washcloth. Remove all old adhesive from the skin; use an adhesive remover, as necessary. Do not apply lotion to the peristomal area.

    Toilet tissue, used gently, will not damage the stoma. The gauze absorbs any drainage from the stoma while the skin is being prepared. Cleaning the skin removes excretions, old adhesive, and skin protectant. Excretions or a buildup of other substances can irritate and damage the skin. Lotion will prevent a tight adhesive seal.

FIGURE 5. Using toilet tissue to remove excess stool from the stoma.

17. Gently pat the area dry. **Make sure the skin around the stoma is thoroughly dry.** Assess the stoma and the condition of the surrounding skin (Figure 6).

    Careful drying prevents trauma to the skin and stoma. An intact, properly applied fecal collection device protects skin integrity. Any change in color and size of the stoma may indicate circulatory problems. Refer to Box 39-1.

18. Apply skin protectant/barrier film to a 2-inch (5 cm) radius around the stoma, and allow it to dry completely, which takes about 30 seconds.

    The skin needs protection from the excoriating effect of the excretion and potentially from the appliance adhesive (WOCN, 2018). The skin must be perfectly dry before the appliance is placed to get good adherence and to prevent leaks.

19. Lift the gauze squares for a moment and measure the stoma opening, using the measurement guide (Figure 7). Replace the gauze. Trace the same-sized opening on the back center of the appliance (Figure 8). Cut the opening 1/8 inch (2 to 3 mm) larger than the stoma size (Hill, 2020) (Figure 9). Using a finger, gently smooth the wafer edges after

    The appliance should fit snugly around the stoma, with only 1/8 inch of skin visible around the opening. A faceplate opening that is too small can cause trauma to the stoma. If the opening is too large, exposed skin will be irritated by stool. The wafer edges may be uneven after cutting and could cause irritation to, and/or pressure on, the stoma.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

cutting.

FIGURE 6. Assessing stoma and peristomal skin.

FIGURE 7. Using measurement guide to measure size of stoma.

FIGURE 8. Tracing the same-sized circle on back and center of skin barrier.

FIGURE 9. Cutting the opening 1/8 inch larger than stoma size.

20. Remove the paper backing from the appliance faceplate (Figure 10). Quickly remove the gauze squares and ease the appliance over the stoma (Figure 11). Gently press it onto the skin while smoothing over the surface. Apply gentle, even pressure to the appliance for approximately 30 seconds (Burch, 2019a; Hill, 2020).

    The appliance is effective only if it is properly positioned and adhered securely. Pressure on the appliance faceplate allows it to mold to the patient's skin and improve adhesion (Burch, 2019a; Hill, 2020).

21. Close the bottom of the appliance or pouch by folding the end upward and using the clamp or clip that comes with the product (Figure 12), or secure the Velcro closure. Ensure the curve of the clamp follows the curve of the patient's body.

    A tightly sealed appliance will not leak and cause embarrassment and discomfort for the patient.

FIGURE 10. Removing paper backing on faceplate.

FIGURE 11. Easing appliance over stoma.

FIGURE 12. Using clip to close bottom of appliance.

22. Remove gloves. Perform hand hygiene. Assist the patient to a comfortable position. Cover the patient with bed linens. Place the bed in the lowest position.

Removing gloves reduces risk of transmission of microorganisms. Hand hygiene prevents the spread of microorganisms. Covering provides warmth and promotes patient comfort and safety. The bed in the lowest position promotes patient safety.

23. Put on clean gloves. Remove or discard equipment and assess the patient's response to the procedure.

Gloves prevent contact with blood, body fluids, and microorganisms that contaminate the used equipment. The patient's response may indicate acceptance of the ostomy as well as the need for health teaching.

24. Remove gloves and additional PPE, if used. Perform hand hygiene.

Proper removal of PPE reduces the risk for infection transmission and contamination of other items. Hand hygiene prevents the spread of microorganisms.

DOCUMENTATION

Guidelines

Document the appearance of the stoma, the condition of the peristomal skin, characteristics of drainage (amount, color, consistency, unusual odor), the patient's reaction to the procedure, and pertinent patient teaching.

Sample Documentation

DocuCare Practice documenting changing and emptying an ostomy appliance in *Lippincott DocuCare*.

7/22/25 1630 Colostomy appliance changed due to leakage. Stoma is pink, moist, and flat against abdomen. No erythema or excoriation of surrounding skin. Moderate amount of pasty, brown stool noted in bag. Patient asking appropriate questions during appliance application; states, "I'm ready to try changing the next one."

—B. Clapp, RN

DEVELOPING CLINICAL REASONING AND CLINICAL JUDGMENT

UNEXPECTED SITUATIONS AND ASSOCIATED INTERVENTIONS

- *Peristomal skin is excoriated or irritated:* Make sure that the appliance is not cut too large. Skin that is exposed inside of the ostomy appliance will become excoriated. Assess for the presence of a fungal skin infection. If present, consult with the health care team to obtain appropriate treatment. Thoroughly cleanse and dry the skin and apply a product made for excoriated skin before reapplication of the appliance. Allow it to dry completely. Reapply the pouch. Monitor pouch adhesion and change the pouch as soon as there is a break in adhesion. Confer with the health care team for a wound, ostomy, and continence nurse consult to manage these issues. Document the assessment findings and related interventions in the patient's health record.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

- *Patient continues to notice odor:* Check the system for any leaks or poor adhesion. Clean the outside of the bag thoroughly when emptying.
- *Bag continues to come loose or fall off:* Thoroughly cleanse the skin and apply a skin barrier. Allow it to dry completely. Reapply the pouch. Monitor pouch adhesion and change the pouch as soon as there is a break in adhesion.
- *Stoma is protruding into bag:* This is called a prolapse. Have the patient rest for 30 minutes. If the stoma is not back to normal size within that time, notify the health care team. If the stoma stays prolapsed, it may twist, resulting in impaired circulation to the stoma.
- *Stoma is dark brown or black:* Stoma should appear pink to red, shiny, and moist. Alterations indicate compromised circulation. If the stoma is dark brown or black, suspect ischemia and necrosis. Notify the health care team immediately.

DEVELOPING CLINICAL REASONING AND CLINICAL JUDGMENT

. Review the Nursing Care Plan for Jeremy Green on pages 1554–1555.

. Discuss the appropriate nursing intervention if an assessment revealed the following:

- Patient has frank blood in stool.
- Parent reports that child's stool is unusually foul smelling and greasy.
- Patient's stool is ribbon-like.
- Patient with cancer and receiving pain medication reports chronic constipation.
- Teenager reports frequent episodes of diarrhea that leave them weak and dehydrated.

. A 52-year-old male presents with acute stomach pain and altered bowel elimination: diarrhea. Role-play with another student the interview you would use to assess the patient's bowel elimination status. Identify variables that make you, as either the nurse or patient, uncomfortable talking about elimination. Discuss how you can best address your discomfort.

PRACTICING FOR NCLEX

. A nurse is performing an abdominal assessment on a patient experiencing frequent bouts of diarrhea. The nurse first observes the contour of the abdomen, noting any masses, scars, or areas of distention. What action will the nurse perform next?

a. Auscultating the abdomen using an orderly clockwise approach in all abdominal quadrants
b. Percussing all quadrants of the abdomen in a systematic clockwise manner to identify masses, fluid, or air in the abdomen
c. Lightly palpating over the abdominal quadrants; first checking for any areas of pain or discomfort
d. Deeply palpating over the abdominal quadrants, noting muscular resistance, tenderness, organ enlargement, or masses

. A nurse is administering a large-volume cleansing enema to a patient prior to surgery. When the enema solution is introduced, the patient reports severe cramping. What nursing intervention would the nurse perform next?

a. Elevating the head of the bed 30 degrees and repositioning the rectal tube
b. Placing the patient in a supine position and modifying the amount of solution
c. Lowering the solution container and checking the temperature and flow rate
d. Removing the rectal tube and notifying the primary care provider

. A nurse working on a GI unit is caring for a group of patients. In patients with which health problems or issues could the assessment possibly reveal decreased or absent bowel sounds after listening for 2 minutes? Select all that apply.

a. Peritonitis
b. Prolonged bedrest
c. Diarrhea
d. Gastroenteritis
e. Early bowel obstruction
f. Postoperative paralytic ileus

. A nurse in a long-term care facility is assessing a group of patients. In which patients would the nurse anticipate increased risk for developing diarrhea? Select all that apply.

a. Patient taking opioids for pain
b. Patient taking metformin for type 2 diabetes
c. Patient taking diuretics
d. Patient who developed dehydration
e. Patient taking amoxicillin clavulanate for infection

f. Patient taking magnesium-containing antacids

. A nurse plans to administer a retention enema to a patient with a fecal impaction. Which nursing action is appropriate for this procedure?

a. Administering a large volume of solution (500 to 1,000 mL)
b. Mixing milk and molasses in equal parts for an enema
c. Instructing the patient to retain the enema for at least 30 minutes
d. Administering the enema while the patient is sitting on the toilet

. A nurse prepares to assist a patient with a newly created ileostomy. Which recommended patient teaching points would the nurse stress? Select all that apply.

a. "When you inspect the stoma, it should be dark purple-blue."
b. "The size of the stoma will stabilize within 2 weeks."
c. "Keep the skin around the stoma site clean and moist."
d. "The stool from an ileostomy is normally liquid."
e. "Eat dark-green vegetables to control the odor of the stool."
f. "You may have a tendency to develop food blockages."

. A nurse is preparing a hospitalized patient for a colonoscopy. Which nursing action is the recommended preparation for this test?

a. Having the patient consume a low-fiber diet several days before the test
b. Having the patient take bisacodyl and ingest a gallon oral polyethylene glycol solution (PEG)
c. Preparing the patient for the use of general anesthesia during the test
d. Explaining that barium contrast mixture will be given to drink before the test

. A nurse is performing digital removal of stool on a patient with a fecal impaction. During the procedure, the patient tells the nurse they are feeling dizzy and nauseated and then vomits. What should be the nurse's next action?

a. Reassuring the patient that this is a normal reaction to the procedure
b. Stopping the procedure, preparing to administer CPR, and notifying the primary care provider
c. Stopping the procedure, assessing vital signs, and notifying the health care provider
d. Pausing the procedure, waiting 5 minutes, and then resuming the procedure

. A nurse is scheduling tests for a patient who has been experiencing epigastric pain. The health care provider ordered the following tests: (a) barium enema, (b) fecal occult blood test, (c) endoscopic studies, and (d) an upper GI series. What is the correct order for performing the tests?

a. c, b, d, a
b. d, c, a, b
c. a, b, d, c
d. b, a, d, c

. A nurse is caring for a patient who had abdominal surgery and has a nasogastric tube attached to low suction. Which nursing actions are appropriate when caring for this patient? Select all that apply.

a. Irrigating the tube with 30-mL normal saline solution
b. Confirming tube placement via pH testing of gastric secretions
c. Positioning the air vent at the level of the patient's umbilicus
d. Instilling irrigation via the blue air vent
e. Monitoring the patient's abdomen for distention
f. Documenting the nasogastric irrigation and drainage with I & O

. A nurse is planning a bowel program for a patient with frequent constipation after sustaining a spinal cord injury. What is the first step the nurse will take?

a. Offering a diet that is low in residue
b. Increasing fluid intake to 3,000 mL daily
c. Administering daily enemas to stimulate peristalsis
d. Assessing the patient's bowel patterns

. A community health nurse is providing an adult education session about colon cancer. Which signs and symptoms of this cancer will the nurse include? Select all that apply.

a. Blood in the stool
b. Previous colonoscopy
c. Passing two large bowel movements daily

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

d. Unintentional weight loss
e. Upper abdominal cramping
f. Previous opioid use

. For a patient with which health problem or issue would a nurse expect the health care provider to order colostomy irrigation?
a. IBS
b. Left-sided end colostomy in the sigmoid colon
c. Postradiation damage to the bowel
d. Crohn disease

. A nurse is assisting a patient to change an ostomy appliance when they note the stoma is protruding into the bag. What would be the nurse's first action in this situation?
a. Reassuring the patient that this is a normal with a new ostomy
b. Notifying the health care provider that the stoma is prolapsed
c. Having the patient rest for 30 minutes to see if the prolapse resolves
d. Replacing the appliance with a larger appliance

. A nurse is caring for an older adult who reports persistent constipation and has a number of laxative prescriptions on the MAR. Which medication would the nurse avoid for this patient?
a. Saline osmotic laxative
b. Bulk-forming laxative
c. Methylcellulose
d. Stool softener

. A nurse caring for a patient who reports frequent constipation learns the patient uses phosphate and sodium citrate enemas several times weekly. What education would the nurse provide?
Electronic Health Record
PMH: Hypertension, chronic kidney disease
a. "Avoid consuming fiber or roughage in the diet."
b. "Sedentary activities will be helpful."
c. "These enemas should be avoided with kidney failure."
d. "Restrict your fluids to 1,000 mL daily."

. A nurse asks a patient for a stool sample to perform the guaiac test. How does the nurse best explain the purpose of this test?
a. "This test replaces the need for screening colonoscopy."
b. "We are looking for infectious organisms in your stool."
c. "The screening assesses for blood in your stool."
d. "This test assesses for antibodies to colon cancer."

ANSWERS WITH RATIONALES

. **a.** The sequence for abdominal assessment proceeds from inspection, auscultation, percussion, and then palpation. Inspection and auscultation are performed before palpation because palpation may disturb normal peristalsis and bowel motility.

. **c.** If the patient reports severe cramping with introduction of an enema solution, the nurse should lower the solution container and check the temperature and flow rate. If the solution is too cold or the flow rate is too fast, severe cramping may occur. The head of the bed may be elevated 30 degrees for the patient's comfort if the patient needs to be placed on a bedpan in the supine position while receiving the enema.

. **a, b, f.** Decreased or absent bowel sounds—documented only after listening for in the epigastric and umbilical area of the abdomen for 2 minutes or longer (Bickley et al., 2021)—signify the absence of bowel motility, commonly associated with peritonitis, paralytic ileus, and/or prolonged immobility. Hyperactive bowel sounds indicate increased bowel motility, commonly caused by diarrhea, gastroenteritis, or early bowel obstruction.

. **b, e, f.** Diarrhea is a potential adverse effect of treatment with amoxicillin clavulanate, metformin, or antacids containing magnesium. Opioids, diuretics, and dehydration may lead to constipation.

. **c.** Instruct the patient to retain the enema solution for at least 30 minutes or as indicated in the manufacturer's instructions. The milk and molasses mixture is a carminative enema that helps to expel flatus. The patient should be instructed to lie on their left side as dictated by patient condition and comfort.

. **d, e, f.** Ileostomies normally have liquid, foul-smelling stool. The nurse should encourage intake of dark-green vegetables for their chlorophyll content, which helps to deodorize the feces. Explain that patients with ileostomies may

tend to develop food blockages, especially when high-fiber foods are consumed. The stoma should be dark pink to red and moist. Stoma size usually stabilizes within 4 to 6 weeks, and the skin around the stoma site (peristomal area) should be kept clean and dry.

. **a.** If possible, a low-residue diet (low fiber) should be followed several days before the procedure, although some may have a full liquid diet the day before the procedure. There are multiple types of bowel preps for this procedure; the health care provider determines the best regimen for the individual.
The prep is usually given as a split dose, with half being given the night before and rest the morning of the procedure. It is recommended the second dose be given at least 5 hours before and completed at least 2 hours before the study. Occasionally, some patients may receive the prep the same day as the procedure, especially if it is scheduled for later in the day.
Conscious sedation, not general anesthesia, will be given for the colonoscopy. A chalky-tasting barium contrast mixture is given to drink before an upper GI and small-bowel series of tests.

. **c.** When a patient reports dizziness, lightheadedness, nausea, and/or vomiting during digital stool removal, the nurse recognizes the vagus nerve may have been stimulated. The nurse should stop the procedure, assess heart rate and blood pressure, and notify the health care provider.

. **d.** A fecal occult blood test is performed first to detect GI bleeding. Lower GI barium studies should be performed next to visualize GI structures and reveal any inflammation, ulcers, tumors, strictures, or other lesions. A barium enema and routine radiography should precede an upper GI series because retained barium from an upper GI series could take several days to pass through the GI tract and obscure anatomic detail on the barium enema studies. Noninvasive procedures usually take precedence over invasive procedures, such as endoscopic studies, when sufficient diagnostic data can be obtained from them.

. **a, b, d, e, f.** Care of a patient with an NG tube connected to suction includes verifying placement before administration of any fluids or medications to avoid aspiration. Radiographic evidence of the tip of the tube in the stomach, measurement of tube length, measurement of tube marking, measurement of aspirate pH, and carbon dioxide monitoring may be used. The nurse irrigates the tube with 30 mL of saline solution (or as prescribed/ per policy) with an irrigating syringe. The nurse separates the tube from the suction device, clamps the NG tube to prevent gastric secretions from leaking, and places the tip of the syringe in the tube to gently insert the saline solution. The nurse should not place irrigant in the blue air vent of a Salem sump or double-lumen tube; rather, the nurse should instill air through the vent. The air vent decreases any pressure that has built up in the stomach during suction; instilling air promotes drainage. The air vent should be placed above the stomach. Abdominal distention may indicate lack of proper drainage or delayed return of GI function. The nurse documents all irrigation and NG tube output with the I & O. If the nurse allows the irrigant to drain out, that is excluded from intake.

. **d.** The nurse follows the steps of the nursing process to plan care. First the nurse assesses the patient's bowel movements including frequency, consistency, shape, volume, and color. Based on the assessment findings, the nurse may recommend 3 of fluid daily or administer an enema, as appropriate. The nurse also monitors bowel sounds, teaches about specific foods that promote bowel regularity, ensures privacy, and encourages adequate fluid intake.

. **a, d.** The nurse discusses **s**igns and symptoms of colon cancer including rectal bleeding or blood in the stool, persistent change in bowel pattern or consistency of stool, persistent cramping or pain in lower abdomen (or gas), a feeling of incomplete bowel emptying, weakness or fatigue, and unintentional weight loss.

. **b.** Irrigations are used to promote regular evacuation of distal colostomies. Colostomy irrigation may be indicated in patients who have a left-sided end colostomy in the descending or sigmoid colon, are mentally alert, have adequate vision, and have adequate manual dexterity needed to perform the procedure. Contraindications include IBS, peristomal hernia, postradiation damage to the bowel, diverticulitis, and Crohn disease (Kent et al., 2015).

. **c.** If the stoma protrudes into the bag after changing the ostomy appliance, the nurse should have the patient rest for 30 minutes. If the stoma is not back to normal size within that time, notify the health care provider. If the stoma stays prolapsed, it may twist, resulting in impaired circulation to the stoma.

. **a.** Certain saline osmotic laxatives can lead to fluid and electrolyte imbalances and should not be used in older adults and those with kidney or cardiac disease.

. **c.** Hypertonic phosphate and sodium citrate solution enemas are avoided in patients with renal impairment or reduced renal clearance due to their inability to adequately excrete phosphate. This can result in hyperphosphatemia (Dougherty & Lister, 2015, as cited in Mitchell, 2019b, p. 154).

. **c.** The guaiac fecal occult blood testing (FOBT) is used to detect occult blood in the stool. It is used for initial/early screening for disorders such as cancer and for GI bleeding in conditions such as ulcer disease, inflammatory bowel disorders, and intestinal polyps (MedlinePlus, 2020). A positive FOBT result indicates that abnormal bleeding is occurring somewhere in the digestive tract.

Oxygenation and Perfusion

Tyrone Jacobs

Tyrone Jacobs, age 12, is brought to the emergency department gasping for breath. His parents are frantic. “It just seemed like he had a really bad cold,” his mother says. An acute asthma attack is suspected, and measures are instituted immediately to protect the child’s airway.

Yan Kim

Yan Kim, age 57, developed respiratory failure from complications associated with pulmonary surgery. He is receiving oxygen therapy and mechanical ventilation via an endotracheal tube (airway into the trachea) and undergoing continuous cardiac monitoring.

Joan McIntyre

Joan McIntyre, age 72, has been admitted to your medical unit with an acute exacerbation of chronic obstructive pulmonary disease (COPD). This is the fifth time she has been in the hospital this year. She is receiving supplemental oxygen and multiple medications to support her breathing. She is very weak, unable to perform activities of daily living (ADLs) for herself and becomes extremely short of breath with minimal exertion. She has verbalized feelings of despair and has asked the staff, “to let me go if I should stop breathing.”

Learning Outcomes

After completing the chapter, you will be able to accomplish the following:

. Describe respiratory and cardiovascular anatomy and physiology.
. Describe the function and role of the respiratory and cardiovascular systems in oxygenation.
. Describe factors that affect respiratory and cardiovascular function and influence the care of patients with oxygenation problems.
. Perform a cardiopulmonary assessment using appropriate interview questions and health assessment skills.
. Diagnose actual and potential health problems and needs related to bowel elimination that may be addressed through nursing intervention.
. Describe nursing interventions and strategies to promote adequate oxygenation and perfusion and identify their rationale.
. Plan, implement, and evaluate nursing care related to selected actual and potential health problems and needs associated with alterations in bowel elimination.

wheezes

Life depends on a constant supply of oxygen. This demand for oxygen is met by the function of the respiratory and cardiovascular systems, also known as the **cardiopulmonary** system. This chapter describes the anatomy and physiology of the respiratory system. Also included is a discussion of the anatomy and physiology of the **cardiovascular** (heart and blood vessels) system as it pertains to its role in **oxygenation**, the process of providing life-sustaining oxygen to the body's cells. Additional information related to the cardiovascular system—including pulse, pulse physiology, blood pressure, and the physiology of blood pressure—is discussed in Chapter 26. In addition, this chapter explores general factors affecting cardiopulmonary functioning and oxygenation. Suggestions for performing a health assessment related to oxygenation are presented, including sample interview questions for both a general and focused history, a description of the nursing examination, and laboratory and radiologic studies related to oxygenation. Additional information related to assessment of these systems is discussed in Chapter 27. Potential and actual health problems and needs related to oxygenation and perfusion are discussed. Expected patient outcomes and specific nursing strategies for implementation are described. The accompanying Evolving Case Study 40-1 on page 1660 provides an opportunity to develop and apply clinical reasoning and clinical judgment skills in caring for a patient with oxygenation and perfusion problems. Refer also to the accompanying Reflective Practice box on pages 1586–1587.

ANATOMY AND PHYSIOLOGY OF OXYGENATION

Oxygenation of body tissues depends on several factors. One is the integrity of the airway system to transport air to and from the lungs. A properly functioning alveolar system in the lungs to oxygenate venous blood and to remove carbon dioxide from the blood is also important. A properly functioning cardiovascular system and blood supply to carry nutrients and wastes to and from body cells is a necessary component of oxygenation.

Knowledge of the basic anatomy and physiology of the respiratory and cardiovascular systems and an understanding of the role of these systems in oxygenation of body tissues provides a foundation for assessing oxygenation and perfusion in patients and for planning and implementing interventions to promote optimal oxygenation and perfusion. This knowledge also helps nurses understand, interpret, and analyze assessment findings and provides the basis for

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

clinical reasoning, clinical judgment, and the rationale for sound nursing interventions.

Respiratory System

Oxygen and carbon dioxide must move through the alveoli as part of the oxygenation process. Thus, an adequately functioning respiratory system is vital for the exchange of gases.

Anatomy of the Respiratory System

The airway, which begins at the nose and ends at the terminal bronchioles, is a pathway for the transport and exchange of oxygen and carbon dioxide. The airway is divided into the upper and the lower airways.

The upper airway is composed of the nose, pharynx, larynx, and epiglottis. Its main function is to warm, filter, and humidify inspired air. The lower airway, known as the tracheobronchial tree, includes the trachea, right and left main stem bronchi, segmental bronchi, and terminal bronchioles (Fig. 40-1 on page 1587). Its major functions are conduction of air, mucociliary clearance, and production of pulmonary surfactant.

The airways are lined with mucus, which traps cells, particles, and infectious debris. This mucus covering also helps to protect the underlying tissues from irritation and infection. **Cilia**, which are microscopic hair-like projections, propel trapped material and accompanying mucus toward the upper airway so they can be removed by coughing. Removal is facilitated when mucus is watery in consistency. An adequate fluid intake is necessary for ciliary action and for the production of watery mucus normally present in the respiratory tract.

QSEN Reflective Practice: Cultivating QSEN Competencies

CHALLENGE TO TECHNICAL SKILLS

Ventilators and telemetry have always intimidated me, so having a patient like Yan Kim was overwhelming. Mr. Kim was a 57-year-old man who had developed respiratory failure from complications secondary to pulmonary surgery. He was receiving oxygen therapy and mechanical ventilation via an endotracheal tube (airway into the trachea) and was also undergoing continuous cardiac monitoring. Providing care for him with all his equipment and so many alarms that could sound seemed insurmountable. The monitor had several different values on it and the continuous ECG monitor always made me feel like the patient was on the verge of dying. We had just recently covered these skills in class, and I felt incompetent for the first 2 weeks of my critical care clinical experience. I could have voiced my concerns with these two machines, and I should have asked the first day what I should and shouldn't be worried about with critical care patients. But I didn't.

Thinking Outside the Box: Possible Course of Action

- Ask my instructor if there was any danger in having a patient who was receiving mechanical ventilation and being monitored by telemetry.
- Ask for someone to explain the ECG waveforms on the monitor and what to be concerned with when looking at them.
- Avoid caring for patients on ventilators and telemetry as part of their care.

Evaluating a Good Outcome: How Do I Define Success?

- Patient is safe and receives care by a competent care provider promoting his health.
- I am confident in my technical skills and able to use technology to deliver the most helpful care.
- I continue to ask questions, challenge my practice, and learn to contribute to improved care, which will lead to enhanced nursing.

Personal Learning: Here's to the Future!

Fortunately, our clinical rotations are planned so that we do not actually assume responsibility for taking care of critical care patients until we learn the necessary skills (telemetry and ventilation). This semester in my critical care clinical experiences, my fears have dissipated. I have learned that having patients that are being monitored continuously via telemetry is quite reassuring: it serves as a constant monitor for me. Although I still assess the patient on my own, having continuous values to check is reassuring. As for the ventilator, I realized I knew a lot more than I thought. My instructor gave me a lesson on the ventilator during my clinical experience and connected the class lectures and bookwork with what I was seeing with my patient. I asked many questions and checked to see if I knew which settings would change with different scenarios. There are several settings and several values constantly being measured with the machine. Once I was able to see what all of these numbers meant and realized that I understood what

each was for, I felt much more comfortable with patients on a ventilator. I realized my concerns and made sure that I provided unbiased care so that my concerns did not force me to neglect a patient.

Before, I would have been scared to get too close to the machine for fear of hitting the wrong button, fearing I would harm the patient. Now I am learning how the settings are specific to each patient. I feel comfortable reading the values and setting the controls. Still, I ask questions about the ventilator and telemetry readings because I want to know that I am interpreting them correctly. I feel it is my responsibility to obtain as much understanding and knowledge as I can so that I can provide the best care to these patients. This is very relieving and rewarding: now critical care patients don't seem so critical! My care for these patients is enhanced since I am more confident in my skills, and this enhances the care I deliver. Next time there is something new to me, I will voice my concern early on even if I am not "supposed to know" it yet.

Overall, although I still do not have much experience, I feel technically competent as a senior nursing student. I am confident because I challenge myself and I am self-motivated when it comes to searching for more information when needed.

Carrie Staines, Georgetown University

QSEN SELF-REFLECTION ON QUALITY AND SAFETY COMPETENCIES DEVELOPING KNOWLEDGE, SKILLS, AND ATTITUDES FOR CONTINUOUS IMPROVEMENT

How do you think you would respond in a similar situation? Why? Do you agree with the criteria that the nursing student used to evaluate a successful outcome? Are there any other criteria that would be appropriate to use? Did the nursing student meet the criteria? Why or why not? What *knowledge, skills,* and *attitudes* do you need to develop to continuously improve the quality and safety of care for patients like Mr. Kim?

Patient-Centered Care: What information should be communicated to the patient about the care provided? What interventions should the nursing student implement to provide care based on respect for the patient's preferences, values, and needs?

Teamwork and Collaboration/Quality Improvement: What communication skills do you need to improve to ensure that you function as a member of the patient-care team? What skills do you need to initiate requests for help and to obtain assistance when needed?

Safety/Evidence-Based Practice: What information did the nursing student receive from the monitors? How did the nursing student use this information? How did the nursing student apply the knowledge obtained through the lessons given by the instructor? What evidence for nursing practice provides guidance for decision making regarding care of this patient? What does this tell you about yourself and about the adequacy of your skills for professional practice? How do you think the nursing student would have responded if the clinical experience were strictly observational?

Informatics: Can you identify the essential information that must be available in Mr. Kim's electronic health record to support safe patient care and coordination of care? Can you think of other ways to respond to or approach the situation?

The lungs, the main organs of respiration, are located within the thoracic cavity on the right and left sides (see Fig. 40-1). The **lungs** extend from the base at the level of the diaphragm to the apex (top), which is above the first rib. The heart lies between the right and left lung.

Each lung is divided into lobes. The right lung has three lobes; the left has two. Each lobe is subdivided into segments or lobules. The main bronchus branches to each lung from the trachea. It immediately subdivides into secondary bronchi, one to each lobe. The bronchi subdivide again and again, becoming smaller and smaller as they branch through the lung. The smallest of these branches are the bronchioles, ending at the terminal bronchioles. The lungs are composed of elastic tissue that can stretch or recoil.

At the end of the terminal bronchioles there are clusters of **alveoli** (singular, alveolus), small air sacs. The alveoli are the site of gas exchange. The wall of each alveolus is made of a single-cell layer of squamous epithelium (see Fig. 40-1). This thin wall allows for exchange of gases with the capillaries covering the alveoli. The average adult has more than 300 million alveoli. **Surfactant**, a detergent-like phospholipid, reduces the surface tension between the moist membranes of the alveoli, preventing their collapse. When surfactant production is reduced, the lung becomes stiff and the alveoli collapse.

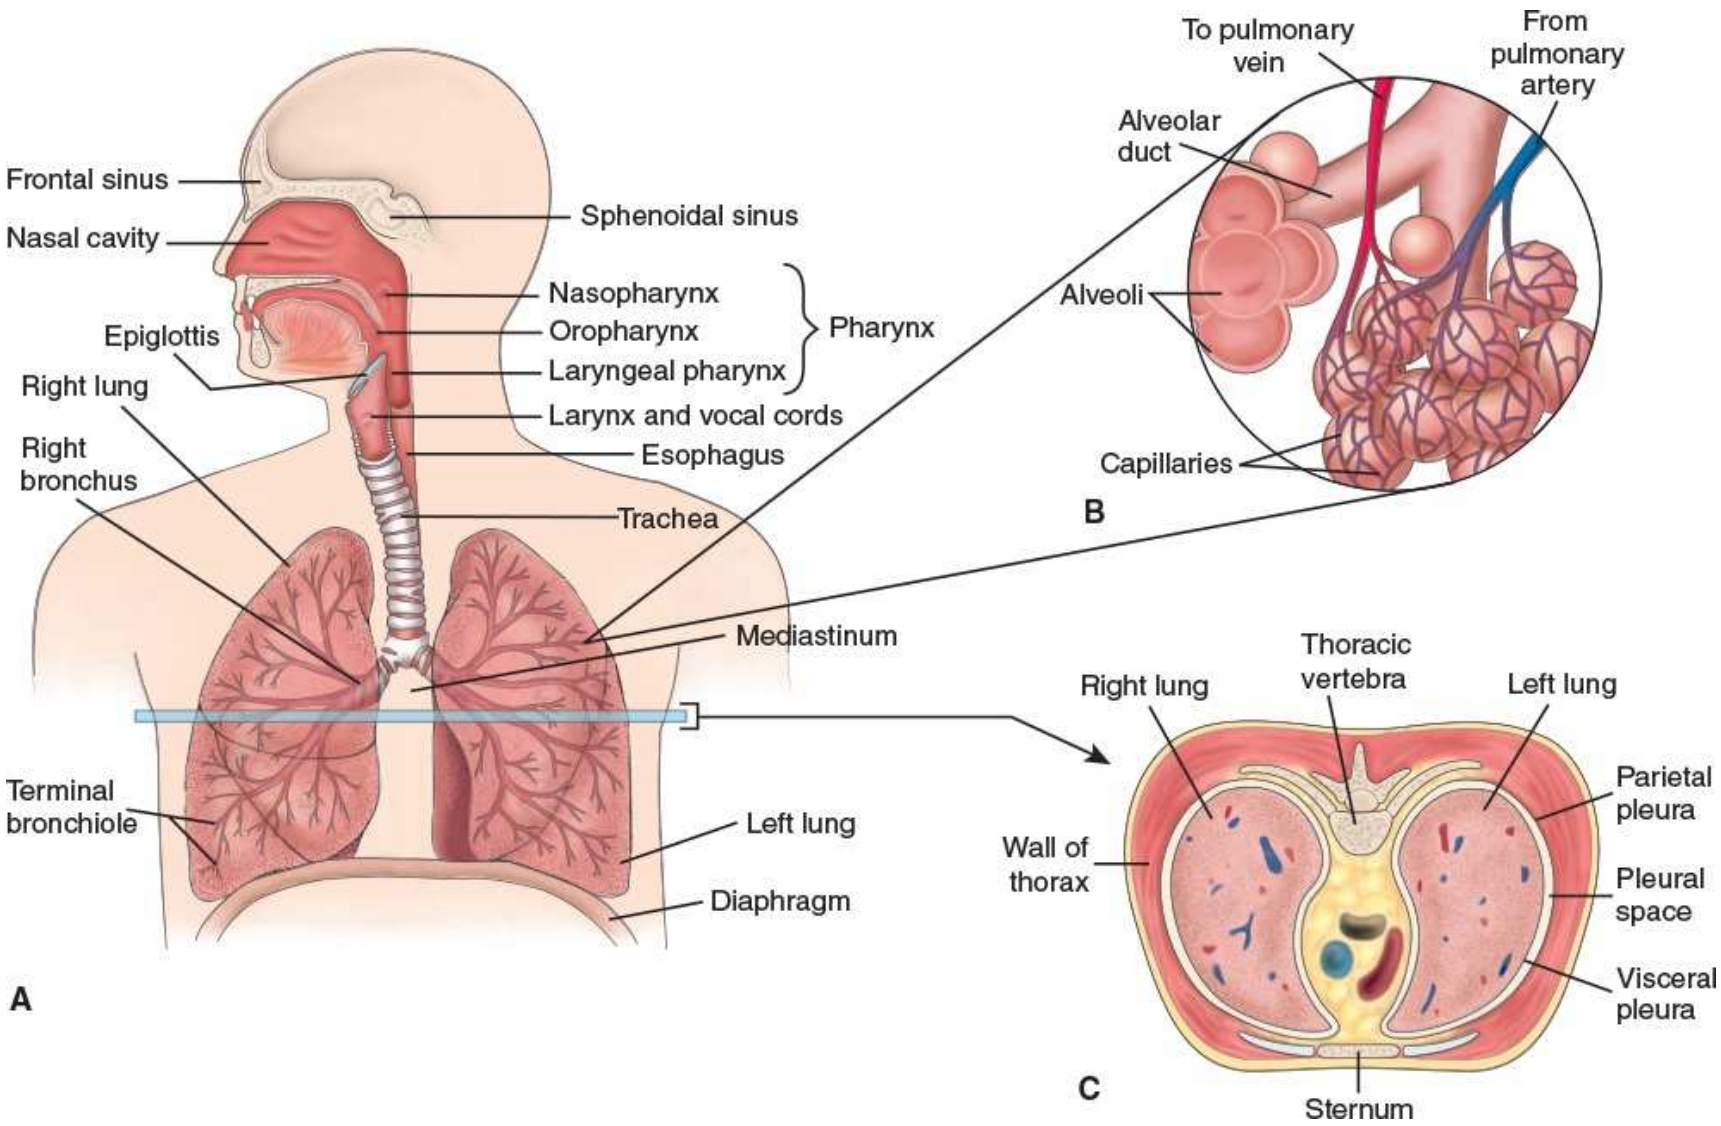

FIGURE 40-1. The organs of the respiratory tract. **A.** Overview. **B.** Alveoli (air sacs) of the lungs and the blood capillaries. **C.** Transverse section through the lungs.

The lungs and thoracic cavity are lined with a serous membrane called the pleura. The visceral pleura covers the lungs, and the parietal pleura lines the thoracic cavity. These two membranes are continuous with each other and form a closed sac. The pleural space lies between the two layers. Pleural fluid between the membranes acts as a lubricant and as an adhesive agent to hold the lungs in an expanded position. A few milliliters of fluid between the pleural surfaces allow the lungs to move easily along the chest wall as they expand and contract. Without this fluid, filling and emptying of the lungs are difficult.

Pressure within the pleural space (intrapleural pressure) is always subatmospheric (a negative pressure). This constant negative intrapleural pressure, along with the pleural fluid, holds the lungs in an expanded position.

Physiology of the Respiratory System

Living cells require oxygen and the removal of carbon dioxide, a byproduct of oxidation. Gas exchange, the intake of oxygen and the release of carbon dioxide, is made possible by pulmonary ventilation, respiration, and perfusion. **Pulmonary ventilation** refers to the movement of air into and out of the lungs. **Respiration** involves gas exchange between the atmospheric air in the alveoli and blood in the capillaries. **Perfusion** is the process by which oxygenated capillary blood passes through body tissues.

PULMONARY VENTILATION

Pulmonary ventilation (breathing) is the movement of air into and out of the lungs. The process of ventilation has two phases: **inspiration** (inhalation) and **expiration** (exhalation). Inspiration, the active phase, involves movement of muscles and the thorax to bring air into the lungs. Expiration, the passive phase, is the movement of air out of the lungs.

During inspiration, the following events occur: the diaphragm contracts and descends, lengthening the thoracic cavity; the external intercostal muscles contract, lifting the ribs upward and outward; and the sternum is pushed forward, enlarging the chest from front to back. This combination of an increased lung volume and decreased intrapulmonic pressure allows atmospheric air to move from an area of greater pressure (outside air) into an area of lesser pressure (within the lungs). The relaxation, or recoil, of these structures then results in expiration. The diaphragm relaxes and moves up, the ribs move down, and the sternum drops back into position. This causes a decreased volume in the lungs and an increase in intrapulmonic pressure. As a result, air in the lungs moves from an area of greater pressure to one of lesser pressure and is expired (Fig. 40-2).

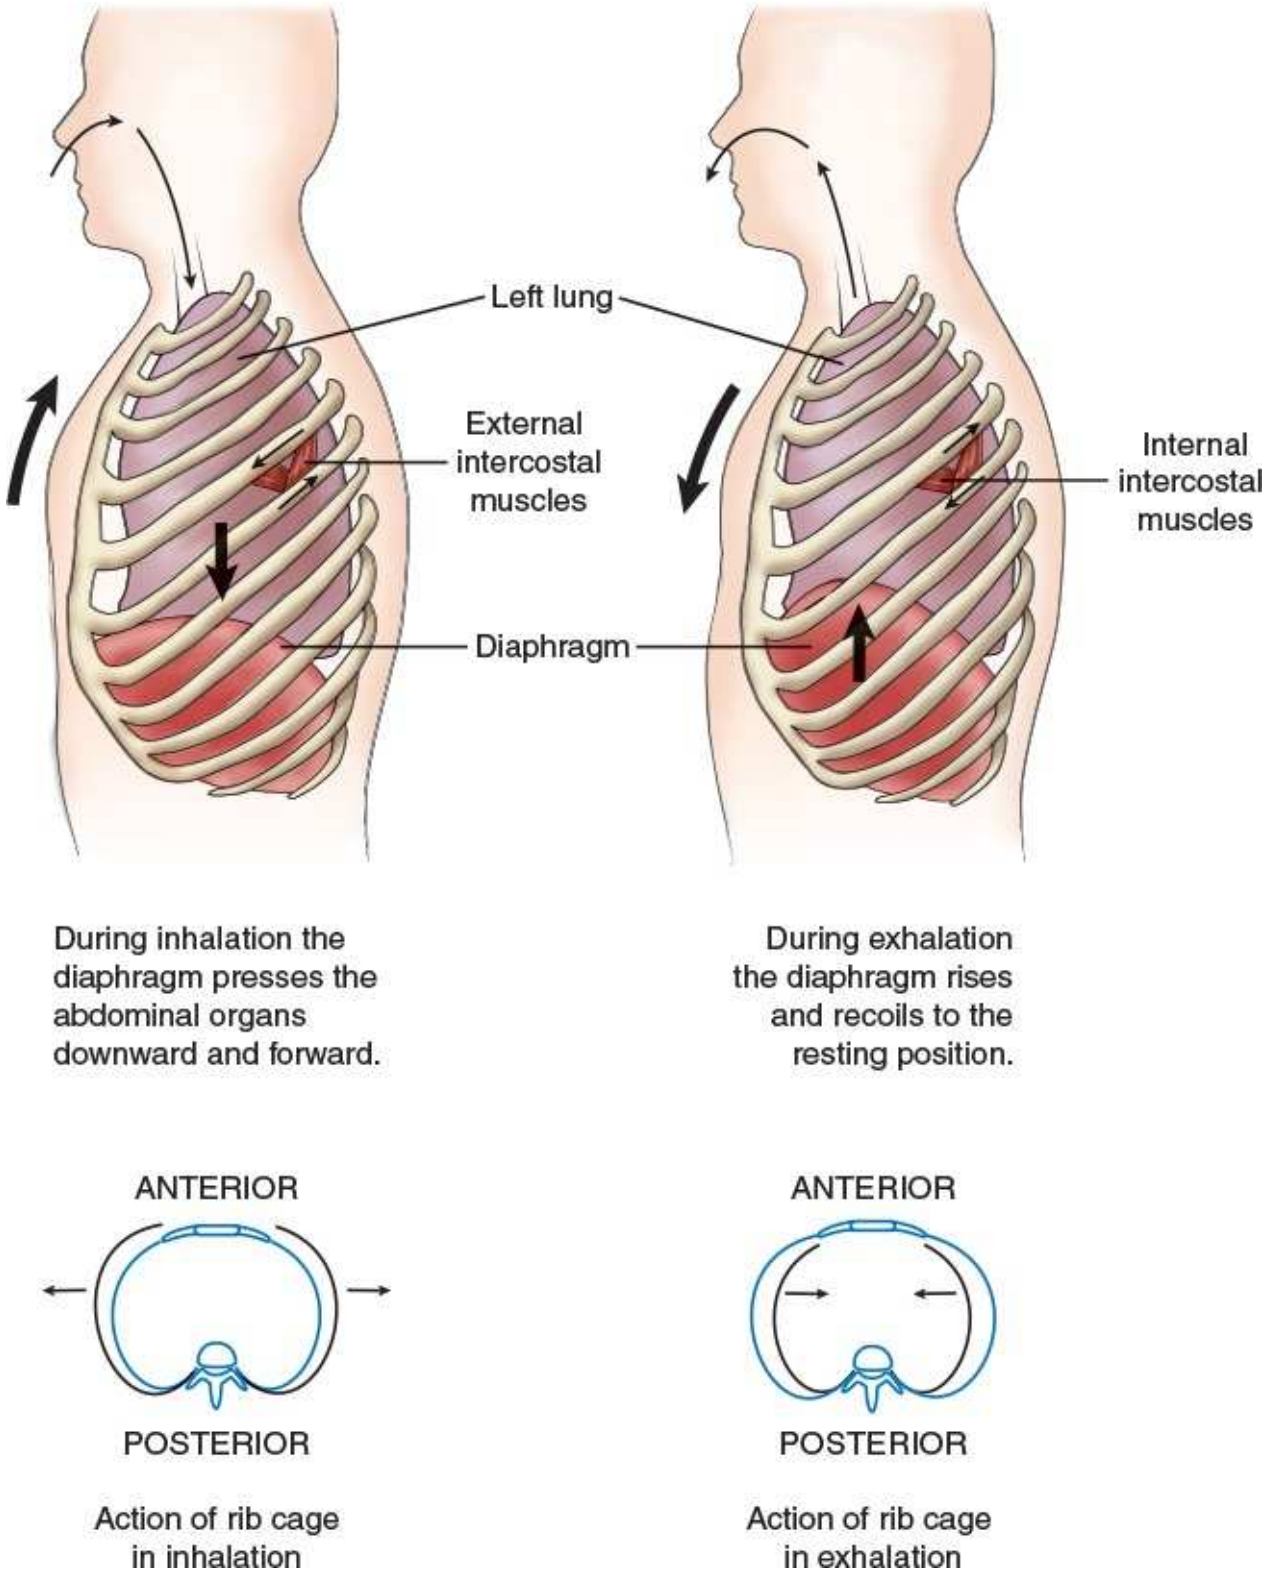

FIGURE 40-2. Pulmonary ventilation.

Other physical factors contribute to airflow in and out of the lungs. These factors include the condition of the musculature, compliance of lung tissue, and airway resistance. The condition of the body's musculature can affect the process of respiration. Weakening of the muscles involved in respiration can contribute to less effective inhalation and exhalation. The accessory muscles of the abdomen, neck, and back are used to maintain respiratory movements at times when breathing is difficult. These muscles are used to facilitate breathing; the movement is called retraction.

Lung compliance refers to the ease with which the lungs can be inflated. The compliance of lung tissue affects lung volume. The ability of the lungs to adequately fill with air during inhalation is achieved by the normal elasticity of lung tissue, aided by the presence of surfactant. The varying changes in lung pressure and resulting lung compliance can be compared to differences in blowing up a new, noncompliant balloon versus one that was inflated previously. A stiff, noncompliant lung (such as a new balloon) requires a greater inspiratory effort to inflate it. Emphysema, a chronic lung condition, and the normal changes associated with aging are examples of conditions that result in decreased elasticity of lung tissue, which, in turn, decreases compliance.

Airway resistance is the result of any impediment or obstruction that air meets as it moves through the airway. Any process that changes the bronchial diameter or width causes airway resistance. Obstruction in any part of the normal passageways impedes respiration. Obstruction can be caused by a foreign substance, such as a piece of food, a coin, or a toy, or by liquids, as in the case of a drowning victim. Obstruction can also result from secretions (e.g., excessive or thickened secretions) or tissues (e.g., tumors or edema of the respiratory tract). A decrease in the size of air passages resulting from constriction or poor neck positioning can also impede respiration. Bronchial constriction in asthma is an example of airway resistance related to a decrease in the size of air passages.

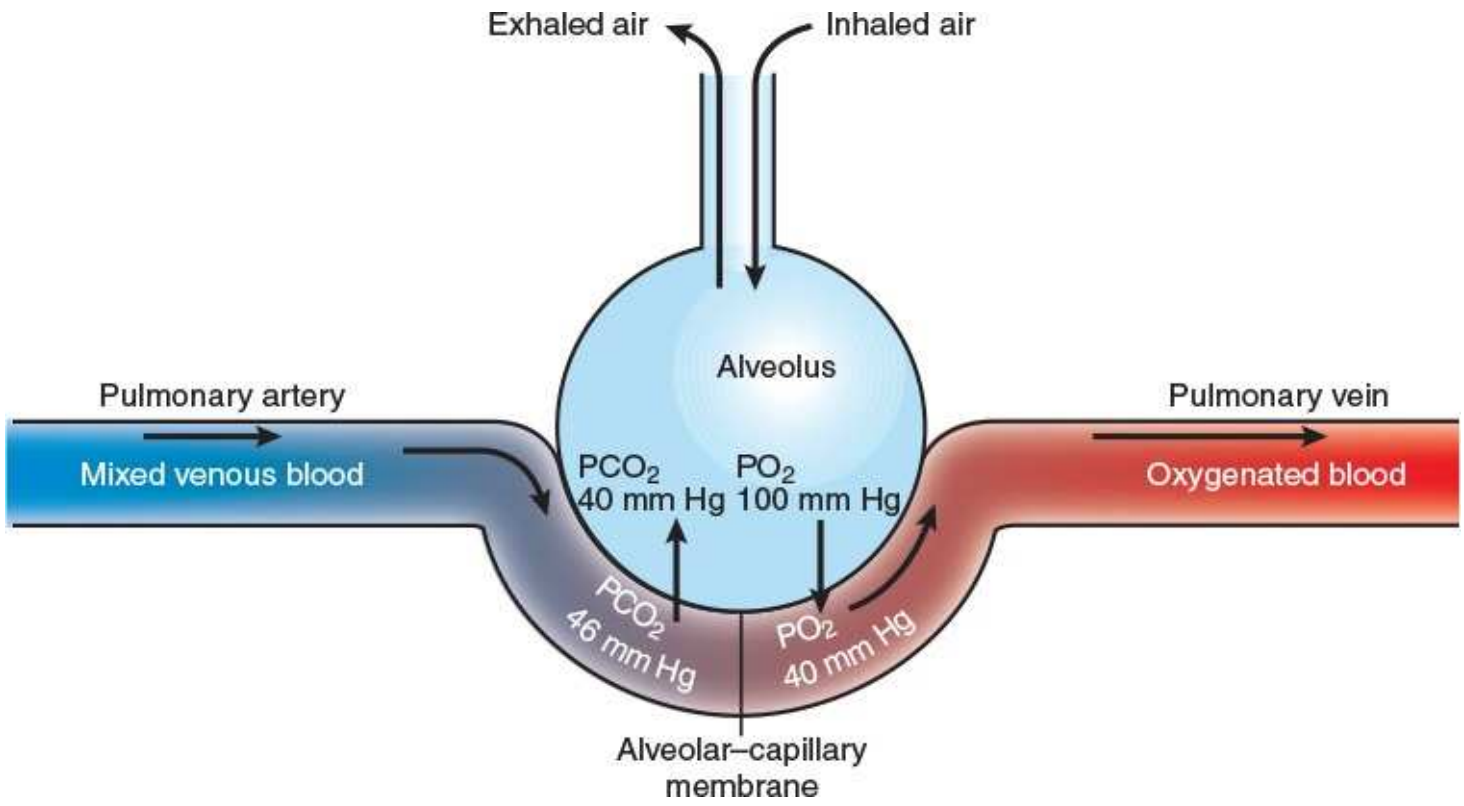

FIGURE 40-3. Gas exchange in the alveolus. The greater pressure of the oxygen in the air inhaled into the alveoli causes the oxygen to move into the capillaries, which contain unoxygenated blood. The carbon dioxide in the returning venous blood moves from the capillaries (area of greater concentration) into the alveoli (area of lesser concentration).

Consider **Tyrone Jacobs**, the 12-year-old boy with suspected asthma. An understanding of the underlying pathophysiologic processes involved with this disorder would provide the basis for the nurse's actions to protect the child's airway.

RESPIRATION

Respiration, gas exchange, occurs at the terminal alveolar capillary system. Gases are exchanged between the air and blood via the dense network of capillaries in the respiratory portion of the lungs and the thin alveolar walls (see Figs. 40-1 on page 1587 and 40-3). Gas exchange occurs via diffusion. **Diffusion** is the movement of gas or particles from areas of higher pressure or concentration to areas of lower pressure or concentration. In respiration, diffusion refers to the movement of oxygen and carbon dioxide between the air (in the alveoli) and the blood (in the capillaries). These gases move passively from an area of higher concentration to an area of lower concentration. The greater pressure of oxygen in the alveoli causes the oxygen to move from the alveoli into the capillaries containing the unoxygenated venous blood. Likewise, the carbon dioxide in the returning venous blood exerts a greater pressure than the carbon dioxide in the alveoli. Therefore, carbon dioxide diffuses across the capillary into the alveoli and ultimately is exhaled.

Diffusion of gases in the lung is influenced by several factors, including changes in the surface area available, thickening of the alveolar–capillary membrane, and partial pressure. Any change in the surface area available for diffusion hinders diffusion. For example, removal of a lung or the presence of a disease that destroys lung tissue can decrease the surface area available, ultimately affecting gas exchange. Incomplete lung expansion or the collapse of alveoli, known as **atelectasis**, prevents pressure changes and the exchange of gas by diffusion in the lungs. Areas of the lung with atelectasis cannot fulfill the function of respiration. Examples of conditions that predispose a patient to atelectasis are obstructions of the airway by foreign bodies, mucus, airway constriction, external compression by tumors or enlarged blood vessels, and immobility. Any disease or condition that results in thickening of the alveolar–capillary membrane, such as pneumonia or pulmonary edema, makes diffusion more difficult.

The partial pressure, or pressure resulting from any gas in a mixture depending on its concentration, can also affect diffusion. If environmental oxygen is reduced, such as when a person is at higher altitudes or in the presence of toxic fumes, less oxygen is available for diffusion. When oxygen is administered, an increased amount of oxygen is available, resulting in greater diffusion across capillary membranes.

PERFUSION

Oxygenated capillary blood passes through the tissues of the body in the process called perfusion. The amount of blood

flowing through the lungs is a factor in the amount of oxygen and other gases that are exchanged. The amount of blood present in any given area of lung tissue depends partially on whether the person is sitting, standing, or lying down. Perfusion is greater in dependent areas. The perfusion of lung tissue also depends on the person's activity level. Greater activity results in an increased need for cellular oxygen by the body's tissues and a subsequent increase in cardiac output (CO) and consequently in increased blood return to the lungs. In addition, perfusion to the body's tissues depends on an adequate blood supply and proper cardiovascular functioning to carry oxygen and carbon dioxide to and from the lungs (discussed later).

Regulation of the Respiratory System

The respiratory center is located in the medulla in the brainstem, immediately above the spinal cord. It is stimulated by an increased concentration of carbon dioxide and hydrogen ions and, to a lesser degree, by the decreased amount of oxygen in the arterial blood. In addition, chemoreceptors in the aortic arch and carotid bodies are sensitive to the same arterial blood gas levels and blood pressure and can activate the medulla. Proprioceptors in the muscles and joints respond to body movements, such as exercise, and cause an increase in ventilation.

Stimulation of the medulla increases the rate and depth of ventilation (both inspiration and expiration) to blow off carbon dioxide and hydrogen and increase oxygen levels (the patient is breathing faster and more deeply). The medulla sends an impulse down the spinal cord to the respiratory muscles to stimulate a contraction leading to inhalation. If a condition causes a chronic change in the oxygen and carbon dioxide levels, these chemoreceptors may become desensitized and not regulate ventilation adequately.

Alterations in Respiratory Function

If a problem exists in ventilation, respiration, or perfusion, hypoxia may occur. **Hypoxia** is a condition in which an inadequate amount of oxygen is available to cells. The most common symptoms of hypoxia are **dyspnea** (difficulty breathing), an elevated blood pressure with a small pulse pressure, increased respiratory and pulse rates, pallor, and cyanosis. Anxiety, restlessness, confusion, and drowsiness also are common signs of hypoxia. Hypoxia is often caused by **hypoventilation** (decreased rate or depth of air movement into the lungs). Hypoxia can also be a chronic condition. The effects of chronic hypoxia can be detected in all body systems and are manifested as altered thought processes, headaches, chest pain, enlarged heart, clubbing of the fingers and toes, anorexia, constipation, decreased urinary output, decreased libido, weakness of extremity muscles, and muscle pain. Additional information related to alterations in respiratory function is discussed in Chapter 26.

Cardiovascular System

Oxygen and carbon dioxide must move through the alveoli and be carried to and from body cells by the blood. Thus, an adequately functioning cardiovascular system is vital for exchange of gases.

Anatomy of the Cardiovascular System

The cardiovascular system is composed of the heart and the blood vessels. The heart is the main organ of **circulation**, the continuous one-way circuit of blood through the blood vessels, with the heart as the pump (Norris, 2020). The heart lies in the thoracic cavity between the lungs, in the center and somewhat to the left of the body's midline (Fig. 40-4). The heart is a cone-shaped, muscular pump, divided into four hollow chambers. The upper chambers, the **atria** (singular, atrium), receive blood from the veins (the superior and inferior vena cava and the left and right pulmonary veins). The lower chambers, the **ventricles**, force blood out of the heart through the arteries (the left and right pulmonary arteries and the aorta). One-way valves that direct blood flow through the heart are located at the entrance (tricuspid and mitral valves) and exit (pulmonary and aortic valves) of each ventricle (Fig. 40-5). The blood vessels form a closed circuit of tubes that carry blood between the heart and the body cells. Arteries and arterioles conduct blood away from the ventricles to the capillaries and the venules and veins and return blood from the capillaries to the atria. Capillaries function in the exchange of substances between the blood and the body cells.

Physiology of the Cardiovascular System

Blood is squeezed through the heart and out into the body by contractions starting in the atria, followed by contraction of the ventricles, with a subsequent resting of the heart. Deoxygenated blood (low in oxygen, high in carbon dioxide) is carried from the right side of the heart to the lungs, where oxygen is picked up and carbon dioxide is released, and then returned to the left side of the heart. This oxygenated blood (high in oxygen, low in carbon dioxide) is pumped out to all other parts of the body and back again (Fig. 40-6 on page 1592). The quantity of blood forced out of the left ventricle with each contraction is called the stroke volume (SV). The CO is the amount of blood pumped per minute and measured in liters per minute (King & Lowery, 2020). This volume is determined by using the following formula: CO = SV × heart rate. CO in an adult is generally 5 to 6 L/min at rest (King & Lowery, 2020). Thus, the CO of an adult with an SV of 70 mL and a heart rate of 70 beats/min is 4.9 L/min. CO increases during physical activity and decreases during sleep; it also varies depending on the body size and metabolic needs.

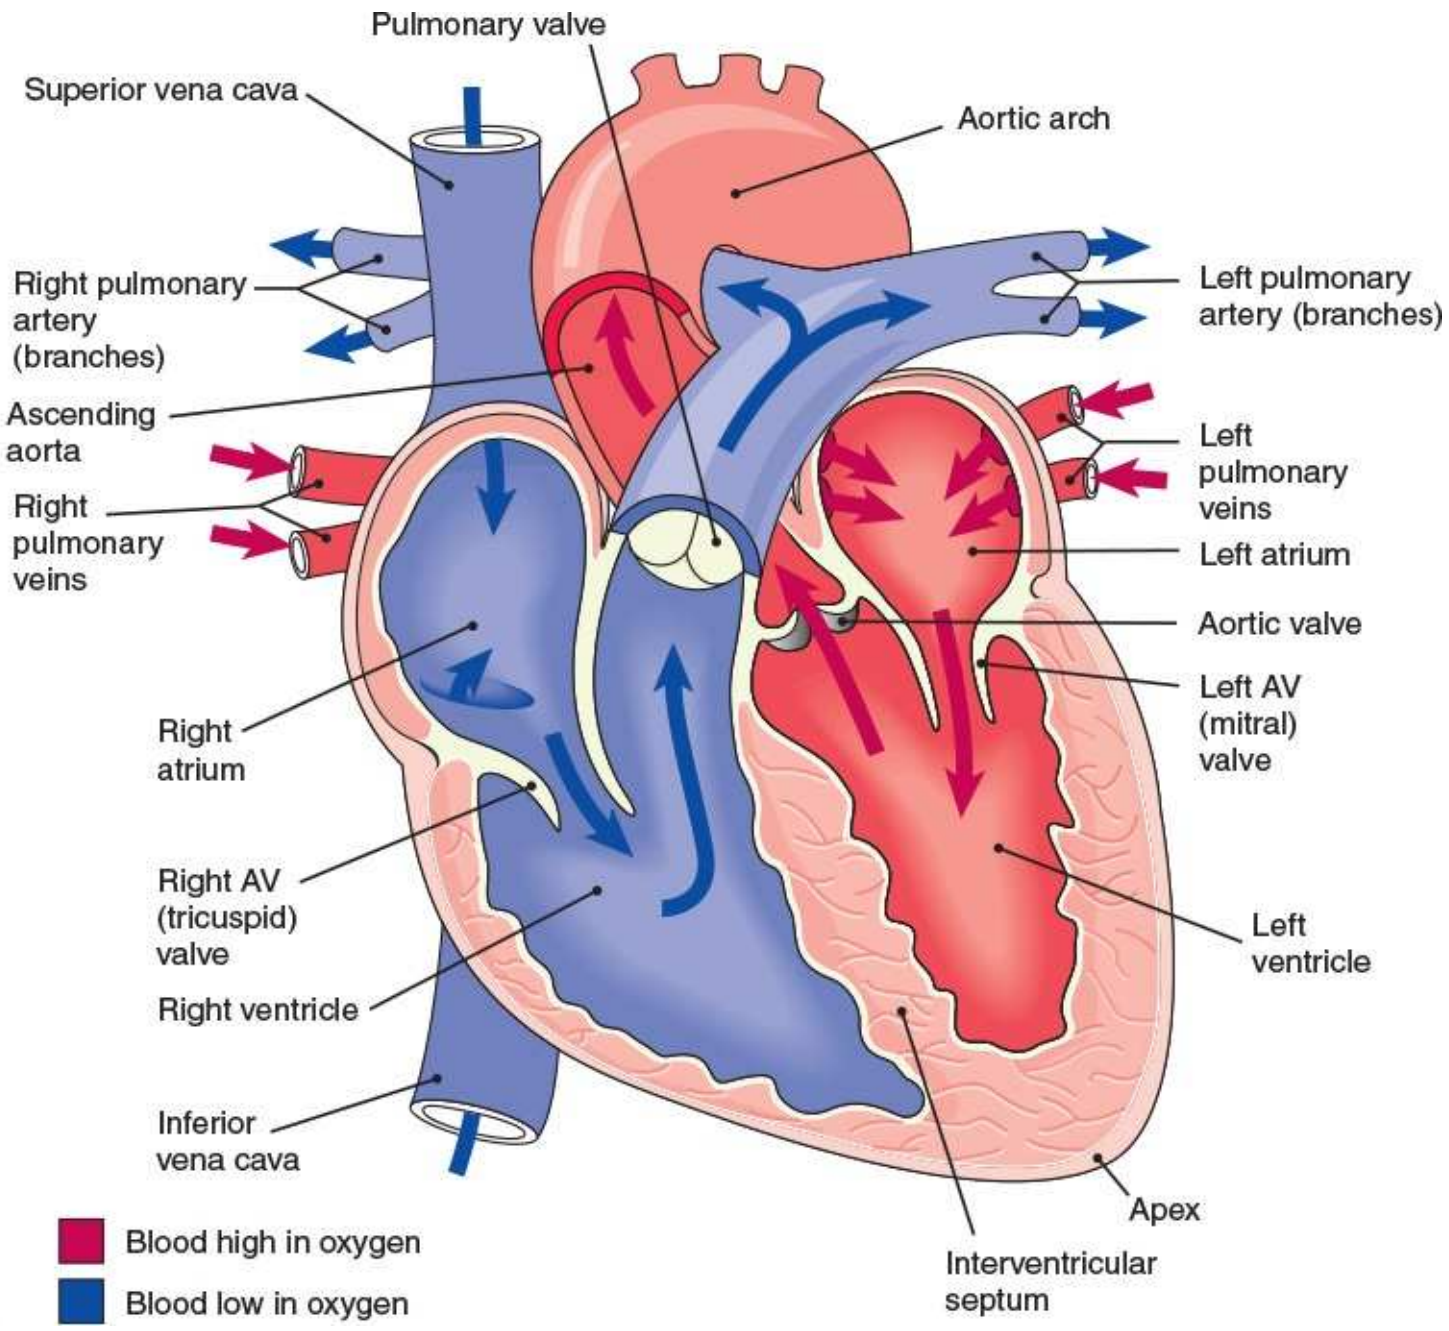

FIGURE 40-5. The heart, valves, and vessels. (*Source:* Adapted from Cohen, B. J., & Hull, K. L. [2016]. Memmler's structure and function of the human body [11th ed.]. Wolters Kluwer.)

Oxygen is carried via plasma and red blood cells (RBCs). It is dissolved in plasma, but because oxygen is insoluble in liquids, little oxygen is carried in this way (2%) (Patel et al., 2021). The majority of oxygen is carried by the RBCs. The hemoglobin in RBCs has a strong affinity for oxygen and most oxygen (98%) is carried in the body by RBCs as part of hemoglobin in the form of oxyhemoglobin (Patel et al., 2021). Hemoglobin also carries carbon dioxide easily in the form of carboxyhemoglobin.

Once the red blood cells reach the tissues, internal respiration must occur. **Internal respiration** is the exchange of oxygen and carbon dioxide between the circulating blood and the tissue cells. Any abnormality in the blood's

components affects internal respiration. For example, hemorrhage or loss of blood can cause a decrease in CO. A decrease in CO causes a reduction in the amount of circulating blood that is available to deliver oxygen to the tissues. Anemia, a decrease in the amount of RBCs or erythrocytes, results in insufficient hemoglobin available to transport oxygen. This may lead to an inadequate supply of oxygen to the tissues of the body. Alternatively, exercise can improve the transport of oxygen. Regular exercise contributes to more effective pumping of the heart muscle, and improved oxygen transport to cells.

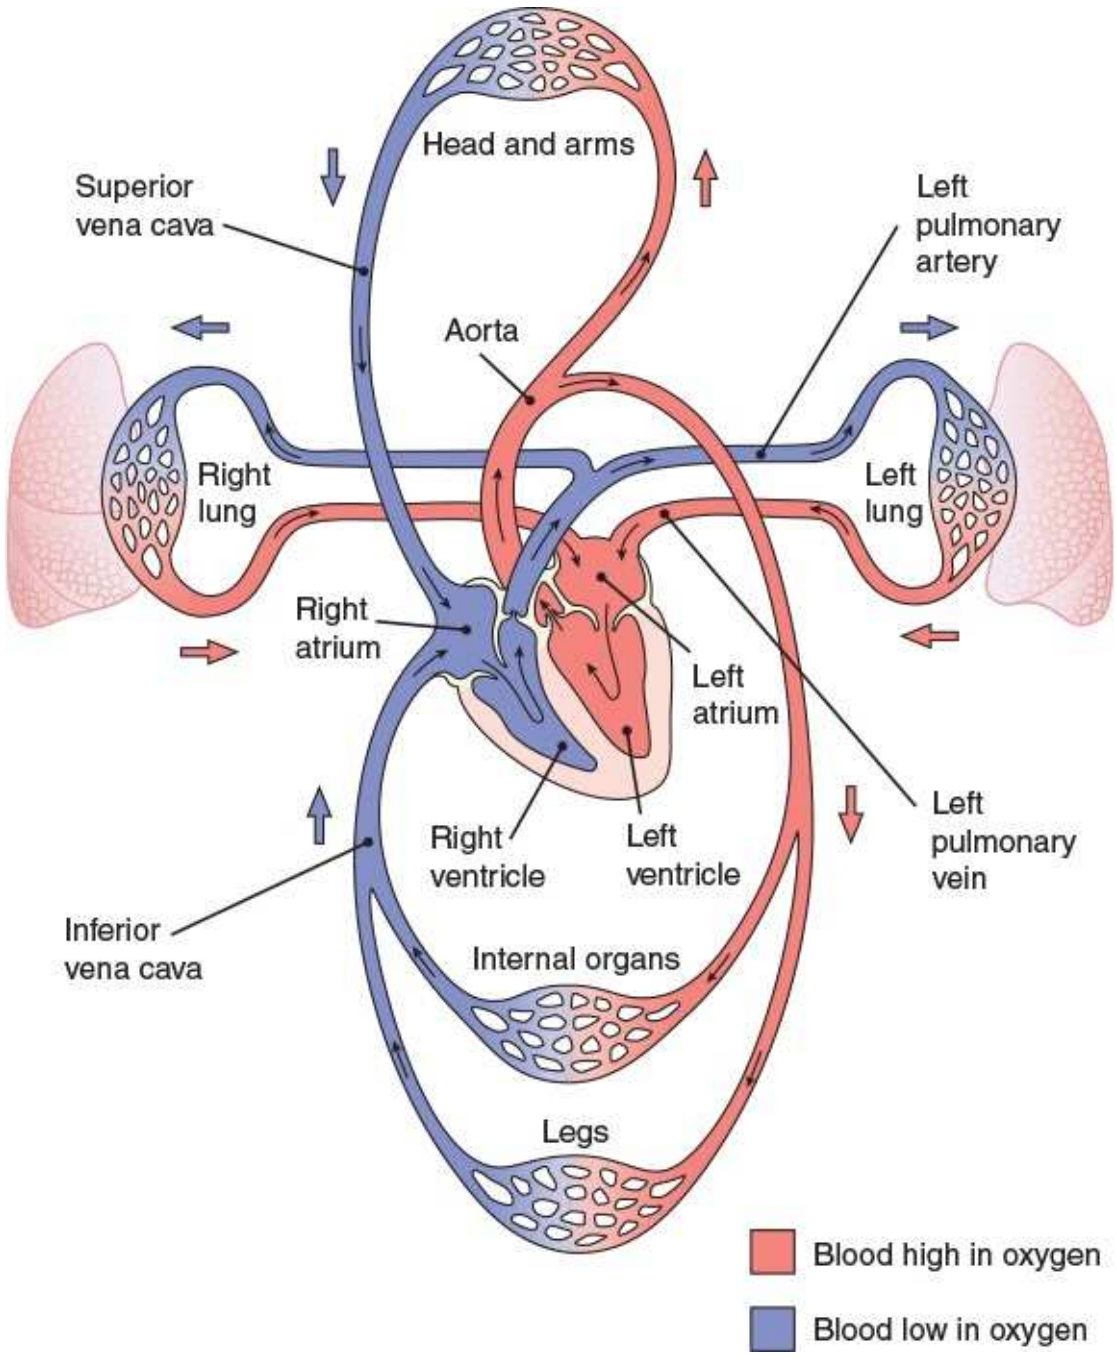

FIGURE 40-6. The right side of the heart pumps deoxygenated blood to the lungs, where oxygen is picked up and carbon dioxide released. The left side of the heart pumps oxygenated blood out to all other parts of the body. (*Source:* Reprinted with permission from Taylor, J. J., & Cohen, B. J. [2013]. Memmler's structure and function of the human body [10th ed.]. Wolters Kluwer.)

Regulation of the Cardiovascular System

Electrical impulses produced in and carried over specialized tissue within the heart control contraction of the muscles of the heart. These tissues make up the heart's conduction system (Fig. 40-7). The **sinoatrial (SA) node** is a mass of tissue in the upper right atrium, just below the opening of the superior vena cava. This node initiates the transmission of electrical impulses, causing contraction of the heart at regular intervals. It is also referred to as the pacemaker. After initiation, the electrical impulse travels throughout the muscle of each atrium, causing contraction of the atrium. The impulse also travels at the same time to the **atrioventricular (AV) node,** a mass of tissue located at the bottom of the right atrium. When the impulse reaches the AV node, it enters a group of fibers called the **atrioventricular bundle**, or bundle of His. This bundle divides into right and left branches. Smaller conduction myofibers (Purkinje fibers) branch off, traveling throughout the ventricles. The right branch extends to the walls of the right ventricle and the left branch travels through the left ventricle. The electrical impulse continues through the atrioventricular bundle and the Purkinje fibers, causing contraction of the ventricles. The contraction of the ventricles, which occurs just a moment after the atrial contractions, completes a cardiac cycle, or a single heartbeat. The heart rests a moment, and another cycle begins almost immediately.

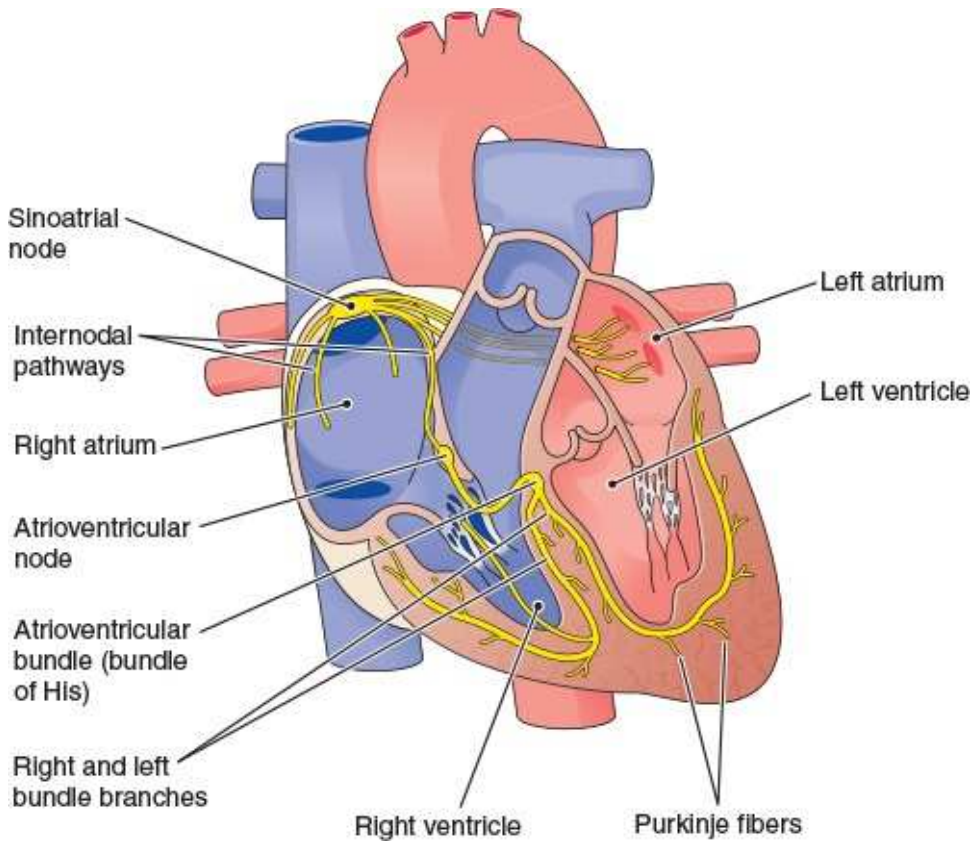

FIGURE 40-7. The conduction system of the heart. (*Source:* Reprinted with permission from Cohen, B. J., & Hull, K. L. [2016]. Memmler's structure and function of the human body [11th ed.]. Wolters Kluwer.)

Many things can influence the function of the heart. A person's heart rate can be modified by the nervous system based on the needs of the body. Stimulation of the SA and AV nodes by the sympathetic nerves increases the heart rate and force of contraction in response to increased activity, and as part of the response to real or perceived threats. Parasympathetic stimulation of the SA and AV nodes by the vagus nerve decreases the heart rate. The balance between the parasympathetic and sympathetic effects on the heart is maintained with the help of input from the medulla in the brainstem. Hormones and other chemicals made by the body, as well as drugs, also affect heart action.

Blood Flow to the Cardiovascular System

The muscles of the heart have their own blood vessels that provide oxygen and nourishment and remove waste products. The main blood vessels that provide coronary circulation are the right and left coronary arteries, which branch off the aorta. They encircle the heart and branch out to all regions of the heart. The coronary arteries fill with blood during relaxation of the ventricles. The blood returns to the right atrium after passing through the heart muscle via the cardiac veins.

Alterations in Cardiovascular Function

If a problem exists in the cardiovascular system, alterations in function of the heart may occur, leading to impaired oxygenation. A **dysrhythmia** (also referred to as **arrhythmia)** is a disturbance of the rate and/or rhythm of the heart (Hinkle et al., 2022). Dysrhythmias are caused by an abnormal rate of electrical impulse generation from the SA node, or from impulses originating from a site or sites other than the SA node. They can also be caused by the abnormal conduction of electrical impulses through the heart. Dysrhythmias can occur with heart disease, hypertension, damage to the heart, in the presence of various drugs, with decreased oxygenation of the heart tissues, and with trauma. Dysrhythmias cause disturbances of the heart rate, heart rhythm, or both, and can affect the pumping action of the heart, interfering with circulation, leading to alterations in oxygenation. Symptoms vary, depending on the cause and type of dysrhythmia. Symptoms may include decreased blood pressure, dizziness, palpitations (awareness of throbbing heart beats), weakness, and fainting.

Myocardial **ischemia**, decreased oxygen supply to the heart caused by insufficient blood supply, can lead to impaired oxygenation of tissues in the body. It is most commonly caused by atherosclerosis, the accumulation of fatty substances and fibrous tissue in the lining of arterial blood vessel walls, creating blockages and narrowing the vessels, reducing blood flow. Angina and myocardial infarction can result from myocardial ischemia. Stable **angina** is a temporary imbalance between the amount of oxygen needed by the heart and the amount delivered to the heart muscles, causing chest pain or discomfort. **Myocardial infarction**, one type of acute coronary syndrome characterized by the death of heart tissue due to lack of oxygen, is also known as a heart attack. Myocardial ischemia causes disturbances of the heart rate, heart rhythm, or both, and can affect the pumping action of the heart, interfering with circulation, leading to alterations in oxygenation. Symptoms vary, based on the problem, but include pain, anxiety, nausea, vomiting, indigestion, and shortness of breath.

Heart failure occurs when the heart is unable to pump a sufficient blood supply, resulting in inadequate perfusion and oxygenation of tissues. It can be the result of many heart conditions, including chronic hypertension, coronary artery disease, and disease of the heart valves. Symptoms include shortness of breath, edema (swelling), and fatigue. Additional information related to alterations in cardiovascular function is discussed in Chapter 26.

FACTORS AFFECTING CARDIOPULMONARY FUNCTIONING

A variety of factors affect adequate cardiopulmonary function, leading to impaired oxygenation and perfusion. Important factors are discussed in the following sections.

Level of Health

Acute and chronic illnesses can affect a person's cardiopulmonary function dramatically. For example, people with renal or cardiac disorders often have compromised respiratory functioning because of fluid overload and impaired tissue perfusion. People with chronic illnesses often have muscle wasting and poor muscle tone. These problems affect all the muscles, including those of the cardiopulmonary system. Alterations in muscle function contribute to inadequate pulmonary ventilation and respiration, as well as inadequate functioning of the heart. Anemia can result in impaired cardiopulmonary function. As discussed previously, anemia may lead to an inadequate supply of oxygen to the tissues of the body. Because hemoglobin also carries carbon dioxide to the lungs, anemia results in diminished carbon dioxide exchange. Myocardial infarction causes a lack of blood supply to the heart muscle. Damage to the heart muscle interferes with effective contractions of the heart muscle, leading to decreased perfusion of tissues and decreased gas exchange. Physical changes such as scoliosis (curvature of the spine) influence breathing patterns and may cause air trapping. Research reveals a statistically significant correlation between obesity and obstructive lung disease, including asthma and chronic obstructive pulmonary disease (Ramos-Nino et al., 2021). Moreover, people who are obese are often short of breath during activity, ultimately leading to less participation in exercise. As a result, the alveoli at the base of the lungs are rarely stimulated to expand fully.

Recall **Yan Kim**, the 57-year-old patient who developed respiratory failure from complications associated with pulmonary surgery. The acuity of the situation played a major role in the patient's current condition. The pulmonary surgery most likely reduced his respiratory function. The effects of anesthesia on his lungs and subsequently the development of complications compounded his situation.

Table 40-1 Respiratory Variations in the Life Cycle

	INFANT (BIRTH–1 YEAR)	EARLY CHILDHOOD (1–5 YEARS)	LATE CHILDHOOD (6–12 YEARS)	OLDER ADULT (65+ YEARS)
Respiratory rate	30–60 breaths/min	20–40 breaths/min	15–25 breaths/min	16–24 breaths/min
Respiratory pattern	Abdominal breathing, irregular in rate and depth	Abdominal breathing, irregular	Thoracic breathing, regular	Thoracic, regular
Chest wall	Thin, little muscle, ribs, and sternum easily seen	Same as infant's but with more subcutaneous fat	Further subcutaneous fat deposited, structures less prominent	Thin, structures prominent
Breath sounds	Loud, harsh crackles at end of deep inspiration	Loud, harsh expiration longer than inspiration	Clear inspiration is longer than expiration	Clear
Shape of thorax	Round	Elliptical	Elliptical	Barrel shaped or elliptical

Developmental Considerations

There are many age-related developmental considerations affecting cardiopulmonary function. Table 40-1 summarizes respiratory variations in the life cycle. Age-related variations in pulse rate and blood pressure can be found in Chapter 26, Table 26-1 on page 718.

Infants

The normal infant's chest is small, the airways are short, and aspiration is a potential problem. The respiratory rate is

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

more rapid in infants than at any other age (see Table 40-1). As the alveoli increase in number and size, adequate oxygenation is accomplished at lower respiratory rates. Surfactant is formed in utero between 34 and 36 weeks. An infant born before 34 weeks may not have produced sufficient surfactant, leading to collapse of the alveoli and poor alveolar exchange. Synthetic surfactant can be given to the infant to help reopen the alveoli. Infants are at risk for upper respiratory tract infections and asthma as a result of exposure to secondhand smoke. Respiratory activity is primarily abdominal in infants. The pulse rate is more rapid in infancy than in adulthood, limiting the infant's ability to increase CO by increasing the heart rate (Kyle & Carman, 2021).

Toddlers, Preschoolers, School-Age Children, and Adolescents

The preschool child's Eustachian tubes, bronchi, and bronchioles are elongated and less angular. Thus, the average number of routine colds and infections decreases until the child enters day care or school and is exposed more frequently to pathogens. Young children who are not placed in day care usually have not had the opportunity to develop antibodies for the variety of viruses and bacteria they may encounter in a school setting. Encourage good hand hygiene and tissue etiquette. Most children at this age have colds or upper respiratory infections, but some have more serious problems of otitis media, bronchitis, and pneumonia. Children in this age group are also at risk for asthma as a result of exposure to secondhand smoke. By the end of late childhood and during adulthood, the immune system is prepared to protect the person from most infections. A child's blood vessels widen and increase in length over time. The blood pressure increases over time, reaching the adult level in adolescence.

Older Adults

Specific physical changes occur in older adults that are unrelated to any pathology. Refer to the accompanying Focus on the Older Adult box. The tissues and airways of the respiratory tract (including the alveoli) become less elastic. The power of the respiratory and abdominal muscles is reduced; therefore, the diaphragm moves less efficiently. The chest is unable to stretch as much, resulting in a decline in maximum inspiration and expiration. Airways collapse more easily. These alterations increase the risk for disease, especially pneumonia and other chest infections.

Think back to **Joan McIntyre**, the 72-year-old woman who is having an exacerbation of her chronic COPD. The nurse needs to consider potential age-related changes when planning the patient's care. The nurse also needs to consider that some of these age-related changes may be intensifying some of the patient's symptoms and contributing to their decreased ability to care for themself.

The normal aging heart can maintain adequate CO under ordinary circumstances but may have a limited ability to respond to situations that cause physical or emotional stress, when the demands on the heart are increased (Eliopoulos, 2018; Hinkle et al., 2022). Decreased physical activity, physical deconditioning, decreased elasticity of the blood vessels, and stiffening of the heart valves can lead to a decrease in the overall function of the heart.

Medication Considerations

Many medications affect the function of the cardiopulmonary system. Patients receiving drugs that affect the central nervous system need to be monitored carefully for respiratory complications. For example, opioids are chemical agents that depress the medullary respiratory center. As a result, the rate and depth of respirations decrease. Be alert for the possibility of respiratory depression or arrest when administering any opioid or sedative. Other medications decrease heart rate with associated decreased cardiac output, with the potential to alter the flow of blood to body tissues.

Focus on the Older Adult

NURSING STRATEGIES TO ADDRESS AGE-RELATED CHANGES IN OXYGENATION

Age-Related Changes	Nursing Strategies
Decreased Gas Exchange and Increased Work of Breathing • Decreased elastic recoil of the lungs • Expiration requiring use of accessory muscles	• Encourage rest periods, as necessary. • Encourage cessation or moderation of smoking and second-hand smoke exposure. • Teach breathing exercises.

• Fewer functional capillaries and more fibrous tissue in alveoli • Decreased skeletal muscle strength in thorax • Reduction in vital capacity and increase in residual volume	• Remind about avoiding air pollutants. • Caution about effect of extreme weather conditions. • Instruct to avoid opioids and sleeping pills. • Discuss home management with patient and family/caregivers. • Teach avoidance of infection and preventive measures (i.e., pneumococcal and flu vaccination). • Use pillows as necessary to sleep.
Decreased Ventilation and Ineffective Cough • Less air exchange; more secretions remain in lungs • Drier mucous membranes • Altered pain sensation • Different norms for body temperature; fever may be atypical • Greater risk for aspiration due to slower gastric motility • Impaired mobility and inactivity, effects of medication	• Encourage increased fluid intake, especially water, as allowed. • Use cool-mist humidifier (teach proper cleaning technique). • Encourage attendance at pulmonary exercise rehabilitation program. • Discourage use of over-the-counter medications. • Teach how to splint thorax and cough effectively. • Instruct in use of supplemental oxygen. • Teach avoidance of milk products if they are troublesome.
Decreased CO and Ability to Respond to Stress • Reduction in the elasticity of the heart's tissues • Heart muscle becomes less efficient—working harder to pump the same amount of blood through the body. • Progressive atherosclerosis (fatty build up or plaques, thickening) in arterial walls and loss of elasticity • Capillary walls thicken slightly, leading to a slower rate of exchange of gases, nutrients, and waste.	• Encourage the inclusion of physical activity in the daily routine; pace activities. • Encourage a healthy low-fat, low-salt diet, including plenty of fruits, vegetables, and whole grains. • Assist with smoking cessation and/or avoid the use of tobacco. • Teach the importance of regular check-ups • Assist with weight control. • Teach the importance of medication compliance. • Teach stress-reduction activities.

Lifestyle Considerations

Activity levels and habits can dramatically affect a person's cardiopulmonary status. For example, sedentary activity patterns do not encourage the expansion of alveoli and the development of pulmonary exercise patterns (deep breathing). People who exercise (e.g., aerobics, walking, swimming) three to six times per week can better respond to stressors to cardiopulmonary health. Regular physical activity provides many health benefits, including increased heart and lung fitness, improved muscle fitness, and reducing the risk of heart disease. Additional considerations related to the effects of exercise on the cardiopulmonary system are discussed in Chapter 34.

Cultural influences can also play a role in a person's lifestyle, encouraging or discouraging healthy choices. Culture is a strong force in the determinants of health and behavior change. An understanding of a patient's cultural background is necessary to promote health and disease prevention in any population (Andrews et al., 2020). An important part of care would be to assess the impact of any practice and beliefs on a patient's readiness to participate in the proposed plan of care related to the health problem or need.

Cigarette smoking (active or passive) is a major contributor to lung disease and respiratory distress, heart disease, and lung cancer. Cigarette smoking is the most important risk factor for COPD (NHLBI, 2019). Smoking is also one of the key risk factors for heart disease, the leading cause of death in the United States (CDC, 2021a). Use of e-cigarettes, or vaping, is associated with e-cigarette, or vaping, product use–associated lung injury (EVALI) and is an emerging health issue of concern (CDC, 2020d). Several lung diseases, including bronchiolitis obliterans, lipoid pneumonia, and spontaneous pneumothorax, are associated with vaping, and there is concern that the chemicals deposited in the lungs through vaping may lead to the development of cancer (Broderick, 2021). EVALI has been connected with increased emergency room visits, hospitalization, and patient deaths (CDC, 2020d). Evidence related to the impact of e-cigarettes on the lungs continues to evolve.

Nurses working with patients to initiate changes in health habits that affect oxygenation and perfusion must also examine themselves as a factor in the success of the plan. Nurses who role model good health behaviors are more effective teachers. Use the display Promoting Health 40-1: Oxygenation and Perfusion for yourself before using it with others.

Social Determinants of Health

A person's neighborhood and built-environment impact their health and well-being (U.S. DHHS & ODPHP, n.d.). Unsafe air and other toxic environmental pollutants increase the risk for cardiovascular and pulmonary disease, as well as cancer (U.S. DHHS & ODPHP, n.d.). Although it is impossible to pinpoint all the effects of air pollution, researchers have demonstrated a high correlation between air pollution and cancer and lung diseases (Kurt et al., 2016; Turner et al., 2020). Air pollution is the most important environmental cardiovascular risk factor as well (Al-Kindi et al., 2020). For example, a person with adequate respiratory functioning who is exposed to air pollution may experience stinging of the eyes and nasal passages, coughing, choking, headache, and dizziness. Occupational exposure to asbestos, silica, or coal dust, as well as environmental pollution, can lead to chronic pulmonary disease (Johns Hopkins Medicine, 2021). Chronic environmental exposure to radon, radiation, asbestos, and arsenic can lead to lung cancer (MFMER, 2021). In addition, people who have experienced an alteration in respiratory functioning in the past often have difficulty continuing to perform self-care activities in a polluted environment.

Economic resources and stability affect cardiopulmonary health. Employment and income coupled with the increasing cost of food may result in a decrease in the nutritional quality of the diet. People who feel unsafe where they live or have poor street infrastructure may be more likely to stay home, resulting in less physical activity (CDC, 2022). Both these sets of factors may increase the risk for cardiovascular diseases.

Additional sociocultural factors affecting cardiopulmonary health and the risk for cardiopulmonary disease include:

- Language barriers
- Knowledge of nutrition to support cardiopulmonary health; limited access to and/or ability to obtain food
- Literacy
- Social isolation
- Access to physical activity opportunities

Psychological Health Considerations

Many psychological factors and conditions can affect the respiratory system. People responding to stress may sigh excessively or exhibit **hyperventilation** (increased rate and depth of ventilation, above the body's normal metabolic requirements). Hyperventilation can lead to a lowered level of arterial carbon dioxide. Generalized anxiety has been shown to cause enough bronchospasm to produce an episode of bronchial asthma. In addition, patients with respiratory problems often develop some anxiety as a result of the hypoxia caused by the respiratory problem.

Think back to **Tyrone Jacobs**, the young boy described at the beginning of the chapter. The patient is gasping for breath, which is extremely frightening and anxiety producing. In addition, his parents are frantic; this would increase Tyrone's anxiety level, further limiting his ability to breathe. The nurse needs to incorporate an understanding of this situation and plan interventions that promote oxygenation while reducing anxiety in both Tyrone and his parents.

Promoting Health 40-1

OXYGENATION AND PERFUSION

Use the assessment checklist to determine how well you are meeting your needs related to oxygenation. Then develop a prescription for self-care by choosing appropriate behaviors from the list of suggestions.

Assessment Checklist

☐ almost always ☐ sometimes ☐ almost never

☐	☐	☐	1. I breathe easily, without discomfort and without feeling short of breath.
☐	☐	☐	2. I exercise regularly.
☐	☐	☐	3. I maintain normal weight for my height and body frame.
☐	☐	☐	4. I live in an environment free of pollution.

☐	☐	☐	5. I avoid substances (tobacco, chemicals) that cause respiratory problems.
☐	☐	☐	6. I arrange to receive recommended immunizations.

Self-Care Behaviors

1. Follow a regular exercise program with activities that requires moderate effort, such as brisk walking for 2.5 to 5 hours or more a week (USDHHS, 2018).
2. Maintain healthy body weight.
3. Obtain medical evaluation for chest pain, problems with breathing, and/or chronic cough with sputum or blood.
4. Evaluate personal use of tobacco.
5. Incorporate a plan to reduce smoking, then stop smoking on a specific target date.
6. Avoid exposure to secondhand smoke when possible.
7. Arrange to have a tuberculin test done annually.
8. Receive a yearly influenza vaccine and a pneumococcal vaccine and COVID-19 vaccines, based on current recommendations.
9. Avoid chemical substances that cause respiratory depression.
10. Maintain a pollution-free environment (as much as possible).
11. Support federal and community efforts to keep the air free of pollution.

Information to promote cardiovascular health and oxygenation is available online.

NURSING PROCESS FOR OXYGENATION AND PERFUSION

Assessing

The patient's health history is an essential component for assessing the patient's cardiopulmonary function and ability to maintain adequate oxygenation. This information can be obtained from either the patient or a family member/caregiver. The nursing examination combined with laboratory findings can provide information to identify a patient's strengths; the nature of any problems; their course; related signs and symptoms; and onset, frequency, and effects on activities of daily living (ADLs). The nurse decides, based on these findings, what problems can be treated independently by nursing and which problems should be addressed in collaboration with other health professionals. Additional assessment information is discussed in Chapter 27.

Nursing History

The nursing history, an important clinical tool in the early steps of the nursing process, always includes a cardiopulmonary component. The information gained provides data about why the patient needs nursing care and what kind of care is required to maintain sufficient oxygenation of tissues. Interview questions help identify current or potential health problems or needs, actions performed by the patient for meeting cardiopulmonary needs, and the effects of such actions. They also help identify any contributing factors, the use of any aids to improve oxygenation, and effects of health problems on the patient's lifestyle and relationships with others.

Before starting the interview, make certain that the patient is not in acute distress. If the patient is experiencing any cardiopulmonary distress, initiate appropriate actions immediately to help relieve symptoms. Enlist the aid of family members/caregivers to help answer questions. Interview the patient at a later point, when the patient is able, to expand the initial database. If no emergency interventions are necessary for the patient's clinical condition, obtain a comprehensive history at this time.

Social determinants of health are conditions in the patients environments that may affect the patient's functioning and quality of life (U.S. DHHS & ODPHP, n.d.). Ask about sociocultural factors that may impact a patient's cardiopulmonary status and health, such as:

Access to physical activity opportunities
Safe neighborhoods and environments
Income
Environmental pollutants
Access to a health care provider and health care

This information helps us to understand factors that may influence a patient's health and use of health care and shape more effective interventions (U.S. DHHS & ODPHP, n.d.).

The accompanying Focused Assessment Guide 40-1 on page 1598 provides examples of appropriate questions for

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

health history assessment related to oxygenation and perfusion. If the patient is experiencing any disturbance in cardiopulmonary function, conduct a more detailed assessment, directing attention to the factors described earlier that may influence oxygenation and perfusion.

Physical Assessment

Examinations of the cardiopulmonary systems are discussed in Chapter 27. Refer to this chapter for details and additional information related to the assessment of these systems. Always proceed in a well-organized manner through a sequence of inspection, palpation, percussion, and auscultation. Note the patient's vital sign measurements, particularly the pulse and respiratory rate, as well as the blood pressure. Information related to vital sign assessment is discussed in Chapter 26. Note: Percussion of the thorax is an advanced assessment technique, usually performed by advanced health care providers. Refer to a health assessment text for details.

Recall **Mr. Kim**, the 57-year-old man who is receiving oxygen therapy and mechanical ventilation via an **endotracheal tube** (airway into the trachea). A complete assessment is necessary to identify specific problems related to oxygenation as well as to determine the effectiveness of current treatments.

INSPECTION

Observe the patient's general appearance. Does the patient appear to be in any distress? Is the patient restless or anxious? Note the patient's level of consciousness and orientation to person, place, and time. Alterations in oxygenation to body tissues can be a result of respiratory or cardiac distress and lead to altered mental status. Inspect the patient's skin, mucous membranes, and general circulation, which can be a general indicator of the patient's health status, as well as indicating problems with oxygenation. Pallor (lack of color) of skin and mucous membranes can indicate less than optimal oxygenation. Cyanosis (bluish discoloration) and/or coolness or decreased temperature may indicate decreased blood flow or poor blood oxygenation. Edema may be the result of overhydration, heart failure, kidney failure, trauma or peripheral vascular disease, conditions which may contribute to altered oxygenation.

Note any abnormalities in the structures of the chest. The adult chest contour is slightly convex, with no sternal depression. The anteroposterior diameter should be less than the transverse diameter. Kyphosis (curvature of the spine) contributes to the older adult's appearance of leaning forward and can limit respiratory ventilation. Barrel chest deformity may be a result of aging or COPD. Note the contour of the intercostal spaces, which should be flat or depressed, and the movement of the chest, which should be symmetrical. Observe the respiratory rate, rhythm, and depth. Normally, respirations are quiet and nonlabored, and occur at a rate of 12 to 20 times each minute in healthy adults. Note any flaring of the nostrils, muscular retractions, **tachypnea** (rapid breathing), or **bradypnea** (slow breathing), which are suggestive of a health deviation requiring further evaluation.

Refer to Chapter 27 for a detailed discussion of inspection as part of the assessment of the respiratory and cardiovascular systems.

Focused Assessment Guide 40-1

OXYGENATION AND PERFUSION

Factors to Assess	Questions and Approaches
Usual patterns of respiration	How would you describe your breathing? Do you have allergies? What type(s) of allergies do you have? What relief measures do you use?
Medications	Are you taking any medications for your breathing, your heart, or for your blood pressure? What other medications are you taking?
Health history	Do you have any heart, lung, or breathing conditions? Does anyone in your family/home have any breathing conditions or respiratory infections?
Recent changes	Have you noticed any changes in your breathing (out of breath, cough, wheezing)? Have you noticed any changes in your ability to perform activities of daily living? Do you have any swelling or redness in your arms or legs? Do you have a respiratory infection?

	If so, what type? What relief measures are you using?
Lifestyle and environment	Do you smoke? If so, how many years have you smoked? How much do you smoke (i.e., how many packs per day or year)? Do you live with a smoker or are there smokers in your workplace? Are you exposed to respiratory irritants in your workplace? Are there other pollutants in your workplace?
Cough	How much and how often do you cough? What is it like (dry, bubbly, hoarse)? Do you cough up mucus? If so, how much and what does it look like? Do you have a history of allergies? Do you ever wheeze? Are you exposed to dust? Fumes?
Sputum	Do you ever cough up and spit out mucus? How much do you spit out and do you associate it with anything (time of day, environment)? What color is it? Is it ever blood tinged? What is its odor?
Pain	Do you have any chest pain? Do you have pain with breathing? Do you have pain in the arms or legs? When did it start? On a scale of 0 to 10 (10 being very painful), how severe is the pain? Where is the pain? Is the pain worse with inspiration? Expiration? Cough? Activity? Does the pain radiate? What measures are you using to relieve the pain?
Dyspnea	Do you have any shortness of breath? Is it constant or remittent or related to any activity? How do different positions affect it? How does it affect your daily activities? Can you sleep lying flat? How many pillows do you use?
Fever	Have you had pneumonia recently? Do you have any contact with people who have tuberculosis? Do you have night sweats? Are others in your household well or ill? Have you traveled anywhere recently?
Fatigue	Have you noticed you feel more tired lately? Are you getting your normal amount of sleep at night? Has your sleep at night been affected by any difficulty breathing? Do you become easily fatigued when you climb stairs?

PALPATION

Palpate the chest. Note skin temperature and color. Skin temperature in this area is typically the same as the rest of the body. Assess chest expansion (thoracic excursion), which should be symmetrical. Note the presence or absence of masses, edema, or tenderness on palpation. Palpate the point of maximal impulse (PMI). Note pulsations in any other area of the chest. Abnormal size or location of the PMI or the presence of vibrations can indicate heart failure, myocardial infarction, disease of the heart valves, or other cardiac diseases. Palpate the patient's extremities. Assess skin temperature and color, pulses, and capillary refill. Note the presence or absence of edema, or tenderness on palpation. The presence of decreased skin temperature, pallor, cyanosis, decreased pulses, and prolonged capillary refill can indicate less than optimal cardiac function and oxygenation. The presence of edema also indicates alterations in cardiovascular function.

Refer to Chapter 27 for a detailed discussion of palpation as part of the assessment of the respiratory and cardiovascular systems.

PERCUSSION

Percussion is used to assess the position of the lungs, density of lung tissue, and identify changes in the tissue. This assessment skill is not used frequently. When used, it is usually included in examinations performed by advanced practice nurses and other advanced practice professionals. Refer to a health assessment text for details.

AUSCULTATION

Auscultation of the lungs assesses air flow through the respiratory passages and lungs. Listen for normal and abnormal lung sounds. Normal breath sounds include **vesicular** (low-pitched, soft sounds heard over peripheral lung fields), **bronchial** (loud, high-pitched sounds heard primarily over the trachea and larynx), and **bronchovesicular** (medium-pitched blowing sounds heard over the major bronchi) sounds. Auscultate as the patient breathes slowly through an open mouth. Breathing through the nose can produce falsely abnormal breath sounds.

In addition to air flow, listen for **adventitious** sounds (extra, abnormal sounds of breathing), such as wheezing or crackles. Abnormal lung sounds can occur as a result of alterations in the respiratory and cardiovascular systems and

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

lead to impaired oxygenation. **Crackles**, frequently heard on inspiration, are soft, high-pitched discontinuous (intermittent) popping sounds. They are produced by air passing through fluid in the airways or alveoli and opening of deflated small airways and alveoli. They occur due to inflammation or congestion and are associated with pneumonia, heart failure, bronchitis, and COPD. **Wheezes** are continuous musical sounds, produced as air passes through airways constricted by swelling, narrowing, secretions, or tumors. They are often heard in patients with asthma, tumors, or a buildup of secretions.

Auscultation of the heart assesses function of the heart, heart valves, and blood flow. Listen for normal and abnormal heart sounds. Listen to the rhythm of the beat and the characteristic "lub–dub." The first sound, the lub, is followed by the second sound, the dub, with a pause before the next lub–dub. These sounds are made by the closure of valves in the heart during the cardiac cycle. The lub correlates with the beginning of systole, the contraction of the ventricles, and is called S_1. The dub correlates with the end of systole and the beginning of diastole, the relaxation of the ventricles, and is called S_2.

In addition to S_1 and S_2, listen for extra and abnormal heart sounds. Abnormal heart sounds occur as a result of alterations in the cardiovascular system that may lead to impaired oxygenation. Refer to Chapter 27 for a detailed discussion of auscultation as part of the assessment of the respiratory and cardiovascular systems.

Concept Mastery Alert

The presence of sputum in the airways can be indicated by coarse crackles that are soft, high-pitched, and discontinuous.

Common Laboratory and Diagnostic Tests

In addition to the nursing history and physical examination, the information provided in Table 40-2 (on page 1600) identifies common laboratory that may be used to assess cardiopulmonary function and can aid in the identification of health problems and needs.

The nurse might anticipate diagnostic procedures such as **arterial blood gas (ABG)** analysis (measurement of blood pH and arterial gases to evaluate acid–base and oxygenation status) for **Joan McIntyre**, the older woman with the acute exacerbation of COPD. This diagnostic test would provide information regarding the adequacy of her oxygenation and ventilation and help titrate (adjust) the administration of supplemental oxygen. It would also be used to evaluate her response to treatment and therapies.

The diagnostic tests described in the next sections are not distinctive for a particular disease but reflect how well the cardiopulmonary systems are functioning.

ELECTROCARDIOGRAPHY

One of the most valuable and frequently used diagnostic tools, electrocardiography, measures the heart's electrical activity. Impulses moving through the heart's conduction system create electric currents that can be monitored on the body's surface. Electrodes attached to the skin can detect these electric currents and transmit them to an instrument that produces a record—the **electrocardiogram (ECG)**—of cardiac activity. The data are graphed as waveforms. ECG can be used to identify myocardial ischemia and infarction, heart damage, rhythm and conduction disturbances, chamber enlargement, electrolyte imbalances, and drug toxicity.

The standard 12-lead ECG uses a series of electrodes placed on the extremities and the chest wall to assess the heart from 12 different viewpoints (leads) by attaching 10 cables with electrodes to the patient's limbs and chest; 4 limb electrodes and 6 chest electrodes. Each lead provides an electrographic snapshot of electrochemical activity of the myocardial cell membrane. The ECG device measures and averages the differences between the electrical potential of the electrode sites for each lead and graphs them over time, creating the standard ECG complex, called PQRST. These electrodes provide views of the heart from the frontal plane as well as the horizontal plane. It is essential that connection or placement of the ECG electrodes/leads is accurate to prevent misdiagnosis.

Table 40-2 Common Laboratory Studies Used to Assess Cardiopulmonary Function

STUDY	PREPARATION	AFTERCARE
Arterial Blood Gas and pH Analysis		
These examine arterial blood to determine the pressure exerted by oxygen and carbon dioxide in the blood and blood pH. This test measures the adequacy of oxygenation, ventilation, and perfusion. Normal results are: pH, 7.35–7.45; PCO_2, 35–45 mm Hg; PO_2, 80–100 mm Hg; HCO_3, 22–26 mEq/L; and base excess or deficit, –2–+2 mmol/L.	• Explain to the patient that this test requires an arterial puncture and collection of a blood specimen. • The radial, brachial, or femoral arteries are usually the sites of choice. • Perform the Allen test to ensure adequate ulnar blood flow when using the radial artery.	• Record supplemental oxygen or respirator settings on specimen information. • The arterial specimen is immediately placed on ice and taken to the laboratory. • Apply pressure for 5–10 minutes and watch for evidence of bleeding. If the patient is taking anticoagulants, pressure must be applied for a longer interval.
Cardiac Biomarkers		
Creatine kinase (CK) and isoenzymes are enzymes that are released as a result of injury to tissues, including the heart muscle. Troponin is a protein found in skeletal and cardiac muscle fibers and is also released after injury to the heart. These biomarkers are used to monitor cardiac injury and myocardial infarction. Measuring the levels of these enzymes can help determine the extent and timing of the damage.	• Review the procedure with the patient. Inform the patient that this test can assist in assessing for heart damage. • Inform the patient that a series of samples will be required; based on facility protocol, samples could be taken three to four times, in 3–4-hour intervals. • Inform the patient that specimen collection takes approximately 5–10 minutes. • Address concerns about pain and explain that there may be some discomfort during the venipuncture (puncture of the vein). • There are no food, fluid, or medication restrictions unless prescribed.	• Recognize anxiety related to test results. Provide teaching and information regarding the implications of the test results. • Reinforce information given by the patient's health care team regarding further testing, treatment, or referral to another health care provider. • Depending on the results of this procedure, additional testing may be performed to evaluate or monitor the progression of illness. • Evaluate test results in relation to the patient's symptoms, health care problems, and other tests performed.
Complete Blood Count (CBC)	• Review the procedure with the patient. Inform the patient that this test can assist in evaluating the body's response to illness. • Inform the patient that specimen collection takes approximately 5–10 minutes. • Address concerns about pain and explain that there may be some discomfort during the venipuncture (puncture of the vein). • There are no food, fluid, or medication restrictions unless prescribed.	• Reinforce information given by the patient's health care team regarding further testing, treatment, or referral to another health care provider. • Depending on the results of this procedure, additional testing may be performed to evaluate or monitor progression of illness. • Evaluate test results in relation to the patient's symptoms, health care problems, and other tests performed.
Cytologic Study		
This involves a microscopic examination of sputum and the cells it contains. It is done primarily to detect cells that	• Collect the specimen, if possible, in the morning before breakfast. The test usually involves 3 successive days of	• Advise the patient to inform the nurse when the specimen has been obtained. • Label and package the

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

may be malignant, determine organisms causing infection, and identify blood or pus in the sputum.	sputum collection. About 1 teaspoon of sputum is needed for a specimen. • The patient should take a deep breath, then expel the air with a deep cough. • Expectorate the specimen into a sterile specimen container with the appropriate preservative, if indicated. • Close the container with a tight-fitting lid.	specimen and send it to the laboratory as soon as possible.

Source: Adapted from Fischbach, F. T., & Fischbach, M. A. (2018). A manual of laboratory and diagnostic tests (10th ed.). Wolters Kluwer; and Hinkle, J. L., Cheever, K. H., & Overbaugh, K. J. (2022). Brunner & Suddarth's Textbook of medical-surgical nursing (15th ed.). Wolters Kluwer.

An ECG is typically accomplished using a multichannel method. All electrodes are attached to the patient at once and the machine prints a simultaneous view of all leads. It is important to reassure the patient that the leads just sense and record and do not transmit any electricity. The patient must be able to lie still and refrain from speaking to prevent body movement from creating artifacts in the ECG. Variations of standard ECG include exercise ECG (stress ECG) and ambulatory ECG (Holter monitoring). Refer to a medical-surgical text for information regarding these tests.

PULMONARY FUNCTION STUDIES

Pulmonary function studies encompass a group of tests used to assess respiratory function to assist in evaluating respiratory disorders. They provide an evaluation of lung dysfunction, diagnose disease, assess disease severity, assist in management of disease, and evaluate respiratory interventions. Most tests are administered by a respiratory therapist, technician, nurses with specialized training, or health care providers. Several tests commonly encountered are described in the next section. More specialized tests and their purposes include:

- Diffusion capacity estimates the patient's ability to absorb alveolar gases and determine if a gas exchange problem exists.
- Maximal respiratory pressures help evaluate neuromuscular causes of respiratory dysfunction.
- Exercise testing helps evaluate dyspnea during exertion.

Refer to Box 40-1: Commonly Measured Values From Pulmonary Function Tests.

Spirometry

Spirometry measures the volume of air in liters exhaled or inhaled by a patient over time. It evaluates lung function and airway obstruction through respiratory mechanics. Spirometry can be used to measure the degree of airway obstruction and evaluates response to inhaled medications. The patient inhales deeply and exhales forcefully into a **spirometer**, an instrument that measures lung volumes and airflow. Patients also use spirometers to promote deep breathing while recovering from surgery, and to monitor health status in management of chronic asthma. A discussion regarding the use of incentive spirometers can be found later in this chapter.

Peak Expiratory Flow Rate

Peak expiratory flow rate (PEFR) refers to the point of highest flow during forced expiration. PEFR reflects changes in the size of pulmonary airways and is measured using a peak flow meter. It is routinely used for patients with moderate or severe asthma to measure the severity of the disease and degree of disease management. With the patient standing or sitting with the back positioned as straight as possible, the patient takes a deep breath and places the peak flow meter in the mouth, closing the lips tightly around the mouthpiece. The patient forcibly exhales into the peak flow meter, and an indicator on the meter rises to a number. The patient is asked to repeat this three times, and the highest number is recorded. This produces a measurement in liters indicating the maximum flow rate during a forced expiration. Predicted normal values are established in regard to height, age, and biologic sex, but patients with moderate to severe asthma cannot achieve the predicted values (Hess et al., 2021). The individual patient's personal best peak flow provides the benchmark value for their asthma management plan (Hess et al., 2021; MFMER, 2020). The personal best peak flow is identified by measuring the daily peak flow rate over a 2- to 3-week period; the highest peak flow rate over this period is the patient's personal best (MFMER, 2020). Patients with asthma commonly measure PEFR at home to monitor airflow. The results are used to track disease progression and regulate treatment by the patient and health care team.

Box 40-1	Commonly Measured Values From Pulmonary Function Tests

- Tidal volume (V_T): Total amount of air inhaled and exhaled with one breath during normal breathing
- Vital capacity (VC): Maximum amount of air exhaled after maximum inspiration
- Forced vital capacity (FVC): Maximum amount of air that can be forcefully exhaled after a maximal inspiration
- Forced expiratory volume ($FEV_{[1,2,3]}$): The volume of air exhaled at a specific time interval; for example, in the first, second, and third seconds after a full inspiration (timed vital capacities)
- Total lung capacity (TLC): The volume of air contained within the lungs at maximum inspiration
- Residual volume (RV): The volume of air left in the lungs at maximal expiration
- Peak expiratory flow rate (PEFR): The maximum flow attained during the FVC

Source: Adapted from Fischbach, F. T., & Fischbach, M. A. (2018). A manual of laboratory and diagnostic tests (10th ed.). Wolters Kluwer; and Hess, D. R., MacIntyre, N. R., Galvin, W. F., & Mishoe, S. C. (2021). Respiratory care: Principles and practice (4th ed.). Jones & Bartlett Learning.

Pulse Oximetry

Pulse oximetry is a noninvasive technique that measures the peripheral arterial oxyhemoglobin saturation (SpO_2) of arterial blood. The reported result is a ratio, expressed as a percentage, between the actual oxygen content of the hemoglobin and the potential maximum oxygen-carrying capacity of the hemoglobin (Fischbach & Fischbach, 2018). Pulse oximetry is useful for monitoring patients receiving oxygen therapy, titrating oxygen therapy, monitoring those at risk for hypoxia, and monitoring postoperative patients. Pulse oximeter measurements are less accurate at SpO_2 less than 80%, but the clinical importance of this is questionable (Hess et al., 2021, p. 25). In addition, a patient's SpO_2 may remain relatively normal initially due to an increase in respiratory rate compensating for inadequate oxygen delivery (Dix, 2018; Elliott & Baird, 2019). Pulse oximetry does not replace ABG analysis. Desaturation (decreased level of SpO_2) indicates gas exchange abnormalities. Oxygen desaturation is considered a late sign of respiratory compromise in patients with reduced rate and depth of breathing.

Be aware of the patient's hemoglobin level before evaluating oxygen saturation because the test measures only the percentage of oxygen carried by the available hemoglobin. Thus, even a patient with a low hemoglobin level could appear to have a normal SpO_2 because most of that hemoglobin is saturated. However, the patient may not have enough oxygen to meet body needs (Morton & Fontaine, 2018). Also, take into consideration the presence of preexisting health conditions, such as COPD. Parameters for acceptable oxygen saturation readings may be different for these patients. For patients with chronic lung disease, a level of 88% to 92% may be considered within normal limits or may indicate the need for oxygen therapy (Mirza et al., 2018; Mitchell, 2015). Be aware of any prescribed interventions regarding acceptable ranges and/or check with the patient's health care team.

A range of 90% to 100% is considered the normal SpO_2 (Bauldoff et al., 2020), depending on the patient's health status and health problems and needs; values <90% are considered low (American Thoracic Society, 2021; MFMER, 2018b), indicate that oxygenation to the tissues may be inadequate, and should be investigated for potential hypoxia or technical error (Hinkle et al., 2022). When administering supplemental oxygen, most patients will have a target oxygen saturation of 94% to 98% (O'Driscoll et al., 2017). Refer also to the discussion of provision of supplemental oxygen later in the chapter on page 1613. Figure 40-8 shows a nurse using a pulse oximetry unit. Skill 40-1 on pages 1632–1636 outlines nursing responsibilities when using a pulse oximetry unit.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

FIGURE 40-8. Using a portable pulse oximetry unit to measure oxygen saturation (SpO_2) of arterial blood.

Consider **Tyrone Jacobs**, the young boy with suspected asthma described at the beginning of the chapter. The nurse would use pulse oximetry initially to obtain baseline information about the patient's oxygen saturation level and then as a means to evaluate the effectiveness of therapy.

CAPNOGRAPHY

Capnography is a technique to measure the carbon dioxide level in expired gas (end-tidal CO_2) (Hess et al., 2021) and is a noninvasive method to monitor and evaluate respiratory function and ventilation (Morton & Fontaine, 2018). Exhaled air passes through a sensor that measures the amount of carbon dioxide (CO_2) exhaled with each breath. The reported results also provide information about the respiratory rate and depth, the presence of apnea, and efficiency of gas exchange. The normal range for end-tidal CO_2 is typically 35 to 45 mm Hg (Burns & Delgado, 2019). When carbon dioxide levels are abnormal, either high or low, adverse effects, including death, can occur. Capnography is useful for assessing and monitoring ventilation and aiding in earlier identification of patients who are at risk for respiratory compromise, are experiencing partial or complete airway obstruction or are experiencing hypoventilation (Burns & Delgado, 2019; Seckel, 2018). It may also be used to confirm and monitor placement of endotracheal or tracheostomy tubes, in management of patients receiving mechanical ventilation, and in confirming and monitoring placement of nasogastric tubes as well as identifying patients with low cardiac output (Burns & Delgado, 2019; Hess et al., 2021). Capnography can detect signs of abnormal ventilation, such as respiratory depression and hypoventilation, earlier than pulse oximetry (Bovino et al., 2018; Kummer & Walden, 2019).

A capnometer (device displaying numeric measurement of CO_2) may be incorporated into a bedside monitor, may be a handheld unit (may be incorporated into a pulse oximeter), can be incorporated into a mechanical ventilator, can be a small device attached directly to an artificial airway, and can be incorporated into nasal cannula for nonintubated patients (Fig. 40-9) (Hess et al., 2021). The use of capnography in monitoring placement nasogastric tube placement is discussed in Chapters 37 and 39.

THORACENTESIS

Thoracentesis is the procedure of puncturing the chest wall and inserting a needle into the pleural space to aspirate pleural fluid, air, or both (Morton & Fontaine, 2018). A thoracentesis may be performed to obtain a specimen for diagnostic purposes, to remove fluid or air that has accumulated in the pleural cavity and is causing respiratory difficulty and discomfort, or to instill medications (Hinkle et al., 2022). The physician or other advanced practice professional can perform a thoracentesis at the bedside with the nurse assisting, or it can be performed in a procedure room, in the radiology department, or in an outpatient setting (Bauldoff et al., 2020). The patient is required to sign a permit for this procedure. Because the cavity being entered is sterile, surgical asepsis is required. Standard precautions also are used; transmission-based precautions are implemented as indicated.

FIGURE 40-9. Nasal cannula designed for oxygen administration with incorporated CO_2 sampling. (*Source:* Nellcor TM Adult/Pediatric Colorimetric CO_2 Detector. 2020 Medtronic. All rights reserved. Used with the permission of Medtronic.)

Procedure

A thoracentesis is usually carried out with the patient sitting on a chair or the edge of the bed with the legs supported and the arms and shoulders raised (arms folded and resting on a pillow on the bedside table) so the ribs lift and separate, to allow easier needle insertion (Fig. 40-10). If unable to sit up, the patient may lie on the unaffected side with the hand of the affected side raised above the shoulder. A local anesthetic is used to minimize pain and discomfort (Morton & Fontaine, 2018).

The location where the needle is inserted depends on where the fluid is present and where the practitioner can best aspirate it. Once this spot is identified, the skin is cleansed with an antimicrobial agent. After the local anesthetic has taken effect, the needle is inserted between the ribs through the intercostal muscles and fascia and into the pleura. After the procedure, the needle or plastic catheter is removed, and a small sterile dressing is placed over the entry site.

FIGURE 40-10. Position of the patient for thoracentesis.

During thoracentesis, fluid or air can be removed from the pleural cavity with a syringe. Another method for removing fluid is to drain the fluid into a bottle in which a partial vacuum has been created. With this technique, a small plastic catheter may be threaded through the needle, allowing the needle to be withdrawn. This catheter reduces the possibility of puncturing the lung. When this method is used, the tubing connecting the needle and the bottle must be sterile. Commonly, a calibrated bottle is used to collect the drainage, allowing the amount of fluid removed to be determined. The maximum amount of fluid removed at one time is generally 1,200 to 1,500 mL, to reduce the risk of cardiovascular collapse from rapid removal of too much fluid (Bauldoff et al., 2020).

Nursing Responsibilities

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

The nurse is responsible for collecting baseline data before the procedure and for preparing the patient physically and emotionally for the procedure. Instruct the patient not to cough or breathe deeply during the procedure. Urge the patient to remain as still as possible to diminish the risk for accidental injury to the lung. Administer analgesics before the procedure as ordered.

During the procedure, observe the patient's reactions. Monitor the patient's color, pulse, oxygen saturation, and respiratory rates, communicating immediately to the health care team any deviation from the patient's baseline. Fainting, nausea, and vomiting may occur. If not applied by the practitioner who completed the procedure, dress the wound with a sterile dressing (Morton & Fontaine, 2018), based on prescribed intervention or facility policy. Ensure that specimens, if obtained, are taken to the laboratory immediately.

After the procedure, assess the patient for complications, which could include pneumothorax, pain, hypotension, and pulmonary edema (Morton & Fontaine, 2018). Assess for changes in vital signs, particularly respirations and oxygen saturation; monitor lung sounds; and assess for the presence or worsening of cough or dyspnea. If a large amount of fluid was removed, respirations usually become easier. If the lung was punctured, respiratory distress becomes acute. If blood appears in the sputum or the patient has severe coughing, notify the health care team promptly. Monitor the puncture site. A chest radiograph is usually done after the procedure to verify the absence of complications.

Diagnosing Actual or Potential Health Problems and Needs

An assessment of a patient's oxygenation and perfusion status may lead to the identification of one or more actual or potential health problems and needs related to oxygenation and perfusion. Following the formulation of the actual or potential health problems and needs, the nurse communicates findings to other nursing and health care professionals through the use of written and spoken word. The written actual or potential health problem or need becomes a permanent part of the patient's health record. Examples of health problems and needs with related etiology and signs and symptoms can be found in the Examples of Actual or Potential Health Problems and Needs: Oxygenation and Perfusion.

Examples of Actual or Potential Health Problems and Needs

OXYGENATION AND PERFUSION

Actual or Potential Health Problems and Needs	Possible Etiologic Factors	Potential Signs and Symptoms
Ineffective Airway Clearance	Fatigue; retained secretions; a 20-year history of COPD, with recent development of pneumonia	"I never feel as though I am getting enough air." • Thick, yellow secretions • Pale skin with circumoral cyanosis; respiratory rate is 40 breaths/min and shallow. Coarse crackles are auscultated bilaterally. • Cannot sit quietly in chair or on bed. • Ineffective cough
Impaired Gas Exchange	Smokes one pack of cigarettes per day; works with asbestos in auto factory; has had a cold for 7 days	Using pursed-lip breathing • Sitting hunched forward with overbed table supporting arms. • Altered blood gases show respiratory acidosis. • Reports shortness of breath for 1 week.
Impaired Breathing	Anxious about results of cardiac catheterization and possible cardiac surgery	Hyperventilating, tachypneic (40 breaths/min) • "I have a tingling feeling in my fingers." • "I can't catch my breath and I can't lie down in bed."

Outcome Identification and Planning

Expected outcomes are derived from the actual or potential oxygenation and perfusion problems identified. The goal is to maintain or restore optimum function related to oxygenation and perfusion, alleviate symptoms or side effects of disease or treatment, and prevent complications. General patient outcomes are listed here. Actual patient outcomes should list specific behaviors and criteria individualized for the patient situation.

When caring for patients with an alteration in oxygenation and perfusion, nursing measures support the following general expected outcomes. The patient will:

- Demonstrate improved gas exchange in the lungs by an absence of cyanosis or chest pain and a pulse oximetry reading more than 95%
- Relate the causative factors, if known, and demonstrate a method of coping with these factors
- Preserve cardiopulmonary function by maintaining an optimal level of activity
- Demonstrate self-care behaviors that provide relief from symptoms and prevent further cardiopulmonary problems

Implementing

Oxygenation and perfusion deficits impair all aspects of daily living. Going to get the mail or cleaning the house may become a monumental task for people with oxygenation and perfusion deficits. Nursing interventions related to oxygenation and perfusion aim to promote optimal functioning of the cardiopulmonary systems, to promote comfort, and to promote and control coughing. Nurses may also need to intervene by suctioning the airway, meeting respiratory needs with medications, providing supplemental oxygen, managing chest tubes, using artificial airways, clearing an obstructed airway, and administering cardiopulmonary resuscitation (CPR).

QSEN TEAMWORK AND COLLABORATION

Patients, nurses, respiratory therapists, physicians, and other advanced practice professionals each have key roles in assessing, addressing, and monitoring oxygenation and perfusion and oxygenation/perfusion-related care issues and concerns. Communication and collaboration between the nurse, patient, and other health care professionals are critical to clarify the roles and responsibilities under conditions of potential overlap in team member functioning.

Promoting Optimal Function

Healthy lifestyle choices and behaviors are an important part of preventing and managing cardiopulmonary diseases, which can have an impact on the level of health and oxygenation and perfusion. Vaccination is an important part of preventing respiratory infections. Teaching patients with problems of oxygenation about pollution-free environments is an important part of respiratory management. Many people with altered oxygenation experience anxiety as a result of their symptoms and the actual or potential loss of independence. It is important to minimize anxiety in patients with alterations in oxygenation in order to promote optimal functioning. Promoting good nutrition is another vital part of promoting optimal cardiopulmonary functioning.

Teach patients about their health conditions and provide information and support to improve patient health literacy. Refer to the accompanying Promoting Health Literacy box.

Promoting Health Literacy

IN PATIENTS WITH COPD

Patient Scenario

Nicoli Romanov, age 69, has been experiencing a morning cough for “several years,” but states, “It wasn’t too bad, so I lived with it.” He reports increasing shortness of breath and fatigue over the last few months, with mucus production. He states that he has noticed increased amounts of mucus during the last few weeks, and significantly increased difficulty breathing with activity. Mr. Romanov reports smoking cigarettes for 40 years but has recently been thinking about quitting. After having a medical workup, including pulmonary function studies, Mr. Romanov was diagnosed with COPD. He tells the nurse that he doesn’t really think that he can use “all these medications, especially that breathing thing,” and doesn’t really understand what COPD is. He asks, “Do you think my smoking is making me worse?”

Nursing Considerations: *Tips for Improving Health Literacy*

Provide Mr. Romanov with easy-to-read information about COPD. Encourage him to ask his health care provider as many questions as needed to understand his condition. Explain that it is a breathing problem that comes on over a long time, but there are things he can do to feel better and help keep from getting

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

worse. Reinforce that it is important to take the medications every day and learn the right way to use inhaled medications. Provide information and resources to help him quit smoking. Encourage Mr. Romanov to ask his health care provider the following three questions:

- What is my main problem?
- What do I need to do?
- Why is it important for me to do this?

What additional measures can you take to help increase health literacy in this patient? What other measures would be helpful for Mr. Romanov if he did not speak English, could not read, or had other learning deficits?

HEALTHY LIFESTYLE

Patients who practice good health-related behaviors can reduce their risk for many cardiopulmonary diseases. Explain that beneficial behaviors should be incorporated into their daily and weekly activities. Encourage patients to eat a healthy diet (see discussion later in the chapter). Encourage patients to maintain a healthy weight. Regular exercise should also be part of a patient's daily activities. Current recommendations suggest adults minimally engage in activity that requires moderate effort, such as brisk walking for 2.5 to 5 hours or more a week (USDHHS, 2018). Teach patients to monitor their cholesterol, triglyceride, high-density lipoprotein (HDL) and low-density lipoprotein levels (LDL) as well as their blood pressure. Encourage patients to limit alcohol intake and stop smoking (see discussion later in the chapter).

VACCINATION

Influenza

Influenza (the flu) is a contagious respiratory illness that causes mild to severe illness, and even death. People at high risk for serious flu complications include young children; pregnant women; people with chronic health conditions like asthma or heart and lung disease; and people ages 65 years and older. The best way to prevent the flu is by getting vaccinated. All people ages 6 months and older should be vaccinated each year (CDC, 2021b).

Pneumococcal Disease

Pneumococcal disease is an infection caused by a type of bacteria called pneumococcus. There are different types of pneumococcal disease, such as pneumococcal pneumonia, meningitis, and otitis media. Pneumococcal disease can be fatal. In some cases, it can result in long-term problems, such as brain damage, hearing loss, and limb loss. Pneumococcal disease is common in young children, but older adults are at greatest risk of serious illness and death (CDC, 2020a). Pneumococcal vaccine is very good at preventing severe disease, hospitalization, and death. Vaccines are recommended for all children younger than 2 years old, all adults ages 65 years and older, adults ages 19 to 64 years who smoke cigarettes, and people ages 2 through 64 years with certain medical conditions (CDC, 2020a). There are two types of pneumococcal vaccines available in the United States, each protecting against different numbers and types of pneumococcal bacteria. Recommendations for use of these vaccines are based on age and health status. Guidelines provided by the Centers for Disease Control can be accessed at http://www.cdc.gov/pneumococcal/vaccination.html

COVID-19

COVID-19 is a disease that became a pandemic in late 2019. COVID-19 is an infection caused by a novel coronavirus (SARS-CoV-2). Most people infected with the COVID-19 virus experience mild to moderate respiratory illness (fever, dry cough, tiredness) and recover without special treatment (CDC, 2021d; WHO, 2021), but some people become severely ill (difficulty breathing or shortness of breath, chest pain or pressure, loss of speech or movement [CDC, 2021d; WHO, 2021]) and/or experience post-COVID conditions. Post-COVID conditions are a wide range of new, returning, or ongoing health problems experienced more than 4 weeks after first being infected with the virus that causes COVID-19 (CDC, 2021d). Various groups of people are at increased risk of getting sick and dying from COVID-19, including many racial and ethnic minority groups and people with disabilities (CDC, 2021e). Patients with underlying alterations in health such as cardiovascular disease, diabetes, chronic respiratory or kidney disease, dementia or other neurologic conditions, immunocompromised state/weakened immune system, overweight or obesity, and cancer as well as those who are older, current or former smokers, or pregnant are more likely to develop serious illness, requiring hospitalization, intensive care, and/or a ventilator to help with breathing, or they may even die (CDC, 2021e). COVID-19 vaccines are effective at protecting patients from getting COVID-19 and significantly decrease the risk of serious illness as a result of infection with the virus (CDC, 2021c). As of this writing (early 2022), scientists and health care providers are still studying and learning about this virus and the impact of the vaccines; however, everyone ages 5 years and older is eligible and encouraged to get a COVID-19 vaccination. Several vaccines are available; the choice of vaccine to be administered and dosing for a particular vaccine depend on the age of the

patient and the details of administration identified by the manufacturer of the particular vaccine. Guidelines provided by the Centers for Disease Control can be accessed at https://www.cdc.gov/coronavirus/2019-ncov/vaccines/your-vaccination.html.

TEACHING ABOUT POLLUTION-FREE ENVIRONMENTS

A pollution-free environment is particularly important for people with cardiopulmonary problems. Teach the patient to assess the environment and make adjustments, whenever possible, to factors that impair respiratory functioning ("triggers"). The patient must actively plan to prevent exposure to pollutants and triggers (EPA, 2021). This might involve a job change, use of protective equipment, requesting enforcement of laws by government facilities, or subcontracting jobs. In order to minimize triggers in the home, dusting and vacuuming the office and home must be done at least twice per week. In some situations, the patient may be asked to wear a mask to prevent some symptoms of respiratory distress. Explain to the patient that exposure to industrial or occupational hazards (e.g., paint, varnish, gaseous fumes, asbestos) must also be restricted.

In the United States, fine pollutants—including carbon monoxide, sulfur dioxide, total suspended particulates, ozone, and nitrogen dioxide—that pose a hazard to health are monitored closely. On days when pollutant levels are elevated significantly, morbidity and mortality rates among people with preexisting pulmonary disease are increased greatly. Thus, on days when pollution alerts are announced, people with altered respiratory function should reduce their activities, stay indoors, and use an air conditioner, electronic air cleaner, or air filter (EPA, 2021). If pollen alters the patient's respiratory function, the same principles apply.

Cigarette smoking is a major risk factor in cardiopulmonary diseases. The inhalation of cigarette smoke increases airway resistance, reduces ciliary action, increases mucus production, causes thickening of the alveolar–capillary membrane, and causes bronchial walls to thicken and lose their elasticity. Smoking is the biggest risk factor for COPD (American Lung Association, 2021a), and increases the risk for many types of cancer, including cancers of the oral cavity, throat, larynx, esophagus, lung, urinary bladder, kidneys, colon and rectum, liver, pancreas, and stomach (CDC, 2021f). In addition, cigarette smoking causes reduced circulation by narrowing the blood vessels (arteries). Smoking causes coronary heart disease, the leading cause of death in the United States, and causes a much greater risk for stroke, peripheral vascular disease, and abdominal aortic aneurysm (abnormal dilation of blood vessels) (CDC, 2020b). These effects occur in both smokers and nonsmokers (children and adults) who live with smokers (CDC, 2021b,g). Habitual smokers usually have great difficulty quitting or reducing their smoking and need much encouragement. The American Lung Association (www.lung.org) and the American Heart Association (AHA, www.heart.org) offer free educational materials online to aid and support patients who are trying to stop smoking. Nurses play a key role in presenting accurate information about the effects of smoking. Encourage the decision to never start smoking or to stop smoking. Provide appropriate information, counseling, support, and resources to assist patients to be successful with smoking cessation.

REDUCING ANXIETY

It is important to create an environment that is likely to reduce anxiety. Help institute measures to alleviate discomfort immediately. Use effective listening skills and accurate observation to display a caring attitude. Attempt to understand the patient's life experiences and habits without judging them. Patients with harmful health habits often fear they will be judged, which may impede implementation of the plan of care and reaching collaborative health goals. Patients who believe nurses are genuinely concerned about them and their families are more willing to work toward achieving mutually desirable outcomes. Refer to Chapter 43 for additional discussion related to anxiety and related nursing care.

Think back to **Joan McIntyre**, the woman requesting to be "let go" if she should stop breathing. The nurse needs to provide support to the patient, showing genuine concern for her welfare. In addition, the nurse needs to act ethically and legally to ensure the patient's rights.

MAINTAINING GOOD NUTRITION

Beneficial behaviors, such as healthy eating, should be incorporated into a patient's daily activities. Encourage patients to follow healthy eating patterns that include a variety of nutrient-dense foods and beverages across all food groups, including fruits and vegetables, low-fat dairy products, whole grains, a variety of protein foods, and reduced

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

amounts of saturated fats and trans fats, added sugars, and sodium. This diet can help patients reduce their risk for chronic disease such as cardiopulmonary diseases and diabetes, improve health, and reduce the prevalence of overweight and obesity and meet nutrient needs (USDA & USDHHS, 2020).

People who work hard at breathing often do not have much energy for eating. Many of the medications used for treatment can cause anorexia and nausea. However, maintaining an adequate nutritional intake is crucial. Consider the use of small meals at frequent intervals distributed over the course of the day instead of the usual three larger meals. Provide frequent oral hygiene and rest periods before eating to help improve the patient's intake. Encourage patients to eat their meals 1 to 2 hours after breathing treatments and exercises.

Patients who have COPD require a high-protein/high-calorie diet to counter malnutrition. If supplemental oxygen is used, reinforce the importance of wearing the cannula during and after meals. Eating and digestion require energy, which causes the body to use more oxygen.

Promoting Comfort

Interventions to promote patient comfort are an important part of nursing care for patients with alterations in the cardiopulmonary function. Promoting proper positioning, adequate fluid intake, humidification of inspired air, and appropriate breathing techniques are used to maximize the patient's sense of well-being. In addition, encourage the patient to pace physical activities and schedule frequent rest periods to conserve energy.

POSITIONING

Proper positioning is important to ease respirations. A proper position for breathing is a position that allows free movement of the diaphragm and expansion of the chest wall. Alternatively, sitting in a slumped position permits the abdominal contents to push upward on the diaphragm, decreasing lung expansion during inspiration. People with dyspnea and orthopnea are most comfortable in a high-Fowler position because accessory muscles can easily be used to promote respiration.

Research has demonstrated that, in patients with pulmonary disease who are acutely ill, such as those with acute respiratory distress syndrome (ARDS) or COVID-19-related respiratory failure/ARDS, turning to the prone position on a regular basis promotes improved oxygenation (Guttendorf, 2021; Morata et al., 2021; Siegmeister et al., 2021; Venus et al., 2020). In this position, the posterior dependent sections of the lungs are better ventilated and perfused, gravitational pressure on lung structures is decreased, compression of the lungs by abdominal contents is decreased, and chest wall compliance is enhanced (Guttendorf, 2021; Venus et al., 2020). Prone positioning should not be used with patients who have facial fractures, unstable spinal or pelvic fractures, or increased intracranial pressure (Guttendorf, 2021). Patients in the third trimester of pregnancy or patients with open chest or abdominal wounds may be candidates for prone positioning, after evaluation and collaboration with the health care team (Guttendorf, 2021). Coordinated multidisciplinary teams utilizing detailed planning and collaboration are essential to successful implementation of prone positioning (Elpern et al., 2021; Mitchell & Seckel, 2018).

MAINTAINING ADEQUATE FLUID INTAKE

Patients can help keep their secretions thin by drinking at least 1.5 to 2 L of fluids daily (American Lung Association, 2021b; Cleveland Clinic, 2020). Fluid intake should be increased to the maximum that the patient's health state can tolerate. Increased fluids are needed by patients who have an elevated temperature, who are breathing through the mouth, who are coughing, who have thickened respiratory secretions, and who are losing excessive body fluids in other ways. Fluid intake (1 to 2 L/day), along with sodium intake (2,000 to 3,000 mg), is individualized for patients with heart failure (Kuehneman et al., 2018).

PROVIDING HUMIDIFIED AIR

Inspiring dry air removes the normal moisture in the respiratory passages that protect against irritation and infection. Inhalation of dry air also compromises ciliary function and mucous production (Hess et al., 2021). This is especially troublesome for patients who cannot breathe through their nose. When air humidity is low, it may be necessary to humidify the air with room humidifiers or vaporizers to add water vapor (moisture) to the air. A vaporizer heats water and adds steam/warm mist to the air. A humidifier releases a fine cool mist into the air. Either steam or cool mist may be useful in humidifying the air (MFMER, 2019). Cool-mist humidifiers should be used for children to prevent burns from hot water or steam from a vaporizer (MFMER, 2019). It is very important to keep a humidifier clean to prevent mineral buildup and the growth of bacteria and mold (MFMER, 2019). The water tank should be emptied, and all surfaces dried daily to help keep it clean. The use of distilled or purified water instead of tap water can be helpful in preventing mineral buildup (MFMER, 2019). Humidification may also be provided as part of supplemental oxygen therapy, and artificial airway and mechanical ventilation systems. Refer to the discussion of humidification as part of providing supplemental oxygen later in this chapter on page 1613.

Promoting Proper Breathing

Many people, both well and ill, have breathing habits that are not conducive to maximal respiratory functioning. Some

people develop a pattern of shallow breathing or walk with a posture that makes the chest wall appear caved in, affecting chest expansion. Ill people may limit their respiratory efforts to compensate for disease symptoms or an illness. Breathing exercises are designed to help patients achieve more efficient and controlled ventilations, decrease the work of breathing, and correct respiratory deficits.

DEEP BREATHING

When hypoventilation occurs, a decreased amount of air enters and leaves the lungs. However, deep-breathing exercises can be used to overcome hypoventilation. Instruct the patient to make each breath deep enough to move the bottom ribs. Unless the patient has a nasal condition that prohibits or prevents normal breathing, have the patient start slowly taking deep ventilations nasally and then expiring slowly through the mouth. Breathing through the nose warms, filters, and humidifies the air. The patient's respiratory status, health problems and clinical status dictate the timing of this exercise; for example, postoperative patients are encouraged to take deep breaths at least every 2 hours to help expel residual anesthetic agents, mobilize secretions, and prevent atelectasis (Hinkle et al., 2022).

USING INCENTIVE SPIROMETRY

Incentive spirometry provides visual reinforcement for deep breathing by the patient (Hess et al., 2021). An incentive spirometer assists the patient to breathe slowly and deeply and to sustain maximal inspiration (Eltorai et al., 2019). Most incentive spirometers direct the patient's inspiratory flow through a tube to lift one or more light balls or disks (Hess et al., 2021). The higher the patient's inspiratory flow, the higher the ball is raised or the greater the number of balls that are raised (Hess et al., 2021). The longer the inspiratory flow is maintained, the larger the volume is and, as a result, the patient is encouraged to take slow, deep breaths (Hess et al., 2021). Visualization of the action of the balls allows the patient to measure one's own progress, providing immediate positive reinforcement. Use of an incentive spirometer encourages the patient to maximize lung inflation and prevent or reduce respiratory complications (Kotta & Ali, 2021). Optimal gas exchange is supported, and secretions can be cleared and expectorated. However, evidence is conflicting in regard to the actual effectiveness of routine use of incentive spirometry, including routine postoperative use; deep breathing without mechanical aids may be as beneficial (Adams, 2018; Eltorai et al., 2018; Hess et al., 2021; Moore et al., 2018). It is important to note that incentive spirometers are not recommended for routine use in postoperative care (Adams, 2018; Eltorai et al., 2018), but may be of more benefit in higher-risk patient populations (Kotta & Ali, 2021).

If the use of incentive spirometry is prescribed for a patient, before use, the patient needs instructions on using the equipment properly. Validate the patient's correct use of this equipment in both health care and community-care environments. See Guidelines for Nursing Care 40-1 for information regarding teaching patients to use this device.

PURSED-LIP BREATHING

Patients who experience dyspnea and feelings of panic can often reduce these symptoms by using pursed-lip breathing. Exhaling through pursed lips creates a smaller opening for air movement, effectively slowing and prolonging expiration. Prolonged expiration is thought to result in decreased airway narrowing during expiration and prevent the collapse of small airways (Lestari et al., 2019). This results in improved air/gas exchange and decreased dyspnea (Hess et al., 2021). Pursed-lip breathing also helps the patient to control the rate and depth of respiration, helping to reduce feelings of dyspnea. It also encourages relaxation, which aids the patient to gain control of dyspnea and reduce feelings of panic. Encourage patients with COPD to try this breathing technique to help manage their daily activities (Hinkle et al., 2022; Mayer et al., 2018; Mendes et al., 2019). Pursed-lip breathing is suggested to increase oxygenation and manage dyspnea in children with ineffective breathing patterns (Lestari et al., 2019).

Instruct the patient to sit upright and inhale through the nose with the mouth closed while counting to two. Then, the patient should pucker or purse their lips, as if they were going to whistle or use a straw, and exhale slowly, gently and evenly against pursed lips while counting to four. The patient should avoid forcing the air out on exhalation; encourage the patient to breathe slowly, easily, and relaxed, breathing out for longer than they breathe in (American Lung Association, 2020a; Cleveland Clinic, 2018a).

Guidelines for Nursing Care 40-1

Teaching Patients to Use an Incentive Spirometer

- Perform hand hygiene and put on PPE, if indicated.

- Identify the patient.
- Establish the volume goal for incentive spirometry.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

- Assist the patient to an upright or semi-Fowler position if possible.
- Remove dentures if they fit poorly.
- Assess for pain. Administer pain medication, as prescribed, if needed. **If the patient has recently undergone abdominal or chest surgery, place a pillow or folded blanket over the chest or abdominal incision for splinting.**
- Place the spirometer on a flat surface, like the overbed table, or have the patient hold it in an upright position. Demonstrate how to steady the device with one hand and hold the mouthpiece with the other hand.
- Instruct the patient to exhale normally and then place lips securely around the mouthpiece.
- Instruct the patient not to breathe through their nose. Use a nose clip if necessary. **Instruct the patient to inhale as slowly and as deeply as possible through the mouthpiece without using the nose.** Note the movement of the inhalation indicator on the spirometer.
- When the patient cannot inhale anymore, **the patient should hold their breath for 3 to 5 seconds** (Hess et al., 2021). Check the position of the gauge to determine the progress and level attained.
- Instruct the patient to remove their lips from the mouthpiece and exhale normally. **If the patient becomes lightheaded during the process, tell them to stop and take a few normal breaths before resuming incentive spirometry.**
- Encourage the patient to complete breathing exercises about 5 to 10 times every 1 to 2 hours, if possible. Rest in between breaths as necessary.

DIAPHRAGMATIC BREATHING

Many people with asthma or COPD experience shortness of breath, and people with COPD may sometimes breathe in a shallow, rapid, and exhausting pattern. Use of diaphragmatic breathing can help to slow down the person's breathing and help them "catch their breath" (American Lung Association, 2020b). Diaphragmatic breathing (belly breathing) helps patients to calm down, better control their breathing, and use less energy to breathe (American Lung Association, 2020b).

To do this, the patient should sit upright in a comfortable chair or lie on their back on a flat surface or in bed, with the knees bent and a pillow under the knees to support their legs (American Lung Association, 2020b; Cleveland Clinic, 2018b). The patient should place one hand on their stomach and the other on the middle of their chest. The patient breathes in slowly through the nose, letting their abdomen protrude out against their hand, as far as it will go (filling like a balloon); the hand on their chest should remain as still as possible (Cleveland Clinic, 2018b). The patient should then breathe out through pursed lips while contracting the abdominal muscles, letting the stomach muscles fall inward and keeping the hand on their chest as still as possible (Cleveland Clinic, 2018b). The patient repeats these steps for 5 to 10 minutes three to four times a day, followed by relaxation. Encourage the patient to practice this breathing pattern several times during the day and increase the amount of time spent doing the exercise, so that eventually it becomes automatic (American Lung Association, 2020b; Cleveland Clinic, 2018b).

Promoting and Controlling Coughing

A cough is a cleansing mechanism of the body. It is a means of helping to keep the airway clear of secretions and other debris. A cough that is dry is termed a nonproductive cough. A cough that produces respiratory secretions is termed a productive cough. The respiratory secretion expelled by coughing or clearing the throat is called **sputum**.

When there are excessive fluids or secretions in an organ or body tissue, the patient is said to be congested. Thus, a person with secretions or fluid in the lungs is said to have congested lungs. If the cough is dry, the patient is said to be congested with a nonproductive cough. If the cough produces sputum, the patient is said to be congested with a productive cough. Thick respiratory secretions are sometimes called phlegm. A patient who is coughing and does not have any congestion or secretions produced is said to be noncongested with a nonproductive cough.

A series of events produce a cough. The cough mechanism (Fig. 40-11) consists of an initial irritation; a deep inspiration; a quick, tight closure of the glottis together with a forceful contraction of the expiratory intercostal muscles; and an upward push of the diaphragm. This causes an explosive movement of air from the lower to the upper respiratory tract. To be effective, a cough should have enough muscle contraction to force air to be expelled and to propel a liquid or a solid on its way out of the respiratory tract. Coughing is most effective when the patient is in an upright position. Coughing can be voluntary or involuntary.

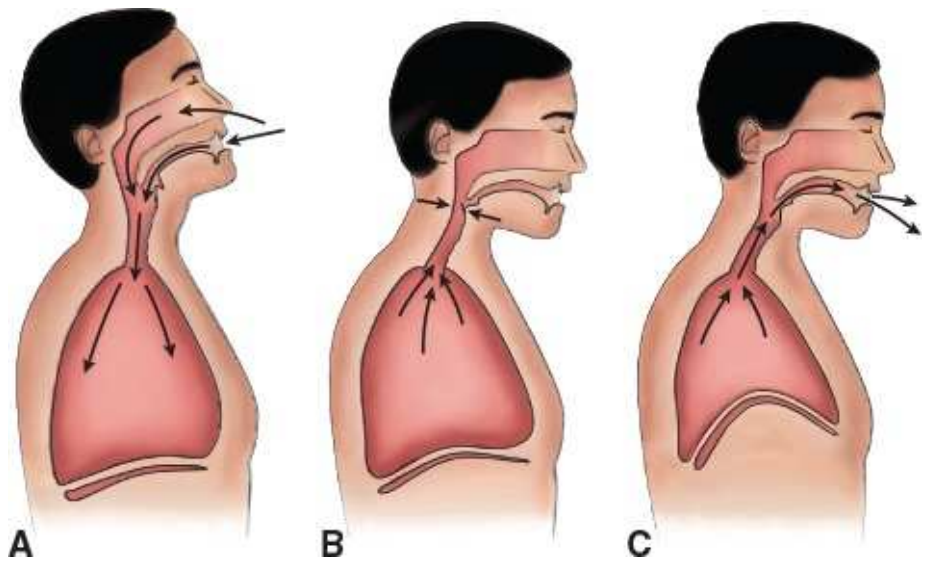

FIGURE 40-11. A. A cough begins with a deep inspiration, distending the trachea and hyperinflating the lungs. **B.** After inspiration, the glottis closes while intercostal and abdominal muscles contract forcibly. **C.** When intrathoracic pressure reaches a high level, the glottis opens slightly, and the diaphragm is pushed up, producing an explosive movement of air.

VOLUNTARY COUGHING

When a cough does not occur as a result of reflex stimulation of the cough-sensitive areas, it can be induced voluntarily. Teaching the patient to cough voluntarily is an important aspect of preoperative and postoperative care. Coughing is more effective when combined with deep breathing. Although teaching a patient to cough and deep breathe is relatively easy, experience has shown that it is difficult to motivate patients to follow through and perform coughing on their own. Refer to Guidelines for Nursing Care 31-2: Effective Coughing in Chapter 31 for detailed instructions for teaching this intervention. Frequently remind patients to perform effective coughing throughout the day. Develop a specific schedule for coughing as part of the patient's plan of care. Coughing early in the morning after rising removes secretions that have accumulated during the night. Coughing before meals improves the taste of food and oxygenation. At bedtime, coughing removes any buildup of secretions and improves sleep patterns.

If the patient has a neuromuscular disorder and is unable to cough physically, an assisted cough may be used. For an assisted cough, the caregiver's hands are placed one on top of each other below the diaphragm and above the naval; firm pressure is applied on the abdomen by pushing upward and under the rib cage, in rhythm with exhalation (Frigerio et al., 2015; University of Michigan Health, 2020). This pressure is similar to the Heimlich maneuver, but with less force. This pressure is used to substitute for the weakened or paralyzed abdominal muscles.

INVOLUNTARY COUGHING

Involuntary coughing often accompanies respiratory tract infections and irritations. Many times, respiratory infections lead to the production of respiratory secretions. These secretions can trigger the cough mechanism. When the cough is productive, it helps clear the airway. However, when the cough is nonproductive, it can be fatiguing and irritating. Medications may control involuntary coughing and are discussed in the next section, Cough Suppressants. Observation of the patient's breathing and coughing characteristics is necessary to determine the appropriate type of interventions.

USING COUGH MEDICATIONS

Various medications can be used to promote coughing, aiding in the movement of mucus through the respiratory tract, and in controlling coughing to allow the patient to rest.

Expectorants

Expectorants are drugs that facilitate the removal of respiratory tract secretions by reducing the viscosity of the secretions. Patients with extremely tenacious (thick) secretions may need the secretions liquefied for their cough to be effective. In that way, for example, the nonproductive cough of a person with respiratory congestion can become productive. Use of an expectorant by a person without congestion is inappropriate. Guaifenesin is widely used as an expectorant in cold and cough medications. Adequate fluid intake and air humidification act as effective expectorants as well.

Cough Suppressants

Suppressants are drugs that depress a body function—in this case, the cough reflex. Codeine, which is present in many cough preparations, is generally considered the preferred cough suppressant ingredient. However, codeine can be addictive, and because of possible abuse, most states require a prescription for its use. Drowsiness is a side effect; thus, it may not be safe to use codeine when the person must remain alert, such as when driving a car. A suppressant that is not addictive is dextromethorphan, which can be found in many over-the-counter cold and cough remedies.

An irritating, nonproductive cough in people without congestion may be treated appropriately with suppressants. Suppression of the productive cough is usually not recommended unless the patient is trying to sleep. If a productive

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

cough is suppressed, secretions can be retained, leading to a pulmonary infection.

Lozenges

Cough lozenges can often relieve mild, nonproductive coughs in people without congestion. A lozenge is a small, solid medication intended to be held in the mouth until it dissolves. Lozenges generally control coughs by the local anesthetic effect of benzocaine. The local anesthetic acts on sensory and motor nerves, controlling the primary irritation and inhibiting afferent and efferent impulses.

Teaching about Cough Medications

Cough medications are readily available, and people who purchase them are usually eager for relief. Often, consumers take excessive amounts of more than one type. Teach about the appropriate choice of expectorants and suppressants and about misuse of cough mixtures. For example, cough syrups with a high sugar or alcohol content can disturb the metabolic balance of patients with diabetes or can trigger a relapse for recovering alcoholics. Preparations containing antihistamines have an anticholinergic action, which can cause serious problems for people with glaucoma or cause urinary retention in men with prostate enlargement. Other cough preparations can be detrimental to people with hypertension or thyroid or cardiac diseases. In addition, prolonged use of self-prescribed cough preparations can conceal more serious health problems. If a cough lasts more than 7 days, urge the person to contact their health care provider. In addition, encourage the person to increase fluid intake if the secretions become too thick to expectorate.

Performing Chest Physiotherapy

Conventional chest physiotherapy (CPT) includes percussion, vibration, and postural drainage and is usually performed by respiratory therapists and physical therapists, or nurses with specialized skills, in acute care environments for select patients (Strickland et al., 2013). CPT may help loosen and mobilize secretions, increasing mucus clearance. This is especially helpful for patients with large amounts of secretions or an ineffective cough. Chest physiotherapy has been shown to have short-term effects in increasing mucus transport and expectoration (Warnock & Gates, 2015). Studies suggest active therapies, such as mobilization, deep breathing and incentive spirometry are more effective than chest physiotherapy (passive treatment) (Beningfield & Jones, 2018). Chest physiotherapy has limited evidence for its effectiveness (Hess et al., 2021) and is not recommended for use in numerous patient populations, including patients with head injury, uncontrolled hypertension, and hypotension; for patients at risk for aspiration, children with pneumonia, adults with COPD, and postoperative adults (Andrews et al., 2013; Hess et al., 2021; Lisy, 2014; Strickland et al., 2013).

SUCTIONING THE AIRWAY

Suctioning of the pharynx is indicated to maintain a patent airway and to remove saliva, pulmonary secretions, blood, vomitus, or foreign material from the pharynx. Suctioning of the oropharynx or nasopharynx may be indicated if the patient is able to raise secretions from the airways but unable to clear from the mouth. Refer to Skill 40-2 on pages 1636–1641. The frequency of suctioning varies with the amount of secretions present but should be done often enough to keep ventilation effective and as effortless as possible. If the patient is unable to raise secretions from the airways, tracheal suctioning may be indicated. Tracheal suctioning is discussed later in the chapter on page 1627.

Suctioning irritates the mucosa and removes oxygen from the respiratory tract, possibly causing **hypoxemia** (insufficient oxygen in the blood). Thus, it is important to preoxygenate the patient before suctioning. This is accomplished by applying or increasing supplemental oxygen and having the patient take several deep breaths before inserting the catheter.

When performed correctly, suctioning provides comfort by relieving respiratory distress. When performed incorrectly, it can increase anxiety and pain and cause respiratory arrest. At minimum, it is an uncomfortable procedure, and it can be a very painful and/or distressing experience. Individualized pain management must be performed in response to the patient's needs (Arroyo-Novoa et al., 2008; Chaseling et al., 2014; Düzkaya & Kuğuoğlu, 2015; Wrona et al., 2021). Anticipate the administration of pharmacologic (analgesic medication) and use of nonpharmacologic interventions for the patient before suctioning. Possible complications of suctioning include infection, cardiac arrhythmias, hypoxia, mucosal trauma, and death.

Wear gloves on both hands, goggles or a face shield, and a mask—and a gown, if necessary—for protection from microorganisms. Depending on the patient's health status, N95 or equivalent mask may be indicated, such as for patients with COVID-19 (Pandian et al., 2020). Continuously monitor the patient's color and heart rate and the color, amount, and consistency of secretions. If cyanosis, an excessively slow or rapid heart rate, or suddenly bloody secretions are noted, stop suctioning immediately, administer oxygen, and notify the health care team. Cyanosis and a change in heart rate can indicate hypoxemia. Blood can indicate damage to the mucosa.

Meeting Oxygenation Needs With Medications

Although treating patients with medications is a dependent nursing intervention, monitoring the patient's response and development of side effects to medications is an independent nursing action. Table 40-3 (on page 1612) lists some

common medications for improving respiratory functioning, their side effects, and nursing implications. Many of the drugs used to dilate bronchial airways interact with caffeine. Encourage patients to avoid caffeine, which may potentiate the side effects of bronchodilators (Karch, 2020).

ADMINISTERING INHALED MEDICATIONS

Inhaled medications may be administered to open narrowed airways (**bronchodilators**), to liquefy or loosen thick secretions (mucolytic agents), or to reduce inflammation in airways (corticosteroids). These medications typically are administered via nebulizer, metered-dose inhaler (MDI), or dry powder inhaler (DPI). Refer to the discussion of administering medications by inhalation in Chapter 30 and to the Guidelines for Nursing Care 30-8 on pages 961–962 for pictures of these devices and additional use and administration details.

Nebulizers utilize the force of high-glow oxygen or compressed air through a fluid medication to disperse fine particles of liquid medication into the deeper passages of the respiratory tract, where absorption occurs. The treatment continues until all the medication in the nebulizer cup has been inhaled.

An MDI is a handheld inhaler that uses an aerosol spray or mist to deliver a controlled dose of medication with each compression of the canister that is then breathed in by the patient. Common mistakes that patients make when using MDIs include the following:

- Failing to shake the canister
- Holding the inhaler upside down
- Inhaling through the nose rather than the mouth
- Inhaling too rapidly
- Stopping the inhalation when the cold propellant is felt in the throat
- Failing to hold their breath after inhalation
- Inhaling two sprays with one breath

To use an MDI, the patient must activate the device while continuing to inhale. The preferred method of use is with a device called a valved holding chamber or spacer (Center for Disease Control, 2018; Quaranta, 2018). The spacer acts as a reservoir. When the MDI is compressed, the medication is deposited in the reservoir, and the patient then inhales the medication from the spacer device. This makes administration less complicated, the dose more predictable, and enhances the delivery of medication to the lungs. For some patients, young children and older adults for example, a spacer or extender device may be necessary to aid delivery of medication by the inhalation route. An MDI can also be used without a chamber. There are a number of different medication inhaler devices, which increases the risk of administration error (Quaranta, 2018). As a result, using the proper technique for the prescribed inhaler is imperative or therapy will not be effective (Price et al., 2017; Quaranta, 2018).

DPIs are another type of delivery method for inhaled medications. A DPI is a handheld inhaler (diskus) that uses a dry powder form of medication, either in a small capsule or disk inserted into the DPI, or in a compartment inside the DPI. DPIs are breath activated and create aerosols by drawing air through a dose of powdered medication (Hess et al., 2021). A quick deep breath by the patient activates the flow of medication, eliminating the need to coordinate activating the inhaler (spraying the medicine) while inhaling the medicine at the same time. DPIs require less manual dexterity than do MDIs. DPIs are actuated by the patient's inspiration, so there is no need to coordinate the delivery of puffs with inhalation. Many types of DPIs are available with distinctive operating instructions. It is important to understand the particular instructions for the medication being used. One disadvantage of DPIs is that the medication in DPIs will clump if exposed to humidity.

Remember **Tyrone**, the 12-year-old boy with suspected asthma. During this acute attack, the nurse would anticipate administering bronchodilators via a nebulizer. The health care provider may order bronchodilators to be administered at home using a nebulizer or possibly an MDI with a spacer, or DPI.

TEACHING PATIENTS ABOUT INHALED MEDICATIONS

Patients need repeated instruction on how to use inhalers and nebulizers effectively and safely. Overuse may result in serious side effects and eventual ineffectiveness of the medication. Nebulizers require cleaning after use; thus, patients

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

must understand how to do this correctly. Patients must understand that it is important to keep track of dosing with MDIs. Many MDIs have integrated dose counters, but some do not, and it can be difficult to know when the canister is empty. Patients must understand the importance of keeping track of dosing to ensure that they are not using an empty canister. Most DPIs have a dose counter, so patients have accurate information about when to refill the medication. Patients should not exhale into the DPI, as they risk blowing out the medication. Information about how to use MDIs, DPIs, and small-volume nebulizers properly, including patient teaching information, is provided in Chapter 30, Guidelines for Nursing Care 30-8 on pages 961–962. Package inserts with the medication also reinforce correct technique for using inhalers.

Table 40-3 Selected Medications Used to Improve Respiratory Function

MEDICATIONS	ACTIVITY	ROUTE	SIDE EFFECTS	NURSING IMPLICATIONS
albuterol	Bronchodilator	PO, inhalation	Tremors, anxiety, insomnia, headache, palpitations, hypertension, vomiting	Caution the patient not to increase dosage without consulting their health care provider. Be aware that children ages 2–years more frequently exhibit CNS stimulation.
Theophylline (aminophylline)	Bronchodilator	PO, IV, rectally (not widely used)	Nausea, vomiting, tachycardia, diuresis, irritability, vertigo, convulsions, nervousness	Monitor vital signs closely. Force fluids as clinical status allows. Monitor serum theophylline levels, especially if the patient does not respond to the drug or if severe side effects develop.
Corticosteroids (prednisone, dexamethasone, budesonide, triamcinolone acetonide)	Reduces inflammation	PO, IV, inhalation, intranasal	Fluid retention, hypertension, mood swings, weight gain, gastritis, hyperglycemia, insomnia	Reduce sodium intake. Make the patient and family/ caregivers aware of potential for labile emotions. Weigh daily in the morning. Monitor blood pressure and blood sugar.
Diphenhydramine	Antihistamine H_1-receptor antagonist	PO	Drowsiness, anorexia, dry mouth, constipation, blurred vision, urinary retention	Warn the patient to use only on the advice of their health care provider in the presence of bronchial asthma.
Cetirizine	Antihistamine H_1-receptor antagonist	PO	Headache with limited sedative effect, not associated with anticholinergic effects	Monitor effectiveness of the drug. Contraindicated while breastfeeding.
Fexofenadine	Antihistamine H_1-receptor antagonist	PO	Drying of respiratory mucous membranes, dysuria, nausea	Contraindicated during pregnancy and while breastfeeding Use with caution in patients with renal or hepatic impairment
Zafirlukast montelukast	Leukotriene receptor antagonist	PO	Headache, dizziness, nausea, pain, fever, infection, elevated liver enzymes	Remind the patient that this medication is used to prevent asthma attacks, not to treat acute episodes. Inform the patient that the drug is effective only continuously as prescribed Remind the patient to avoid over-the-counter products containing aspirin, which might interfere with effectiveness

CNS, central nervous system; PO, orally; IV, intravenously; MDI, metered-dose inhaler.

To ensure correct administration when a spacer is used, slow, deep inspirations are necessary. To prevent inhaling too quickly, some spacers are equipped with a whistle device that sounds if inhalation is too rapid. A spacer is also recommended for patients using inhaled corticosteroid agents because it reduces the risk of acquiring an oral fungal infection (AIM, n.d.; NHS Inform, 2020).

Providing Supplemental Oxygen

Oxygen, which constitutes 21% of normal air, is a tasteless, odorless, and colorless gas. Oxygen is an essential

requirement for cellular respiration and cell function (Rolfe & Paul, 2018a). Oxygen therapy provides a higher concentration of oxygen than ambient air (supplemental oxygen) to increase the pressure difference to aid in the diffusion of gas across the membrane between the alveoli in the lungs and the pulmonary capillaries, with the resulting increased saturation of hemoglobin and delivery of oxygen via the blood to all cells (Hess et al., 2021; Rolfe & Paul, 2018a). Oxygen therapy is indicated when hypoxemia is suspected by history, physical examination or laboratory data and to maintain oxygen saturations within the patient's specified target range (O'Driscoll et al., 2017; Rolfe & Paul, 2018b). Most patients will have a target oxygen saturation of 94% to 98% (O'Driscoll et al., 2017). Patients with chronic obstructive pulmonary disease (COPD) and other risk factors for hypercapnia may have a target oxygen saturation of 88% to 92% (Mirza et al., 2018; Mitchell, 2015; O'Driscoll et al., 2017). Supplemental oxygen is supportive therapy; the cause of the hypoxemia in individual patients should be addressed and corrected (Hess et al., 2021).

Oxygen is considered a medication and must be prescribed by a health care provider. However, in situations where there is a clear clinical indication, such as decreasing oxygen saturations or tachypnea, or an emergency situation, the absence of a prescription should not delay the administration of oxygen to the patient (Higginson et al., 2016; Nippers & Sutton, 2014; O'Driscoll et al., 2017; Rolfe & Paul, 2018b).

Oxygen therapy can be intimidating or frightening for patients. Therefore, provide clear explanations about the procedures and purpose to help reduce anxiety. Encourage patients to discuss concerns. If oxygen is given in an emergency, explanations concurrent with administration are appropriate.

Oxygen supports combustion. To prevent fires and injuries, take the following precautions:

- Check to see that electrical equipment used in the room, such as electric bell cords, razors, radios, and suctioning equipment, is in good working order and emits no sparks.
- Avoid wearing and using synthetic fabrics that build up static electricity.
- Avoid using oils in the area. Oil can ignite spontaneously in the presence of oxygen.
- Avoid contamination of medical devices and medical gas cylinders; contamination with dirt, oil, grease, hand cream, or alcohol hand gel must be avoided. Ensure hands are clean and hand gel has dried completely before handling oxygen equipment (Ford & Robinson, 2021).

Refer to the Teaching Tips 40-1 later in this section for information for patients and families regarding safety measures when oxygen is used in the home.

SOURCES OF OXYGEN

In acute and other clinical care environments, therapeutic oxygen is supplied from a wall outlet or a portable cylinder or tank. A specially designed flow meter is attached to the wall outlet (see Skill 40-3 on pages 1641–1644 for an illustration of a flow meter). A valve regulates the oxygen flow in liters per minute. To release oxygen safely and at the desired rate from a cylinder or tank, a regulator is used. The regulator has two gauges. The one nearest the tank shows the pressure or amount of oxygen in the tank. The other gauge indicates the number of liters per minute of oxygen being released.

Oxygen concentrators are another means to provide supplemental oxygen. This oxygen delivery system concentrates room air to provide the appropriate prescribed concentration of oxygen to the patient. Oxygen concentrators are frequently used in home situations. The concentrator may have a cylinder refill system with a portable oxygen cylinder that can be filled with oxygen for use when the patient leaves the home (McCoy, 2016). Portable oxygen concentrators are available as well, offering the ability to leave home for extended periods of time without the worry of running out of oxygen (Jacobs et al., 2020).

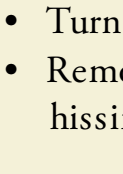
The use of oxygen-conserving devices is another method to deliver oxygen. These systems conserve the oxygen supply, reducing consumption and enabling the use of either smaller and lighter systems or extending the length of time between cylinder refilling (McCoy, 2016; Murphie, 2015). Conservation of oxygen is achieved via various methods, such as integrated reservoirs or by the intermittent flow of oxygen. Further discussion of oxygen-conserving devices is provided in the "Oxygen Therapy in the Home" section on page 1617.

OXYGEN FLOW RATE

The flow rate of oxygen, measured in liters per minute, determines the amount of oxygen delivered to the patient. The rate varies depending on the condition of the patient and the route of administration of the oxygen. The flow rate does not necessarily reflect the oxygen concentration actually inspired by the patient because there is leaking and mixing with atmospheric air. If more precise doses are necessary, they are usually prescribed in terms of percentage of inspired oxygen. To regulate the oxygen percentage concentration accurately, samples of the air mixture the patient is actually inhaling may be analyzed every 4 hours. Several types of commercial oxygen analyzers are available.

HUMIDIFICATION

Supplemental oxygen dries and dehydrates the respiratory mucous membranes, and patients may experience related discomfort, including feelings of dryness and soreness (Hess et al., 2021; Rolfe & Paul, 2018b). Use of humidification



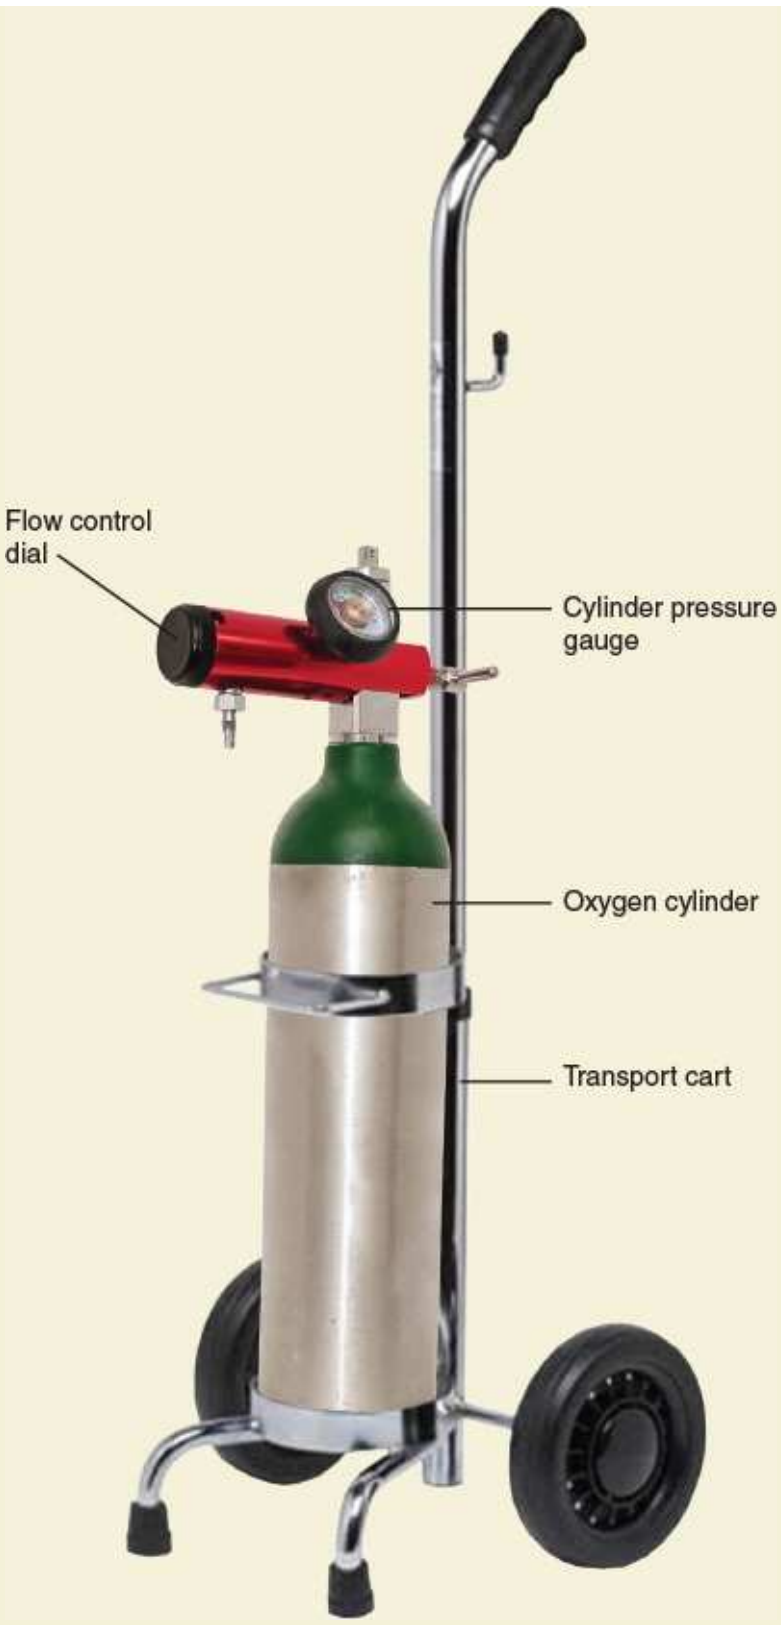
for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

is not necessary with very–low-flow oxygen (4 L/min or less), when delivered by nasal cannula (see oxygen delivery systems to follow) to adults, or when anticipated as a therapy for less than 24 hours (O'Driscoll et al., 2017). However, humidifying devices is recommended for patients who experience any discomfort associated with dry upper respiratory tract mucosa and when oxygen is delivered at higher flow rates (greater than 35%) (O'Driscoll et al., 2017). Humidification should also be provided with oxygen therapy for patients with a tracheostomy or artificial airway and patients experiencing difficulty expectorating sputum (O'Driscoll et al., 2017). Distilled or sterile water is commonly used in various humidification systems to add molecular water to gas (humidify oxygen) (Ford & Robinson, 2021). When moving patients receiving humidified oxygen, make sure that water from the humidifier does not enter the tubing through which the oxygen is flowing. Additional suggestions for transporting a patient with a portable oxygen tank are given in Guidelines for Nursing Care 40-2.

Guidelines for Nursing Care 40-2

Transporting a Patient With a Portable Oxygen Cylinder

Before the Transfer



- Perform hand hygiene and put on PPE, if indicated.

- Identify the patient.
- Check that an additional oxygen source is available where the patient is being transferred.
- Check the amount of oxygen in the cylinder (place the cylinder key or wrench on the valve stem and turn fully counterclockwise until the needle on the gauge indicates the amount of available oxygen; turn the key back a half turn; use the cylinder only if the gauge indicates more than 500 psi).
- If available, use a table that gives the estimated minutes of available oxygen according to the amount of oxygen in the cylinder and the rate of flow ordered for the patient. This can help to determine whether the supply of oxygen is adequate for the transfer (Gardner, 2015).
- Connect the oxygen tubing to the flow meter adapter and adjust the flow-control dial to the prescribed setting.
- Attach the patient's oxygen cannula to transport oxygen.
- Ensure that the cylinder is secured in a holder before transporting the patient (it is a dangerous practice to place the cylinder between the patient's legs or next to the patient during transfer because injury to the patient may result).
- Place the coiled tubing under a pillow or attach it to the linen or the patient's gown.

After the Transfer

- Attach the patient's oxygen cannula to wall oxygen.
- Turn off the oxygen flow from the cylinder by turning the cylinder key clockwise until it is tight.
- Remove any excess oxygen in the pressure gauge by "bleeding" it. Turn the flow-control dial back on until the hissing sound stops and the needle on the gauge has fallen to zero. Turn the flow-control dial off.

SUPPLEMENTAL OXYGEN DELIVERY SYSTEMS

Oxygen can be administered by many different delivery systems.

Low-flow/variable performance systems are based on the patient's own inspiratory flow (how deeply and fast the patient is breathing) and the oxygen inhaled is composed of some of the supplemental oxygen mixed with inhalation of some air present in the room, reducing the accuracy of the concentration of oxygen that the patient is actually receiving (Hess et al., 2021; Rolfe & Paul, 2018b). Low-flow devices provide variable performance because the inspired oxygen concentration cannot be accurately known (Hess et al., 2021). Examples of low-flow devices include low-flow nasal cannula/prongs, simple mask, partial rebreather mask, nonrebreather mask, and transtracheal oxygen catheter (discussion of transtracheal catheters is provided in the Oxygen Therapy in the Home section on page 1617).

Table 40-4 Oxygen Delivery Systems

METHOD	AMOUNT DELIVERED FiO_2 (FRACTION INSPIRED OXYGEN)	PRIORITY NURSING INTERVENTIONS
Nasal cannula	*Low flow* 1–2 L/min = 24–28% 3–5 L/min = 32–40% 6 L/min = 44%	Check frequently that both prongs are in the patient's nares. For patients with chronic lung disease, limit rate to the minimum needed to raise arterial oxygen saturation to maintain a level of 88–92% (Mitchell, 2015).
Nasal cannula	*High flow*	Closely monitor the patient's respiratory status

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

	Maximum flow 60 L/min 10 L/min = 65% 15 L/min = 90%	for changes indicating impending respiratory failure. Pharyngeal pressure is affected by mouth-opening or closing, delivered flow, and size of nasal prongs. High-flow nasal cannula oxygen delivery is often better tolerated by children than other noninvasive delivery methods
Simple mask	*Low flow* 5–8 L/min = 40–60% (5 L/min is minimum setting)	Monitor the patient frequently to check placement of the mask. Support the patient if claustrophobia is a concern. Secure a prescribed intervention to replace the mask with a nasal cannula during mealtime.
Nonrebreather mask	*Low flow* 10–15 L/min = 80–95%	Maintain flow rate so that the reservoir bag collapses only slightly during inspiration. Check that the valves and rubber flaps are functioning properly (open during expiration and closed during inhalation). Monitor SaO_2 with pulse oximeter.
Venturi mask	*High flow* 4–6 L/min = 24–40%	Requires careful monitoring to verify FiO_2 at flow rate ordered. Check that air intake valves are not blocked.

Wolters Kluwer; and additional information adapted from Nishimura, M. (2016). High-flow nasal cannula oxygen therapy in adults: Physiological benefits, indication, clinical benefits and adverse effects. *Respiratory Care*, *61*(4), 529–541. https://doi.org/10.4187/respcare.04577

High-flow/fixed performance devices produce oxygen flow outputs with a constant mix of air and oxygen as a result of the design of the device (inclusion of a venturi barrel to control the oxygen concentration), rather than the rate and depth of the patient's breathing (Venturi masks) (Rolfe & Paul, 2018b). These devices produce oxygen flow outputs that meet or exceed the patient's full inspiratory flow demand; the flow is such that the patient is not likely to inhale any room air (Hess et al., 2021). Venturi masks are more likely to maintain a fixed concentration of oxygen (fixed-performance) and deliver a more precise amount of oxygen (Hess et al., 2021; Rolfe & Paul, 2018). A high-flow nasal cannula is relatively new supplemental oxygen therapy with an increasing role in patient care (Hess et al., 2021; Messika, 2019; Rolfe & Paul, 2018b; Scott, 2020).

Oxygen enclosures (tents, incubators) have been used historically to deliver supplemental oxygen and provide an oxygen enriched environment (Hess et al., 2021). Current use of oxygen enclosures occurs primarily in infant and pediatric applications, including use of oxygen hoods, incubators, and croup tents; oxygen and aerosol tents, even for children, are, for the most part, not used (Hess et al., 2021, p. 308). An infant oxygen hood is a rigid plastic dome or box with a half-moon cutout that is place over an infant's neck to enclose the entire head (Hess et al., 2021; Medline Plus, 2018). Heated and humidified oxygen is delivered to the hood. While some facilities continue to use infant oxygen hoods, infant nasal cannulas are favored (Hess et al., 2021, p. 308).

Table 40-4 compares several oxygen delivery systems.

Nasal Cannula

A *low-flow nasal cannula*, also called nasal prongs, is a low-flow/variable-performance device and the most commonly used oxygen delivery device for administering low-flow oxygen to infants, children, and adults in the hospital and community settings (Hess et al., 2021). Low-flow nasal cannula can be set to deliver oxygen flows of 1 to 6 L/min in usual circumstances and to deliver an increased flow of 10 to 15 L/min for short-term use (Hess et al., 2021). The cannula is a disposable plastic delivery tubing with two protruding prongs that are inserted into the nostrils; prongs are available in a variety of styles, including curved or straight and tapered or nontapered. The prongs are held in place with an elastic band around the patient's head or by loops of the delivery tubing over the patient's ears, held in place by an adjustable slide placed under the chin (Hess et al., 2021). The delivery tubing is connected to an oxygen source with a flow meter and, many times, a humidifier (refer to the discussion of humidification in the previous section on p. 1613). The cannula does not impede eating or speaking and is used easily in the home. Oxygen may be administered using nasal cannula by a low-flow or high-flow system (refer to the separate discussions of high-

flow nasal cannula oxygen therapy). Disadvantages of using a nasal cannula include that it can be dislodged easily, and low-flow rates can cause dryness of the nasal mucosa. There is no evidence that mouth breathing influences the efficiency of oxygen delivery; even when the patient inspires through the mouth oxygen still flows through the nose into the pharynx (O'Driscoll et al., 2017; Hess et al., 2021). Refer as well to Table 40-4 on page 1615. Skill 40-3 (on pp. 1641–1644) describes oxygen administration by nasal cannula.

High-flow nasal cannula (HFNC) is an oxygen therapy that involves the continuous delivery of an air/oxygen mixture through a heater/humidifier to a wide-bore nasal cannula. HFNC delivers oxygen flow greater than 30 L/min up to 60 L/min and up to 100% humidified oxygen (Hernández et al., 2017; Lu et al., 2020; Zemach et al., 2019). The mechanisms of this therapy maintain a small amount of continuous positive pressure during the entire cycle of breath, resulting in a higher level of oxygen delivery, improved breathing and oxygen saturation, reduced dyspnea, and reexpansion of collapsed alveoli (Hernández et al., 2017; Hess et al., 2021; Lu et al., 2020; Zemach et al., 2019). High-flow nasal cannula oxygen therapy reduces patient discomfort and upper airway dryness, improves extubation outcomes and weaning, reduces the risk of intubation, and improves the management of respiratory secretions (Hernández et al., 2017; Liu et al., 2019). It has been used for patients in intensive care units and critical care areas with mild to moderate acute respiratory failure to try to avoid invasive mechanical ventilation and associated risks (Hess et al., 2021; Messika, 2019; Rolfe & Paul, 2018b; Scott, 2020). This therapy is increasingly being investigated for use in other clinical situations as well, such as for the prevention and treatment of respiratory failure, in adult surgical and nonsurgical patients, in patients with COVID-19; and in infants and children with bronchiolitis (Lu et al., 2020; Moreel & Proesmans, 2020; Pruitt, 2020; Scott, 2020; Wang et al., 2020). Close monitoring of the patient's status is critical to avoid the delay of timely airway intervention and intubation in patients who are not doing well on HFNC (Zemach et al., 2019).

Implement medical device–related pressure injury prevention strategies, including appropriate selection, fitting, and securing of the mask; pressure redistribution by frequent repositioning or rotation; and use of a prophylactic cushioning/proactive dressing between the skin and mask (Pittman & Gillespie, 2020). The nasal cannula may cause pressure injuries behind the ears, around the nostril, or in the nasal vestibule; use soft nasal cannulas whenever possible and protect the back of the ears with a hydrocolloid or foam dressing (Camacho-Del Rio, 2018).

Face Masks

Disposable and reusable face masks are available. Fit the mask carefully to the patient's face to avoid leakage of oxygen. It should be comfortably snug but not tight against the face. The most commonly used types of masks are the simple face mask, the partial rebreather mask, the nonrebreather mask, and the Venturi mask. Implement medical device–related pressure injury prevention strategies, including appropriate selection, fitting, and securing of the mask; pressure redistribution by frequent repositioning or rotation; and use of a prophylactic cushioning/proactive dressing between the skin and mask (Pittman & Gillespie, 2020). Masks for oxygen delivery may cause injuries to the cheeks, chin, or bridge of the nose; place silicone border or hydrocolloid dressings over bony prominences or other areas that come in contact with the device and between the device and the skin (Camacho-Del Rio, 2018). Skill 40-4 (on pp. 1644–1648) describes the actions and rationales involved in using face masks.

The *simple face mask* (nonreservoir mask) is a low-flow/variable-performance device and is used when a higher oxygen level is needed than can be attained with a nasal cannula or when a cannula is not appropriate, such as with nasal obstruction (Hess et al., 2021). The simple face mask is connected to oxygen tubing, a humidifier, and a flow meter, just like the nasal cannula, and is used using a flow rate of 5 to 10 L/min (Rolfe & Paul, 2018b). This mask has vents on its sides that allow room air to leak in at many places, thereby diluting the source oxygen. The vents also allow exhaled carbon dioxide to escape. Often a simple mask is used when an increased delivery of oxygen is needed for short periods (e.g., less than 12 hours). The mask should fit closely to the face to deliver this higher concentration of oxygen effectively. Patients may have difficulty keeping the mask in position over the nose and mouth, and because of this pressure and the presence of moisture, skin breakdown is a possibility. Eating or talking with the mask in place can be difficult. Because of the risk of retaining carbon dioxide, never apply the simple face mask with a delivery flow rate of less than 5 L/min (Hess et al., 2021; O'Driscoll et al., 2017). Refer as well to Table 40-4 on page 1615.

The *partial rebreather mask* is a low-flow/variable-performance device and is similar to a simple face mask but is equipped with a reservoir bag for the collection of the first part of the patient's exhaled air. The remaining exhaled air exits through vents. The air in the reservoir is mixed with 100% oxygen and some room air inhaled through the mask ports for the next inhalation. Thus, the patient rebreathes about one third of the expired air from the reservoir bag. This type of mask is used to administer relatively high oxygen concentrations. The oxygen flow rate must be set high when using this type of mask, at 10 to 15 L/min. Monitor the reservoir bag carefully. It should deflate slightly with inspiration; if it deflates completely, the flow rate should be increased until only a slight deflation is noted. An advantage is that the patient can inhale room air through openings in the mask if the oxygen supply is briefly interrupted. The disadvantages are those of any mask: eating and talking are difficult, a tight seal is required, and there is the potential for skin breakdown. Note: partial rebreathing masks are not commonly used in present-day practice (Hess et al., 2021, p. 300).

The *nonrebreather mask,* a low-flow/variable-performance device, delivers the highest concentration of oxygen via

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

a low-flow mask. It is similar to the partial rebreather mask but incorporates valves between the bag and the mask and on at least one of the exhalation side ports on the mask. Supplemental oxygen is directed via tubing into the mask and into the reservoir bag. A one-way valve prevents exhaled gas from entering the reservoir and the entire exhaled volume exits the mask through the mask ports and between the patient's face and mask, preventing the patient from rebreathing exhaled air (Hess et al., 2021). During exhalation, the reservoir bag refills with oxygen. At the beginning of inspiration, the mask exhalation port valves close, minimizing room air from being drawn in, and the reservoir valve opens, allowing the patient to inhale oxygen from the reservoir in addition to the oxygen flow. The oxygen flow rate must be set high when using this type of mask, not below 10 L/min. Monitor the reservoir bag carefully. It should not deflate with inspiration (Rolfe & Paul, 2018b). A malfunction of the bag or oxygen flow could cause carbon dioxide buildup and suffocation. As a result, manufacturers provide either an antisuffocation valve at the neck of the reservoir bag that opens when the oxygen supply fails or provide only one valve on the mask ports on the side of the mask (Hess et al., 2021). The disadvantages are those of any mask: eating and talking are difficult, a tight seal is required, and there is the potential for skin breakdown. Refer as well to Table 40-4 on page 1615.

The *Venturi mask*, a high-flow/fixed performance device, gets its name from the Venturi effect, which allows the mask to deliver the most precise concentrations of oxygen. This mask has a large tube with an oxygen inlet, a Venturi barrel, to control the oxygen concentration. As oxygen passes through the narrow opening in the barrel, the pressure drops, causing a high velocity stream that draws a constant proportion of room air to be pulled in through the base of the mask (Rolfe & Paul, 2018b). The Venturi barrel on the mask can be changed to deliver a different percentage of oxygen; changing the flow rate of the oxygen alone will not change the percentage of oxygen the patient receives (Rolfe & Paul, 2018b). The barrel is changed according to the prescription for oxygen concentration. Be sure that the ports on the barrel are always open. If these are occluded by linens, clothing, or a patient rolling on the mask, the oxygen delivered might be at an unsafe (too high or too low) concentration. The disadvantages are those of any mask: eating and talking are difficult, a tight seal is required, and there is the potential for skin breakdown. Refer as well to Table 40-4 on page 1615.

MONITORING OF PATIENTS RECEIVING SUPPLEMENTAL OXYGEN THERAPY

The patient's past and current health history are considered when initiating supplemental oxygen therapy (Rolfe & Paul, 2018b). The prescribed intervention should identify the method and rate for supplemental oxygen administration, and the appropriate target saturation range (Rolfe & Paul, 2018b). Initiation and continued administration of oxygen therapy should be based on the patient's target oxygen saturation range and clinical status (Lellouche & L'Her, 2020; O'Driscoll et al., 2017; Rolfe & Paul, 2018b).

Careful observation, monitoring and assessment are necessary when administering oxygen therapy: monitor the flow rate to verify oxygen deliver as prescribed, patient color (signs of cyanosis), respiratory rate (e.g., tachypnea), respiratory depth, increase work of breathing (use of accessory muscles), pulse oximetry measurements, and ABG results closely for changes (Hess et al., 2021; Rolfe & Paul, 2018b). Refer to the discussion of assessment related to oxygenation and perfusion earlier in this chapter as well as assessment information discussed in Chapter 27. Continuous pulse oximetry may also be used to monitor the patient receiving oxygen. Titrate the oxygen flow according to the device and patient requirement. Oxygen therapy should be provide using minimal oxygen to maintain adequate SpO_2 in the patient's target range to avoid complications (Hess et al., 2021; Joint Formulary Committee, 2020, as cited in Ford & Robinson, 2021). Change the oxygen delivery system/device as prescribed or indicated, based on the patient's health status and assessment findings and facility/agency policy.

Assess and monitor the patient's comfort with the delivery device; device comfort can have a direct impact on the patient's acceptance of oxygen therapy (Rolfe & Paul, 2018b). Assess and monitor the oral and nasal mucous membranes, the lips and nose, and face and ears (refer to Chapter 32). Pressure- and moisture-related injuries are possible (Rolfe & Paul, 2018b) (refer to Chapter 33). Monitor fluid status and maintain hydration through adequate fluid intake (refer to Chapters 37 and 41). Provide routine oral hygiene (refer to Chapter 32).

OXYGEN THERAPY IN THE HOME

Liquid oxygen and oxygen concentrators, rather than compressed gas cylinders, are used more commonly in the home setting. Liquid oxygen is kept inside a small container that can be refilled from a larger storage tank kept in the home. An oxygen concentrator removes nitrogen from the room air and concentrates the oxygen left in the air. The oxygen concentrator needs a power source such as an electrical outlet, battery pack, or car charger, but never runs out and does not need to be refilled. Oxygen concentrators are portable, cost-effective, and easy to use (Hanlon, 2014). Refer to the previous discussion related to oxygen concentrators in the "Sources of Oxygen" section of this chapter on page 1613.

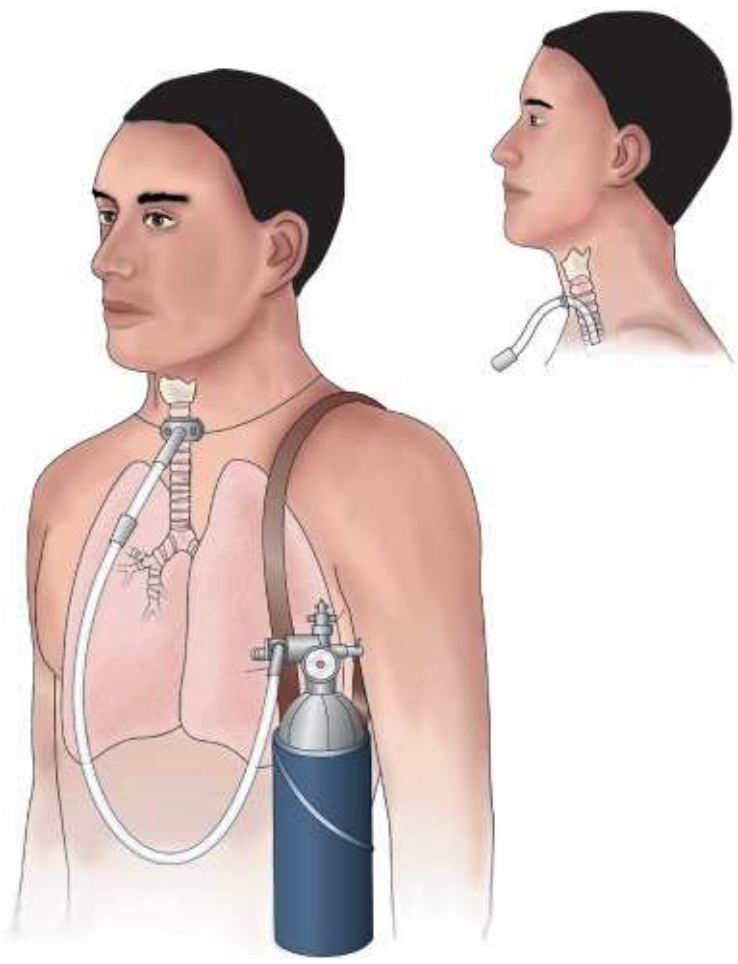


FIGURE 40-12. Transtracheal oxygen.

Patients with chronic hypoxemia may be treated with transtracheal oxygen delivery (Fig. 40-12). With this type of delivery system, a small catheter is inserted into the trachea under local anesthesia and then the catheter is attached to an oxygen source. A transtracheal catheter does not interfere with talking, eating, or drinking and delivers oxygen throughout the respiratory cycle rather than just at inspiration and is associated with reduced amount of oxygen flow needed at rest and exercise, reduced symptoms of shortness of breath, improved patient mobility, and increased patient adherence with therapy (Hess et al., 2021; University of California San Diego Health, 2021). The patient or family/caregiver must assume responsibility for daily catheter care (Goodman, 2014). Patients usually report improved mobility, comfort, and appearance, and lower cost with this delivery system.

Oxygen-conserving devices (OCDs) are also available for use in community-based settings. Reservoir cannulas are one type of OCD and have a reservoir space that stores oxygen during exhalation. On subsequent inhalation, the patient receives that stored oxygen, essentially adding a bolus volume to the continuous-flow oxygen delivery (Hess et al., 2021). The patient receives the same oxygen therapy at a lower continuous-oxygen flow rate, conserving oxygen use. Intermittent-flow devices operate by turning oxygen delivery on during some portion of inhalation and off for the balance of the breathing cycle (Hess et al., 2021; Jacobs et al., 2020). Patient-exhaled oxygen is conserved, allowing a supply of oxygen to last two to four times as long as if it was delivered continuously (Hess et al., 2021). If an oxygen-conserving device is used, the patient should be tested using the device during exertion, similar to what they would do in daily life, to ensure adequate oxygenation (Jacobes et al., 2020, p. e134). Use of intermittent flow delivery has resulted in much less use of continuous-flow oxygen in community-based settings (Hess et al., 2021).

Patients and families using oxygen at home need education about long-term oxygen use and associated equipment to improve patient adherence and implementation of safety precautions (Henrichs & Makic, 2021). See Teaching Tips 40-1 for information regarding the use of oxygen in the home setting.

Teaching Tips 40-1

USING OXYGEN AT HOME

Health Topic	Teaching Tip	Why Is This Important?
Safety	• Do not smoke in a home where oxygen is in use. Place “No Smoking” signs in conspicuous places in the patient’s home. Instruct the patient and family/caregivers about the hazard of smoking when oxygen is in use. • Keep oils, grease, alcohol, and other liquids that can burn away from oxygen. • Keep oxygen at least 6 ft away from any source of fire, such as a stove, fireplace, or	Oxygen supports combustion; a spark may ignite the oxygen.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

	candle (MedlinePlus, 2020). • Keep oxygen 6 ft away from toys with electric motors, electric baseboard or space heaters, hairdryers, electric razors, and electric toothbrushes (MedlinePlus, 2020). • Do not use electrical equipment near oxygen administration set (e.g., electric blanket—see also above). • Use caution with gas or electric appliances. • Ground oxygen concentrators. • Secure the oxygen tank in a holder and away from direct sunlight or heat. • Allow adequate airflow around the oxygen concentrator (avoid placing flush against the wall). • Notify local fire department of the use of oxygen in the home. • Have working smoke detectors and a working fire extinguisher in the home (MedlinePlus, 2020).	
Administration	• Follow the prescription for the oxygen flow rate. • Ensure enough available oxygen prior to leaving the house for errands or trips. • Tubing length of up to 98.42 ft (30 m) may be used by patients with flow rates up to 5 L/min for home oxygen delivery to provide freedom of movement within the home. • Know signs and symptoms that indicate the need to call for emergency assistance. • Have the health care provider's and nurse's phone number readily available. • Know how to reach the oxygen equipment vendor and the reasons for contacting the vendor.	• Too much or too little oxygen may be detrimental to the patient. • Tubing length of up to 98.42 ft (30 m) may be used by patients with flow rates up to 5 L/min for home oxygen delivery with no important changes in flow or fraction of inspired oxygen (Aguiar et al., 2015). • This enables the patient and family/caregivers to obtain assistance when necessary.

PICOT in Practice

ASKING CLINICAL QUESTIONS: CONTINUOUS POSITIVE AIRWAY PRESSURE

Scenario: You are a staff nurse in the neonatal intensive care unit working with preterm infants. Those that are born less than 32 weeks' gestation lack surfactant, a detergentlike substance produced by the lung. You notice that early initiation with continuous positive airway pressure (CPAP) decreases mortality in preterm infants. You would like to develop a protocol that highlights signs and symptoms of preterm infants that should have CPAP initiated early or prophylactically.

- **Population:** Preterm infants in the neonatal intensive care unit
- **Intervention:** Early or prophylactically initiation of continuous positive airway pressure
- **Comparison:** Continuous positive airway pressure (or compared to O_2 therapy)
- **Outcome:** Decreased mortality
- **Time:** Duration of hospitalization

PICOT Question: Does initiation of early or prophylactic continuous positive airway pressure (CPAP) compared to continuous CPAP decrease mortality in preterm infants during hospitalization?

Findings:

Level of Evidence: Level I: systematic review

Three pertinent resources were located.

1. Ho, J. J., Subramaniam, P., Davis, P. G. (2020). Continuous positive airway pressure (CPAP) for respiratory distress in preterm infants. *Cochrane Database of Systematic Reviews*, *10(*10*)*, CD002271. https://doi.org/10.1002/14651858.CD002271.pub3

In 5 studies involving 322 infants; 2 studies used face mask CPAP, 2 studies used nasal CPAP, and 1 study used endotracheal CPAP and continuing negative pressure for a small number of less ill infants. In preterm infants with respiratory distress, the application of CPAP is associated with reduced respiratory failure, use of mechanical ventilation, and mortality and an increased rate of pneumothorax compared to spontaneous breathing with supplemental oxygen as necessary.

2. Ho, J. J., Subramaniam, P., Sivakaanthan, A., Davis, P. G. (2020). Early versus delayed continuous positive airway pressure (CPAP) for respiratory distress in preterm infants. *Cochrane Database of Systematic Reviews*, *10*(10), CD002975. https://doi.org/10.1002/14651858.CD002975.pub2

In 4 studies that recruited a total of 119 infants, all 4 small trials included in this review were performed in the 1970s or the early 1980s and were very uncertain whether early application of CPAP confers clinical benefit in the treatment of respiratory distress, or whether it is associated with any adverse effects. The applicability of these findings to the current practice of neonatal intensive care was uncertain, given that all trials in this Cochrane Review were conducted in the presurfactant era, when antenatal steroid usage was uncommon.

3. Subramaniam, P., Ho, J. J., Davis, P. G. (2016). Prophylactic nasal continuous positive airway pressure for preventing morbidity and mortality in very preterm infants. *Cochrane Database of Systematic Reviews*, (6), CD001243. https://doi.org/10.1002/14651858.CD001243.pub3

Seven trials recruiting 3,123 infants were included in the metaanalysis. Four trials recruiting 765 infants compared CPAP with supportive care and 3 trials (2,364 infants) compared CPAP with mechanical ventilation. In trials comparing CPAP with assisted ventilation with or without surfactant, CPAP resulted in a small but clinically significant reduction in the incidence of bronchopulmonary dysplasia (BPD) at 36 weeks. When compared to mechanical ventilation, prophylactic nasal CPAP in very preterm infants reduces the need for mechanical ventilation and surfactant and also reduces the incidence of BPD and death.

Recommendations: Prophylactic continuous positive airway pressure (CPAP) in very preterm infants reduces the need for mechanical ventilation and surfactant and also reduces the incidence of bronchopulmonary dysplasia (BPD) and death. Furthermore, early application of CPAP does not appear to be associated with any adverse effects. This information is provided to others in the unit through an educational in-service that highlights signs and symptoms of preterm infants that should have CPAP initiated early or prophylactically.

Positive Airway Pressure

Noninvasive positive airway pressure (PAP) therapy uses mild air pressure to keep airways open delivered via a mask. This treatment can help the body to maintain better carbon dioxide and oxygen levels in the blood. PAP therapy may be used to treat many adult disorders, such as sleep apnea, obstructive sleep apnea, obesity hypoventilation syndrome, acute cardiogenic pulmonary edema, heart failure, COPD, and acute hypoxemic respiratory failure (Hess et al., 2021; Martin, 2020; Medline Plus, 2021). It also may be used to treat disorders in infants and children, such as respiratory distress syndrome in preterm infants (Stanford Children's Health, 2021), bronchiolitis in infants (Franklin et al., 2019), and obstructive sleep apnea in children (Al-lede et al., 2018). See the accompanying PICOT in Practice box.

Continuous positive airway pressure (CPAP) provides continuous mild air pressure to keep airways open. *Bilevel positive airway pressure (BiPAP)* changes the air pressure while the patient breathes in and out. *Autotitrating (adjustable) positive airway pressure (APAP)* changes pressure throughout the therapy, based on the patient's breathing patterns (Medline Plus, 2021). All therapies use a mask or other device that fits over the nose or nose and mouth. Straps keep the mask in place. A tube connects the mask to the machine, which blows air into the tube.

Adjusting to the therapy and machine can take time. Patients report feeling strange wearing a mask on the face at night or feeling the flow of air. Some people feel confined by the mask. Nurses can assist patients by reinforcing accurate information about treatment; encourage patients to ease into use of the device. It may help for patients to start by practicing wearing just the mask for short periods of time while awake, for example, while watching TV. Then patients should try wearing the mask and hose with the air pressure on, still during the daytime, while awake. Once patients become accustomed to how the equipment feels, they should shift to using the device every time they sleep—at night and during naps. Inconsistently wearing the device may delay getting used to it.

Provide support and encouragement so that the patient persists with the therapy; it may take several weeks or more to see if the mask and pressure settings will work for the patient. If the device is used in the hospital or other facility or in the community, nursing responsibilities also may include monitoring the settings, ensuring correct use by the patient, and assessment of respiratory status. Careful assessment of the patient's skin on the face, in the areas the mask sits, is an important part of care. Pressure and moisture from the mask can cause alterations in skin integrity (Alqahtani et al., 2018). Implement medical device–related pressure injury prevention strategies, including appropriate selection, fitting and securing of the mask; pressure redistribution by frequent repositioning or rotation; and use of a prophylactic cushioning/proactive dressing between the skin and mask (Pittman & Gillespie, 2020). Masks for oxygen delivery may cause injuries to the cheeks, chin or bridge of the nose; place silicone border or hydrocolloid dressings over bony prominences or other areas that come in contact with the device and between the device and the skin

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

(Camacho-Del Rio, 2018).

MANAGING CHEST TUBES

A chest tube is indicated when negative pressure in the pleural space is disrupted, as from thoracic surgery (postthoracotomy) or unanticipated trauma (Muzzy & Butler, 2015). Patients with fluid (pleural effusion), blood (hemothorax), or air (pneumothorax) in the pleural space require a chest tube to drain these substances, restore the negative intrathoracic pressure, and allow the compressed lung to reexpand (Hinkle et al., 2022). A chest tube may also be indicated for pleurodesis (pleural sclerosing; installation of anesthetic or sclerosing agent to achieve inflammatory adherence of the visceral and parietal pleural to each other) (Burns & Delgado, 2019; Hinkle et al., 2022). A mediastinal chest tube may be placed after cardiac surgery to drain blood from around the heart (Morton & Fontaine, 2018). A tunneled pleural catheter (tunneled under the skin before entering the pleural space) may be used to improve quality of life in patients with recurrent pleural effusions related to some end-stage diseases, such as malignancy (Miller et al., 2018).

A chest tube is a plastic tube with drainage holes in the proximal end that is inserted in the pleural space. Once inserted, the tube is secured with a suture at the insertion site, covered with a dressing, secured with tape a few inches below the insertion site, and attached to a drainage system that may or may not be attached to suction. Other components of the system may include a closed water-seal drainage system that prevents air from reentering the chest once it has escaped and a suction control chamber that prevents excess suction pressure from being applied to the pleural cavity. The suction chamber may be a water-filled or a dry chamber. A water-filled suction chamber is regulated by the amount of water in the chamber (Fig. 40-13), whereas dry suction has a one-way mechanical valve system that allows air to leave the chest and prevents air from moving back into the chest and is automatically regulated to changes in the patient's pleural pressure. There are also portable drainage systems that utilize gravity for drainage. Table 40-5 compares different types of chest drainage systems.

FIGURE 40-13. A chest drainage system. (*Source:* Used with permission from Shutterstock. *Photo by Rick Brady.*)

The type of drainage determines the placement of the chest tube. When air is to be drained, the tube is placed higher in the chest (Morton & Fontaine, 2018). If fluid needs to be drained, the tube is inserted lower in the lung because fluids settle at the base of the lung (Morton & Fontaine, 2018).

Nursing responsibilities include assisting with insertion, monitoring the patient's status and response to the treatment, monitor the patency of the chest drainage system, patient education, and assisting with removal of the chest tube. Once the tube is in place, monitor the patient's response, including respiratory status and vital signs, check the site and site dressing, and maintain the patency and integrity of the drainage system. Guidelines for monitoring and caring for a patient with a chest tube are shown in Guidelines for Nursing Care 40-3 on page 1622.

An advanced practice professional usually performs chest tube removal. The health care provider will determine when the chest tube is ready for removal by evaluating the chest x-ray and assessing the patient and the amount of drainage from the tube. Some facilities are developing programs to train and support nurses and to ensure their continued competency to remove chest tubes. This would improve control of the timing of the procedure and allow for

appropriate preprocedure analgesia, reducing the pain and anxiety associated with tube removal (Hood et al., 2014; Muzzy & Butler, 2015). Removal of chest tubes can be a painful and stressful process for patients (Hood et al., 2014; Kane et al., 2013; Muzzy & Butler, 2015; Yarahmadi et al., 2018). Administer analgesics prior to the tube removal, at a sufficient interval to allow for the medication to take effect, based on the medication prescribed. The application of cold to the chest prior to removal may also be implemented to decrease patient discomfort during chest tube removal (Yarahmadi et al., 2018). Nursing responsibilities related to chest tube removal also include providing emotional support for the patient, as well as monitoring the patient's status after removal. Monitor the patient's respiratory status, vital signs, pain, and site dressing.

Table 40-5 Comparison of Chest Drainage Systems

TYPE	DESCRIPTION	COMMENTS
Traditional water-seal (also referred to as wet-suction) chamber	Has three chambers: a collection chamber, water-seal chamber (middle chamber), and wet-suction control chamber. Generally, used to provide 20 cm H_2O of suction	• Requires that sterile fluid be instilled into the water-seal and suction chambers. • Has positive and negative pressure-release valves. • Intermittent bubbling indicates that the system is functioning properly. • Additional suction can be added by connecting the system to a suction source.
Dry-suction water seal (also referred to as dry suction)	Has three chambers: a collection chamber, water-seal chamber (middle chamber), and dry-suction control chamber. Provides up to 40 cm H_2O of suction	• Requires that sterile fluid be instilled in the water-seal chamber at the 2-cm level. • No need to fill the suction chamber with fluid. • Suction pressure is set with a regulator. • Has positive and negative pressure-release valves. • Has an indicator to signify that the suction pressure is adequate. • Quieter than traditional water-seal systems.
Dry-suction (also referred to as one-way valve system)	Has a one-way mechanical valve that allows air to leave the chest and prevents air from moving back into the chest.	• No need to fill suction chamber with fluid; can be set up quickly in an emergency. • Works even if knocked over, making it ideal for patients who are ambulatory. • Not able to easily observe air leaks, monitor intrapleural pressures, or use suction

USING ARTIFICIAL AIRWAYS

Artificial airways are used to preserve a functioning airway in patients who are unable to maintain a patent airway without assistance. Communicating effectively with patients with artificial airways, such as endotracheal tubes or tracheostomies, is essential. Patients with endotracheal tubes, and most tracheostomies, are unable to speak. The communication needs of these patients must be part of the nursing assessment. Identify appropriate alternative communication strategies to ensure that the patient's needs are conveyed. Consider the patient's impaired ability to

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

communicate and keep communication tools (e.g., writing board, letters, vocabulary cards) close at hand, along with the call light or bell. Offer frequent reassurance and explanations and anticipate the patient's needs to promote positive patient outcomes.

Oropharyngeal and Nasopharyngeal Airways

An oropharyngeal or nasopharyngeal airway is a semicircular tube of plastic or rubber inserted into the back of the pharynx through the mouth (oro) or nose (naso) in a patient who is breathing spontaneously (Hinkle et al., 2022). The oropharyngeal airway is used to keep the tongue clear of the airway. It is often used for postoperative patients until they regain consciousness. It is important to ensure use of an airway of the correct size. Incorrect sizing can hinder airway maintenance; using an oropharyngeal airway that is too big will obstruct the airway, and one that is too small will not aid in opening the airway (Higginson et al., 2016). (Refer to Guidelines for Nursing Care 40-4 on page 1623 for details of sizing.) Once the patient regains consciousness, remove the oropharyngeal airway. Do not use tape to hold the airway in place because the patient should be able to expel the airway once they become alert.

A nasopharyngeal airway is inserted through the naris and protrudes into the back of the pharynx. The nasal trumpet allows for frequent nasotracheal suctioning without trauma to the nasal passageway. This airway may be left in place, without much discomfort, in the patient who is alert and conscious. Techniques to use when inserting an oropharyngeal and nasopharyngeal airway are outlined in Guidelines for Nursing Care 40-4 on page 1623.

Guidelines for Nursing Care 40-3

Monitoring a Patient With a Chest Tube

- Perform hand hygiene and put on PPE, if indicated.

- Identify the patient.

- Assess the patient's vital signs, respiratory status, oxygen saturation, mental status, and breath sounds. Assess for pain. Monitor for any indication of change in the respiratory status.
- Observe the dressing around the chest tube insertion site. Gently palpate around the insertion site, feeling for crepitus, a result of air or gas collecting under the skin (subcutaneous emphysema). Tape all connections securely.
- Check that the drainage tube has no dependent loops or kinks. Make sure the drainage collection device is positioned below the tube insertion site to facilitate drainage.
- Observe the water-seal chamber for fluctuations of the water level with the patient's inspiration and expiration (tidaling). If suction is used, temporarily disconnect the suction to observe for fluctuation. Assess for the presence of bubbling in the water-seal chamber. Add water, if necessary, to maintain the level at the 2-cm mark or the mark recommended by the manufacturer.
- Assess the suction control chamber if suction is in use. If water suction is used, ensure that water is at the appropriate level; add water to ensure that suction is adequate. Gentle bubbling in the suction chamber indicates that suction is being applied to assist drainage.
- Assess the amount and type of fluid drainage. Measure drainage output at the end of each shift by marking the level on the container or placing a small piece of tape at the drainage level to indicate date and time. Document the color and consistency of the drainage. Drainage is never emptied. Drainage that dramatically increases or becomes bright red indicates fresh bleeding. Notify the health care team immediately.
- Keep the drainage collection device secure so that it does not tip over.
- Keep two rubber-tipped clamps and additional dressing material at the bedside for quick access, if needed. If the drainage unit requires changing, engage the clamp integrated on the drainage tubing. (Alternatively, position one clamp 1½ to 2½ inches from the insertion site; position the second clamp 1 inch down from the first one until the unit has been switched.) The chest tube may be clamped before its removal to observe the patient's tolerance when it is discontinued (Sasa, 2019). However, chest tubes are rarely clamped because this increases the risk of causing tension pneumothorax and is a prescribed intervention (Sasa, 2019).
- Keep a bottle of sterile saline or water at the bedside. If the chest tube disconnects from the drainage unit, submerge the end in water, creating a water seal, but allowing air to escape, until a new drainage unit can be attached. This is done instead of clamping to prevent another pneumothorax.
- Never clamp the tube if the patient leaves the unit for a test or moves away from the bed. Disconnect the suction tubing from the drainage system, allowing the unit to continue to collect drainage by gravity.
- **Do not** perform "milking" of the tubing (squeezing and releasing small segments of tubing between the fingers) and "stripping" of the tubing (squeezing the length of the tube without releasing it). This creates excessive

negative pressure that can damage delicate lung tissue (Sasa, 2019). Stripping and milking are not necessary to maintain chest tube patency and probably do more harm than good (Makic et al., 2015, p. 44).

Endotracheal Tube

An endotracheal tube is a polyvinyl chloride airway that is inserted through the nose or mouth into the trachea, using a laryngoscope as a guide. It is used to administer oxygen by mechanical ventilator, to suction secretions easily, or to bypass upper airway obstructions (e.g., tongue or tracheal edema). Although uncomfortable and easy to manipulate with the tongue, orotracheal insertion is often the method of choice, especially in an emergency, as it is associated with less trauma and lesser rates of infection and typically accommodates a larger diameter endotracheal tube than the nasal route, making ventilation easier (Hinkle et al., 2022). Placement of the tube through the nasotracheal route, although tolerated better by patients, is more difficult and requires the use of a narrower tube. Most commonly, a cuffed endotracheal tube is used (Fig. 40-14). This type of tube prevents air leakage and bronchial aspiration of foreign material while allowing more precise control of oxygen and mechanical ventilation. However, careful monitoring of cuff pressure is necessary to decrease the risk for tracheal necrosis, tracheal rupture, laryngeal nerve palsy, tracheal stenosis, microaspiration, and/or inadequate ventilation (Turner et al., 2020). The smallest amount of air that results in an airtight seal between the trachea and the tube is desirable and less likely to result in complications; cuff pressures should be checked at least once per shift and maintained between 20 and 30 cm H_2O (AACN, 2018; Hess et al., 2021; Hinkle et al., 2022; Turner et al., 2020). Endotracheal tubes are secured via tape, twill tape, or a commercial device (Hess et al., 2021).

Implement medical device–related pressure injury prevention strategies to reduce the risk for alterations in skin integrity. Interventions may include the use of a prophylactic cushioning/proactive dressing between the skin and securement device, an endotracheal tube repositioning schedule, routine skin and oral assessments, and provision of scheduled skin and oral hygiene interventions (Holdman et al., 2020).

Guidelines for Nursing Care 40-4

Inserting an Artificial Airway

Inserting an Oropharyngeal Airway

- Perform hand hygiene and put on PPE, if indicated.

- Identify the patient.
- Use an airway that is the correct size. Measure the oropharyngeal airway by holding the airway on the side of the patient's face. The airway should reach from the opening of the mouth to the back angle of the jaw, and the tip of the airway should reach no farther than the pinna of the ear (Hess et al., 2021).
- Put on gloves; put on a mask and goggles or face shield as indicated.
- Check for loose teeth, dentures, or other foreign material. Remove dentures or material, if present.
- Position the patient in the semi-Fowler position.
- Open the patient's mouth by using your thumb and index finger to gently pry their teeth apart.
- Insert the airway with the curved tip pointing up toward the roof of the mouth.
- Slide the airway across the tongue to the back of the mouth.
- Rotate the airway 180 degrees as it passes the uvula (a flashlight can confirm the position of the airway with the curve fitting over the tongue).
- Ensure accurate placement and adequate ventilation by auscultating breath sounds.
- Position the patient on their side when the airway is in place.
- Remove the airway for a brief period every 4 hours, or according to facility policy. Assess the mouth and provide mouth care and a clean airway before reinserting it.

Inserting a Nasopharyngeal Airway (Nasal Trumpet)

- Perform hand hygiene and put on PPE, if indicated.

- Identify the patient.
- Put on gloves; put on mask and goggles or face shield as indicated.
- Use an airway that is the correct size. Measure the nasopharyngeal airway for correct size. Measure the

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

nasopharyngeal airway length by holding the airway on the side of the patient's face. The airway should reach from the tip of the nose to the earlobe. The airway with the largest outer diameter that fits the patient's nostril should be used (Morton & Fontaine, 2018).

- **If the patient is awake and alert, position in the semi-Fowler position. If the patient is not conscious or alert, position in a side-lying position.**
- Lubricate the airway with the water-soluble lubricant, covering the airway from the tip to the guard rim.
- Gently insert the airway into the naris, narrow end first, pointing it down, toward the back of the throat, until the rim is touching the naris. If resistance is met, stop and try inserting in the other naris.
- Check placement by closing the patient's mouth and placing your fingers in front of the tube opening to check for air movement. Assess the pharynx to visualize the tip of the airway behind the uvula. Assess the nose for blanching or stretching of the skin.
- Remove the airway, clean it, and place it in the other naris at least every 8 hours, or according to facility policy. Assess for any evidence of alterations in skin integrity.
- The airway may be used for suctioning to prevent trauma to the mucosa.

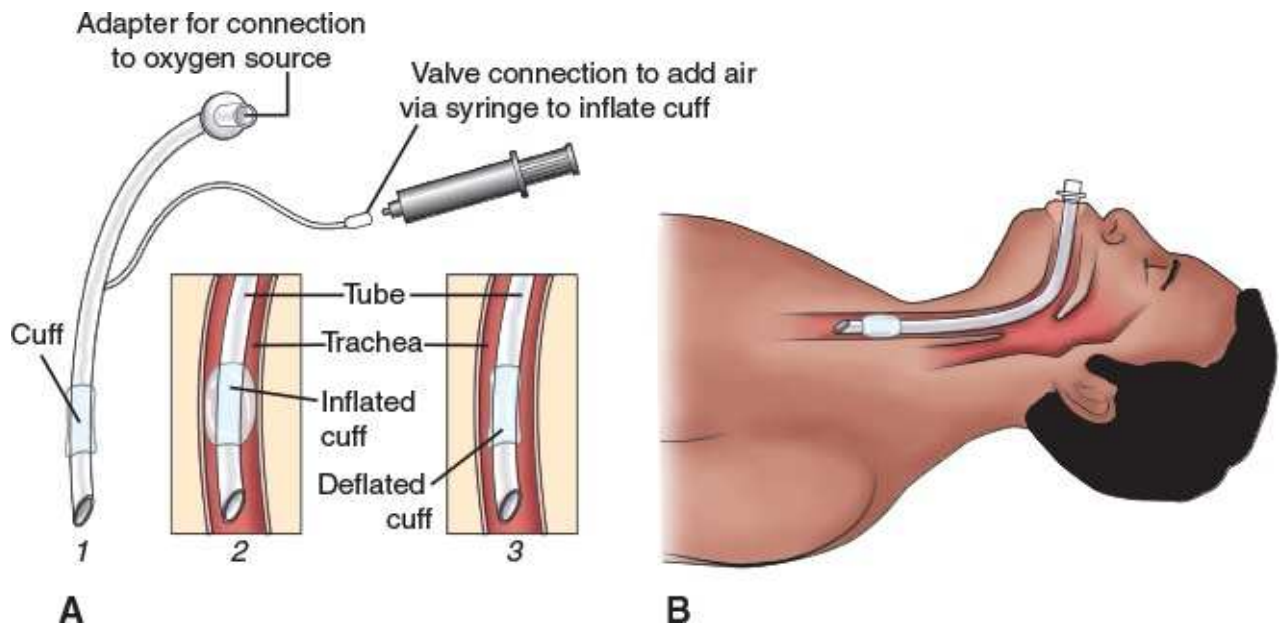

FIGURE 40-14. Endotracheal tube. **A.** (*1*) Parts of a cuffed endotracheal tube; (*2*) tube in place with the cuff inflated; (*3*) tube in place with the cuff deflated. **B.** Endotracheal tube in place.

Technology Alert

Maintaining endotracheal tube cuff pressure within a narrow range is an important part of patient care. Automated cuff pressure regulators and controllers have been developed to provide continuous real-time monitoring and control of optimal cuff pressure. These devices automatically adjust the cuff pressure within preset target, minimum, and maximum pressure values, removing the need for frequent manual monitoring and adjustment of cuff pressure and reducing nursing workload. Cuff pressure regulators have been shown to significantly reduce the drop in cuff pressure observed when pressure is set manually and prevent low and high average pressures (Chenelle et al., 2015; Lorente et al., 2014; Vottier et al., 2016) and reduce the risk of microaspiration (Hess et al., 2021).

Placement of an endotracheal tube results in the inability to speak, which can be frightening and frustrating for the patient and may contribute to ineffective responses to patient concerns and needs. Assess the patient's ability to use alternative methods of communication. Plan for and provide alternative methods of communication. Establishing a rapport with the patient through eye contact and careful attention to nonverbal cues and communication is important.

Patients with endotracheal tubes often require suctioning via the endotracheal tube to remove secretions from the airway. Refer to the discussion related to tracheal suctioning later in the chapter on page 1627. Routine oral suctioning to aspirate secretions that accumulate above the cuff of the tube is also necessary to reduce the risk of pneumonia and provide patient comfort (AACN, 2018; Hess et al., 2021; Morton & Fontaine, 2018). Poor oral hygiene contributes to the colonization of the oropharyngeal secretions by respiratory pathogens. Diligent oral hygiene care can improve oral health and limit the growth of pathogens in the oropharyngeal secretions, decreasing the incidence of aspiration pneumonia, community-acquired pneumonia, nonventilator health care–associated pneumonia (NV-HAP), and ventilator-associated pneumonia (VAP) (AACN, 2017; Chick & Wynne, 2020; Jenson et al., 2018; Quinn et al., 2020). Refer to the previous discussion related to suctioning the airway on page 1610. Oral hygiene measures are discussed in Chapter 32.

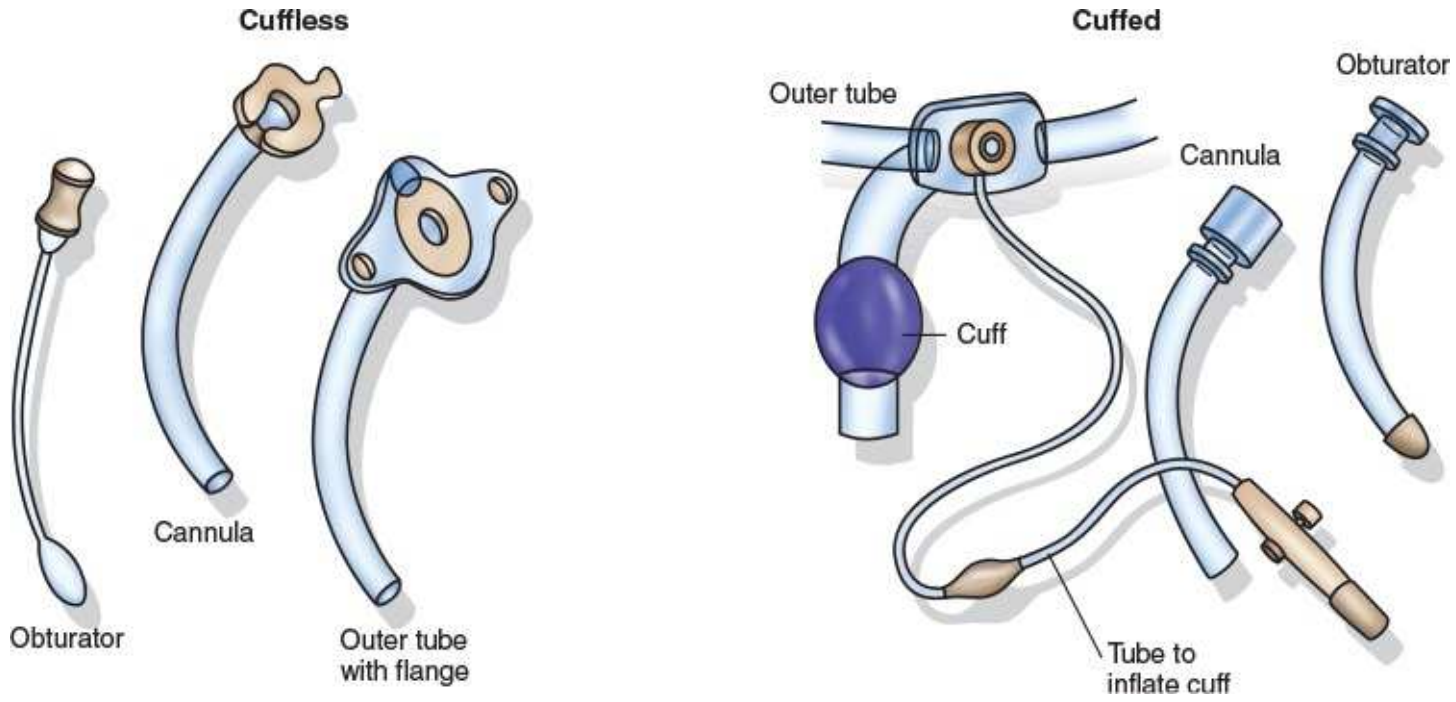

FIGURE 40-15. Two types of tracheostomy sets: cuffless and cuffed.

Consider **Mr. Kim**, the 57-year-old man receiving oxygen therapy and mechanical ventilation via an endotracheal tube. When developing the patient's plan of care, the nurse needs to assess him closely and frequently for signs and symptoms indicating an increase in secretions. If secretions increase, the nurse needs to suction the patient to maintain a patent airway and minimize his risk for hypoxemia and infection.

TRACHEOSTOMY TUBE

A **tracheostomy** is an artificial opening made into the trachea, usually at the level of the second or third cartilaginous ring. A curved tube, called a **tracheostomy tube**, is inserted through the opening. It is inserted in the operating room or intensive care unit under sterile conditions using local anesthesia and can be temporary or permanent. It may be used to replace an endotracheal tube, to provide a method for mechanical ventilation of the patient, to bypass an upper airway obstruction, in conditions in which endotracheal tube intubation is not possible (e.g., facial trauma, cervical fractures), or to remove tracheobronchial secretions (Hinkle et al., 2022; Morton & Fontaine, 2018).

The tube is made of semi-flexible plastic (polyethylene, polyvinyl chloride, polyurethane or silicone), rigid plastic, rubber, Teflon, or metal and is available in different sizes with varied angles (Hess & Altobelli, 2014; Hess et al., 2021). The most commonly used tubes are made from PVC, silicone or polyurethane (Hess & Altobelli, 2014). As a result of improvements in material design, metal tracheostomy tubes are rarely used today (Hess et al., 2021). The conditions and needs of the patient determine the selection of tube. A tracheostomy tube consists of an outer cannula or main shaft, an inner cannula, and an obturator (Fig. 40-15). An obturator, which guides the direction of the outer cannula, is inserted into the tube during placement and removed once the outer cannula of the tube is in place. Many tubes also have inner cannulas that may or may not be disposable. The outer cannula remains in place in the trachea, and the inner cannula is removed for cleaning or replaced with a new one (Morton & Fontaine, 2018). Periodic cleaning or replacement of the inner cannula prevents airway obstruction from secretions that have accumulated on the tube's inner surface (Patton, 2019). A tube with an inner cannula is necessary when patients have excessive secretions or have difficulty clearing their secretions. It also may be recommended for a patient who will be discharged with a tracheostomy tube in place.

Tracheostomy tubes may be either cuffed or cuffless (see Fig. 40-15). The inflated cuff seals the opening around the tube to create a seal in the trachea. This prevents air leakage and aspiration and permits mechanical ventilation. Newer tracheal cuffs are low pressure, do not require deflating for short intervals every few hours, and can be maintained at lower than tracheal capillary pressure (Hess et al., 2021). Uncuffed tubes are used in adult patients who do not require invasive respiratory support and have an effective gag and cough reflex; adults who need frequent suctioning but do not need mechanical ventilation; as a method of weaning from the tracheostomy tube; and in pediatric patients under the age of six, to avoid tracheal deformation related to thinner tracheal tissues and softer laryngeal and tracheal cartilage cuff pressure (Hess et al., 2021; Patton, 2019).

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

A fenestrated tracheostomy tube has one large or several small openings or windows on its outer curve, has an inner cannula, and can be cuffed or cuffless. When the patient is being mechanically ventilated, the inner cannula is in place, blocking the small openings. After the patient is no longer connected to the ventilator, the inner cannula can be removed, the cuff deflated, and the tube plugged, allowing the patient to speak. Because the tube has these openings, it should be considered only for patients with normal upper airway reflexes (Hess et al., 2021).

The tracheostomy is initially held in place with sutures, which are removed after 7 days (O'Toole et al., 2017). After the sutures are removed, the tube is held in place by twill tapes or a commercially available tube holder, which is a wide neck band with elastic to distribute pressure and prevent skin irritation fastened around the patient's neck. Regularly check cuff pressure, although some tubes have a pressure-release valve that prevents pressure from increasing to damaging levels. Careful monitoring of cuff pressure is necessary to decrease the risk for tracheal necrosis, tracheal rupture, laryngeal nerve palsy, tracheal stenosis, microaspiration, and/or inadequate ventilation (Turner et al., 2020). The smallest amount of air that results in an airtight seal between the trachea and the tube is desirable and less likely to result in complications; cuff pressures should be maintained between 20 and 30 cm H_2O (AACN, 2018; Hess et al., 2021; Hinkle et al., 2022; Patton, 2019). Measurement of cuff pressure should occur at least once per shift or following any procedure where movement of the tube may have taken place (e.g., dressing/securement device change, patient repositioning), if there is an audible leak, or following any changes in the volume of the cuff (Hess et al., 2021; Patton, 2019). Continuous cuff monitoring is available and is associated with reduced risk of microaspiration (Hess et al., 2021).

Because the tracheostomy tube bypasses the natural humidifying and heating mechanisms in the nose and mouth, administer heated, humidified oxygen to prevent secretions from becoming dry (Patton, 2019). Keep the tracheostomy tube free from foreign objects and nonsterile materials, such as cotton balls, loose threads from dressings, needles, and other small objects, to reduce the risk of obstruction and infection.

Patients with tracheostomies frequently have an ineffective cough mechanism and copious secretions, which necessitate tracheal suctioning to remove secretions. Refer to the discussion related to tracheal suctioning later in the chapter on page 1627. Routine oral suctioning to aspirate secretions that accumulate above the cuff of the tube and frequent oral hygiene are also necessary to reduce the risk of pneumonia and provide patient comfort (AACN, 2018; Hess et al., 2021; Morton & Fontaine, 2018). Refer to the previous discussion related to suctioning the airway on page 1610. If the patient eats by mouth, it is recommended that the tracheostomy tube be suctioned prior to eating to prevent the need for suctioning during or after meals, which may stimulate excessive coughing and could result in vomiting (Hess et al., 2021, p. 429). Poor oral hygiene contributes to the colonization of the oropharyngeal secretions by respiratory pathogens. Diligent oral hygiene care can improve oral health and limit the growth of pathogens in the oropharyngeal secretions, decreasing the incidence of aspiration pneumonia, community-acquired pneumonia, nonventilator health care–associated pneumonia (NV-HAP), and ventilator-associated pneumonia (VAP) (AACN, 2017; Chick & Wynne, 2020; Jenson et al., 2018; Quinn et al., 2020). Oral hygiene measures are discussed in Chapter 32.

Placement of tracheostomy tube may result in the inability to speak, depending on the type of tube in use. The inability to communicate verbally can be frightening and frustrating for the patient and may contribute to ineffective responses to patient concerns and needs (Tolotti et al., 2018). Assess the patient's ability to use alternative methods of communication. Plan for and provide alternative methods of communication. Establishing a rapport with the patient through eye contact and careful attention to nonverbal cues and communication is important.

Replace a disposable inner cannula or cleaning a nondisposable one at least once per 8 hours; more frequent cleaning may be required based on the patient's status (Patton, 2019). For example, cleaning or replacement may be necessary every 4 hours or more if thick, viscous, or copious secretions are present (Patton, 2019). The inner cannula requires cleaning or replacement to prevent accumulation of secretions that can interfere with respiration and occlude the airway. Because soiled or wet tracheostomy dressings place the patient at risk for the development of skin breakdown and infection, regularly change any dressings and ties. Use gauze dressings that are not filled with cotton to prevent aspiration of foreign bodies (e.g., lint or cotton fibers) into the trachea. The Research in Nursing display (on page 1626) examines the use of a novel tracheostomy dressing applicator to assist in changing tracheostomy dressings and minimizing discomfort to the patient. Clean the skin around a tracheostomy to prevent buildup of dried secretions and skin breakdown. Exercise care when changing the tracheostomy ties to prevent accidental decannulation or expulsion of the tube. Have an assistant hold the tube in place during the change or keep the soiled tie in place until a clean one is securely attached.

Research in Nursing

Bridging the Gap to Evidence-Based Practice

Tracheostomy Dressing Changes and Nurse Innovators

Routine tracheostomy care includes cleaning of the stoma site and changing the site dressing, which acts as a cushion and a barrier between the skin and the tube. Changing the site dressing involves placing the new dressing

under the tracheostomy tube flanges, which can be difficult due to the presence (immediately postoperatively) of sutures and limited space between the tube flanges and the patient's neck. The process may also be uncomfortable and/or painful for the patient due to manipulation of the surgical site. Nurses must balance the need to avoid injury at the site, the need for interventions to prevent complications, and patient comfort (Morris et al., 2021). Nurses may resort to using forceps, hemostats, their fingers, or another tool in efforts to successfully place site dressings (Morris et al., 2021). Are there better options for tools to assist with dressing placement?

Related Research

Morris, L. L., Kuncis, M., Perleberg, D., Kuczek, A., Kashul, K., Zabel, D., Heinemann, A. W., & Semik, P. (2021). New device makes tracheostomy dressing changes easier and more comfortable. *Rehabilitation Nursing*, *46*(2), 95–103. https://doi.org/10.1097/rnj.0000000000000302

The purpose of this quasi-experimental study was to compare the use of a novel tracheostomy dressing applicator (TDA) for tracheostomy dressing changes to the standard procedure for tracheostomy dressing changes regarding nurses' ease of use as well as patient discomfort in an inpatient rehabilitation setting. The TDA was developed and patented by two critical care registered nurses and was designed to assist caregivers in changing tracheostomy dressings quickly and efficiently while minimizing discomfort to the patient. Patients older than age 18 years (n = 19) and registered nurses (n = 117) at the rehabilitation center participated in the study. The participating nurses were trained on proper use of the device. Nurse participants agreed to change the patients' tracheostomy dressings twice during their usual 12-hour shift: once using the standard method and once using the TDA. The nurses used the same dressing procedure for both dressing changes, but, when completing the dressing with the TDA, used the TDA rather than their fingers alone to apply the dressing. Nurses were randomized into two groups. Group A completed the first dressing change of the shift (completed near the beginning of their shift) without the TDA and the second dressing change (completed near the end of their shift) with the TDA. Group B completed the first dressing change of the shift with the TDA and the second without the TDA. After each dressing change, nurses and patients rated their experience using the TDA compared to the standard method of dressing change via surveys. Nurses rated the ease of dressing change perceived discomfort and also documented their observations of discomfort. Patients who were able to respond were asked to rate discomfort during the dressing changes, and a general description of their neck sized was recorded. Outcome measures were ease of use of the TDA, degree of patient discomfort with the dressing change, and a comparison of ease of use and degree of discomfort on patients with average-sized versus large-sized necks. Nurses rated the TDA easier to use in patients with average-sized necks and more favorably on observed discomfort in patients with average-sized and larger necks. Patients rated less discomfort with the TDA compared with the standard method of dressing change. The researchers concluded the TDA is an effective device to facilitate tracheostomy dressing changes, possibly improving compliance and efficiency and improving outcomes.

Relevance to Nursing Practice

Nursing interventions related to decreasing pain and increasing patient comfort are an important nursing responsibility. Interventions that can improve patient outcomes and improve time management should be considered by nurses. Nurses could easily incorporate this simple intervention as part of nursing care for these patients. This study also reinforces the importance of the role of nurses as innovators, developing, testing, and implementing new and improved products and processes to promote health and deliver optimal care (Spader, 2020).

Implement medical device–related pressure injury prevention strategies to reduce the risk for alterations in skin integrity. Interventions may include the use of a hydrocolloid dressing under the tracheostomy flange during the postoperative period, removing the tracheostomy plate sutures within 7 days of the procedure, placing a polyurethane foam dressing at the tracheostomy site after suture removal (Dixon et al., 2018; O'Toole et al., 2017), routine skin and oral assessments, and provision of scheduled skin and oral hygiene interventions (Holdman et al., 2020).

Preparation for emergency situations is an important part of nursing care for these patients. The tracheostomy is the patient's only airway, and measures to maintain its patency need to be readily available. Standard bedside equipment for emergency use should include the obturator from the current tube, replacement inner cannula of the same size, suction equipment, oxygen, a manual ventilation bag, a spare tracheostomy tube of the same size, and one a size smaller (Dawson, 2014; Patton, 2019).

Patient condition, nursing assessment and judgment, and facility policy determine specific procedures and schedules, but a newly inserted tracheostomy may require attention every 1 to 2 hours. Skill 40-5 (on pp. 1648–1653) outlines tracheostomy care.

TRACHEAL SUCTIONING

The purpose of suctioning is to maintain a patent airway and remove pulmonary secretions, blood, vomitus, or foreign material from the airway. When performed correctly, suctioning provides comfort by relieving respiratory distress.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

When performed incorrectly, it can increase anxiety and pain and cause respiratory arrest. Tracheal suctioning may be performed by passing a sterile catheter through a tracheostomy or endotracheal tube. Suctioning to remove secretions is performed using the sterile technique; sterile technique is discussed in Chapter 25.

Tracheal suctioning should be performed only when clinically indicated based on assessment and not routinely (AARC, 2010; Burns & Delgado, 2019; Hess et al., 2021; Morton & Fontaine, 2018). Indications for the need for suctioning include audible and/or visible secretions, reduced oxygen saturation, presence of coarse crackles over the trachea, deterioration of arterial blood gas values, reduced breath sounds, and the patient's inability to generate an effective spontaneous cough, acute respiratory distress, or suspected aspiration of secretions (AARC, 2010; Patton, 2019). The suction catheter should be small enough not to occlude the airway being suctioned but large enough to remove secretions. In adults, use a suction catheter that occludes less than 50% of the lumen of the tracheostomy or endotracheal tube; in infants, the catheter should occlude less than 70% of the lumen (AARC, 2010; Pasrija & Hall, 2020). Several sizes of catheters are available. Wear gloves on both hands, goggles, and a mask—and a gown, if necessary—for protection from microorganisms.

Tracheal suctioning is an uncomfortable procedure at minimum, and it can be a very painful and/or distressing experience. Individualized pain management must be performed in response to the patient's needs (Arroyo-Novoa et al., 2008; Chaseling et al., 2014; Düzkaya & Kuğuoğlu, 2015; Wrona et al., 2021). Anticipate the administration of pharmacologic (analgesic medication) and use of nonpharmacologic interventions for the patient before suctioning (Arroyo-Novoa et al., 2008; Düzkaya & Kuğuoğlu, 2015; Ruan et al., 2017). As mentioned previously, perform suctioning only when clinically necessary because there are many potential risks. Risks include hypoxia, infection, tracheal tissue damage, cardiac dysrhythmias, bronchospasm, and atelectasis (AARC, 2010; Gilder et al., 2020). Sterile technique is used for tracheal suctioning, to reduce the risk of introduction of disease-causing organisms. In the home setting, clean technique is used, as the patient is not exposed to disease-causing organisms that may be found in health care settings, such as hospitals (Johns Hopkins Medicine, n.d.; Sterni et al., 2016; University of Iowa Health Care, 2017). Closely assess the patient before, during, and after the procedure to limit negative effects. In order to prevent hypoxia, hyperoxygenate the patient before and after suctioning for a minimum of 30 seconds (Burns & Delgado, 2019) and limit the application of suction to no more than 10 to 15 seconds (AARC, 2010; Burns & Delgado, 2019; Hess et al., 2021; Pasrija & Hall, 2020). Monitor the patient's pulse frequently to detect potential effects of hypoxia and stimulation of the vagus nerve. Using an appropriate suction pressure (no more than 150 mm Hg for adults) will help prevent atelectasis related to the use of high negative pressure (Hess et al., 2021). Research suggests that insertion of the suction catheter should be limited to a predetermined length (no more than the tip of the artificial airway to no more than 1 cm past the length of the endotracheal tube [adults] and 0.5 cm [pediatric patients] [Boroughs & Dougherty, 2015; Hess et al., 2021; Kendrick, 2020]) to avoid tracheal mucosal damage, including epithelial denudement, loss of cilia, edema, and fibrosis (Boroughs & Dougherty, 2015; Hahn, 2010; Ireton, 2007; Pasrija & Hall, 2020; Pate & Zapata, 2002). The practice of instillation of saline solution directly into the airway during tracheal suctioning is not supported by evidence and is not recommended for inclusion as part of evidence-based practice and suctioning (AARC, 2010; Boroughs & Dougherty, 2015; Burns & Delgado, 2019; Leddy & Wilkinson, 2015; Owen et al., 2016; Wang et al., 2017).

Skill 40-6 (on pp. 1653–1659) describes suctioning a patient with a tracheostomy using the open suctioning system and the procedure is similar for a patient with an endotracheal tube. The open suctioning system requires disconnection of the endotracheal or tracheostomy tube from the ventilator or oxygen therapy source and insertion of a suction catheter each time the patient requires suctioning (Burns & Delgado, 2019). A closed suctioning system (Fig. 40-16) makes use of an in-line suction catheter device that remains attached to the ventilator or oxygen source circuit. The closed suctioning system is another method to provide tracheal suctioning that allows periodic insertion of the suction catheter without disconnection of the endotracheal or tracheostomy tube from the ventilator or oxygen therapy source (Burns & Delgado, 2019). This closed system prevents gas exchange deterioration, atelectasis, and hypoxia; is cost-effective because only one catheter is used daily; and reduces bioaerosol exposure risk for caregivers and contamination of the surrounding environment (Hess et al., 2021; Imbriaco & Monesi, 2021; Yazdannik et al., 2019).

ASSISTING VENTILATION

Mechanical ventilators are used to assist or completely control ventilation. These machines are used with patients who have endotracheal or tracheostomy tubes in place. Mechanical ventilation can be performed in acute care facilities, in extended-care settings, and in the home. Mechanical ventilation improves oxygenation and ventilation and supports the patient's breathing function during emergency or acute care episodes as well as long-term situations.

Many types of ventilators are available. The nurse is responsible for addressing the physical and psychological concerns of the patient and family/caregivers. In addition, key interventions include evaluating the patient's response to ventilation therapy, using safe practices and techniques, and monitoring the patient carefully for complications. (See clinical texts and evidence for practice that discuss the use of mechanical ventilators in greater detail.)

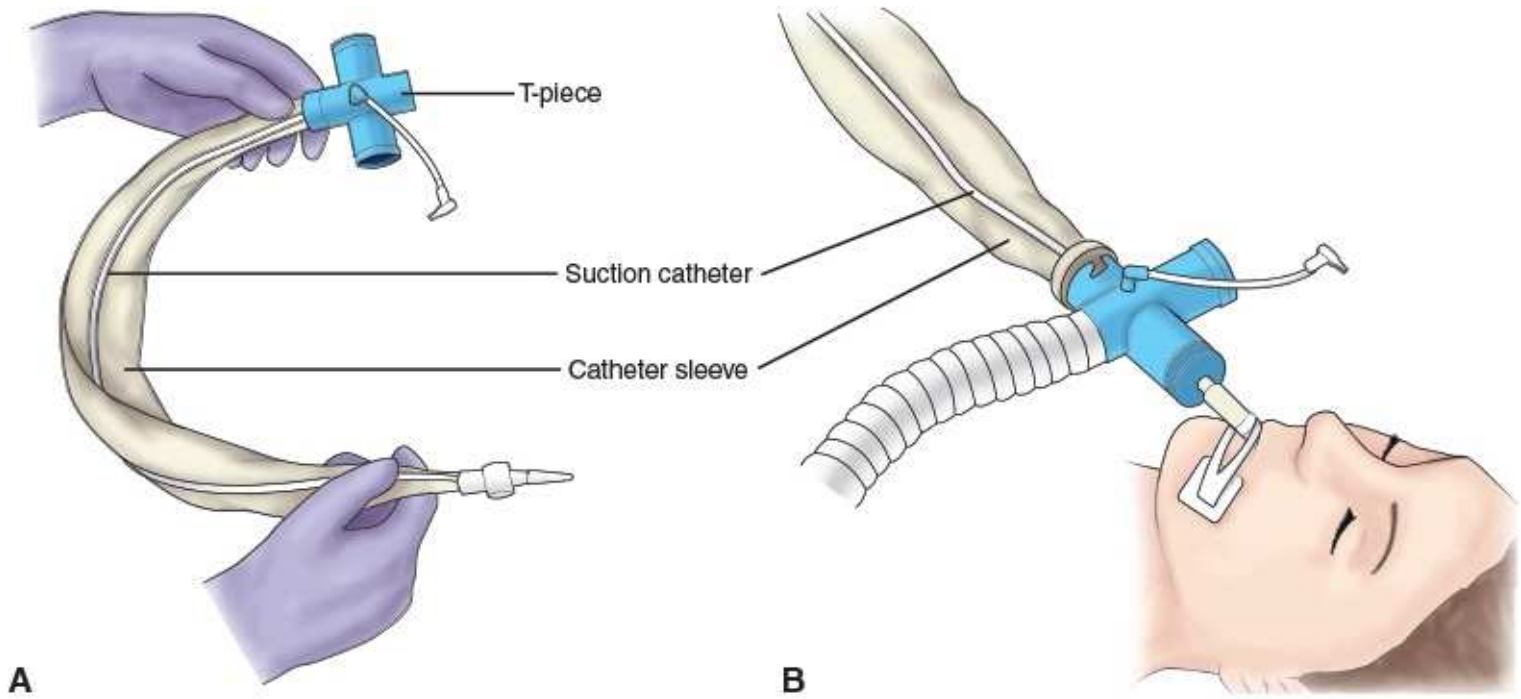

FIGURE 40-16. Closed airway suction system. **A.** Closed tracheal suction system. **B.** Closed system connected by a T-piece to the endotracheal tube and ventilator.

Another mechanical device used to assist ventilation is intermittent positive pressure breathing (IPPB). This is a method of providing a specific amount of air, oxygen, and aerosolized medication under increased pressure to the respiratory tract and is used for short-term hyperinflation therapy. IPPB forces deeper inspiration by positive pressure inhalation and then permits passive exhalation. The amount of pressure varies with each patient. Use of IPPB may be indicated for patients with atelectasis, reduced pulmonary function resulting in an effective cough, neuromuscular disorders, fatigue or muscle weakness with impending respiratory failure, acute severe bronchospasm, and in COPD exacerbations that fail to respond to other therapy (Hess et al., 2021). The use of IPPB is controversial, as evidence supporting its use is weak; in spontaneously breathing patients, it does not appear to have any benefit greater than other lung expansion techniques and its use for lung expansion should be considered after other interventions have been ineffective (Hess et al., 2021).

In emergency situations, the manual resuscitation bag (or bag-mask device) can be used to assist ventilation in patients whose respirations have ceased (Fig. 40-17). With the patient's head tilted back, jaw pulled forward, and airway cleared, the mask is held tightly over the patient's nose and mouth. The bag also fits over tracheostomy and endotracheal tubes. The operator's other hand compresses the bag at a rate of one breath every 6 seconds (about 10 breaths/min, adults) (American Heart Association [AHA], 2020b). The one-way valve in the mask allows exhaled air to escape. Artificial ventilation can be sustained until spontaneous breathing starts, until other mechanical assistance is available, or until death is confirmed. The bag is self-inflating and may be attached to supplemental oxygen (10 to 12 L/min) (Hess et al., 2021) if available.

FIGURE 40-17. Manual resuscitation bag.

Clearing an Obstructed Airway

Foreign-body obstruction of the airway often occurs during eating. In adults, meat is the most common food-related cause. In children, any variety of foods or objects can obstruct the upper airway. A patient who is semiconscious or unconscious develops airway obstruction as the tongue falls back, covering the pharynx. In fact, the tongue is the most common cause of airway obstruction.

Foreign bodies can cause a mild or severe airway obstruction. In mild airway obstruction with good air exchange, the patient can cough forcefully. Allow the person to cough and encourage spontaneous breathing. Do not interfere

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

with the patient's efforts to expel the object. With a partial airway obstruction, good air exchange can progress to poor air exchange. Poor air exchange may be indicated by a weak, ineffective cough, high-pitched noises while inhaling, increased breathing difficulties, and cyanosis. When this occurs, it is managed in the same way as complete airway obstruction. If mild airway obstruction continues or progresses, activate the emergency response system.

With a severe airway obstruction, the victim is unable to speak, cry or cough and may demonstrate poor or no air exchange; weak, ineffective cough or no cough; a high-pitched noise while inhaling or no noise at all; increased respiratory difficulty; and/or the universal choking sign (clutching the throat with both hands (AHA, 2020b) (Fig. 40-18). If the victim is an adult or child, ask "Are you choking?" If the victim nods "yes" and cannot talk, severe airway obstruction is present (AHA, 2020b). Immediate action is necessary—take steps to relieve the obstruction (choking relief). Choking relief in a responsive adult or child includes the use of abdominal thrusts to relieve choking. Do not use abdominal thrusts to relieve choking in an infant. Give each thrust with the intention of relieving the obstruction. It may be necessary to repeat the thrust several times to clear the airway. Follow and refer to the American Heart Association protocols for choking relief, which provide separate guidelines for other patient populations, including infants and pregnant, obese, and unresponsive victims (AHA, 2020b). If severe airway obstruction continues and the victim becomes unresponsive, start CPR. Follow the American Heart Association protocols for cardiopulmonary resuscitation (see next section). These protocols are continually being developed and updated.

FIGURE 40-18. Universal choking sign.

Administering Cardiopulmonary Resuscitation

The American Heart Association (AHA, 2020b) identifies interventions to provide emergency cardiovascular care, using the metaphor "Chain of Survival" for the elements of the emergency cardiovascular care systems (AHA, 2022). Elements of this emergency care include cardiopulmonary resuscitation (CPR), which is the combination of chest compressions that circulate blood; mouth-to-mouth breathing, which supplies oxygen to the lungs; and defibrillation, which interrupts or stops an abnormal heart rhythm using controlled electrical shocks. The elements and order of actions in the Chain of Survival differ based on the situation; whether the patient has the cardiac arrest outside the hospital or inside the hospital; and whether the patient is an adult, child, or infant (AHA, 2020b). The brain is very sensitive to hypoxia, and damage to the brain begins to occur within minutes without oxygen; after 5 minutes; permanent anoxic brain injury can occur (Headway, 2021; Lacerte et al., 2020). The faster emergency cardiovascular care (CPR) is initiated, the greater the chance of survival (AHA, 2020b). *The following discussion addresses the main elements in the Chain of Survival and focuses on the interventions for health care providers for the adult patient inside the hospital.* Refer to specific details in the AHA's (2020b) Basic Life Support Provider Manual for further information and details for the other Chains of Survival.

- Verifying scene safety (making sure the environment is safe for rescuers and the victim).
- Check for responsiveness.
- Shout for nearby help.
- Activate the emergency response system.
- Get an automated external defibrillator (AED) or defibrillator and emergency equipment (or send someone to do so).
- Look for no breathing or only gasping and check the carotid pulse (simultaneously) for no more than 10 seconds. If the victim has no breathing or only gasping and no pulse is felt, initiate CPR with the **CAB** sequence. Perform cycles of 30 compressions and two breaths.

- Use the AED as soon as it is available.
- **C** (Chest Compressions): Start compressions within 10 seconds after recognizing cardiac arrest. Push hard (at least 2 inches) and fast (100 to 120/min). Allow complete chest recoil after each compression.
- **A** (Airway): Tilt the head and lift the chin. Check for breathing.
- **B** (Breathing): Deliver two breaths, each over 1 second. Note visible chest rise with each breath. Resume chest compressions in less than 10 seconds.
- Check the rhythm.
  - If it is a shockable rhythm, give one shock. Resume CPR immediately for 2 minutes (until prompted by AED for rhythm check). Continue until ALS (advance life support) provides take over, or the victim starts to move.
  - If it is not a shockable rhythm**,** resume CPR immediately for 2 minutes (until prompted by AED for rhythm check). Continue until ALS (advance life support) provides take over, or the victim starts to move.

During CPR, standard precautions are followed even though contact with a patient's blood or body fluids does not always occur. Occupational Safety and Health Administration (OSHA) standards require health care facilities to provide an ample supply of ventilation masks along with other protective barriers for staff to use during resuscitation efforts. A barrier device, such as a pocket mask (preferred) (Fig. 40-19) or face shield, should be used by health care providers when giving breaths (AHA, 2020b). Use a bag-mask device if available (refer to previous discussion). Bag-mask ventilation during CPR is more effective when two rescuers provide it together, with one rescuer opening the airway and sealing the mask against the face while the other squeezes the bag (AHA, 2020b).

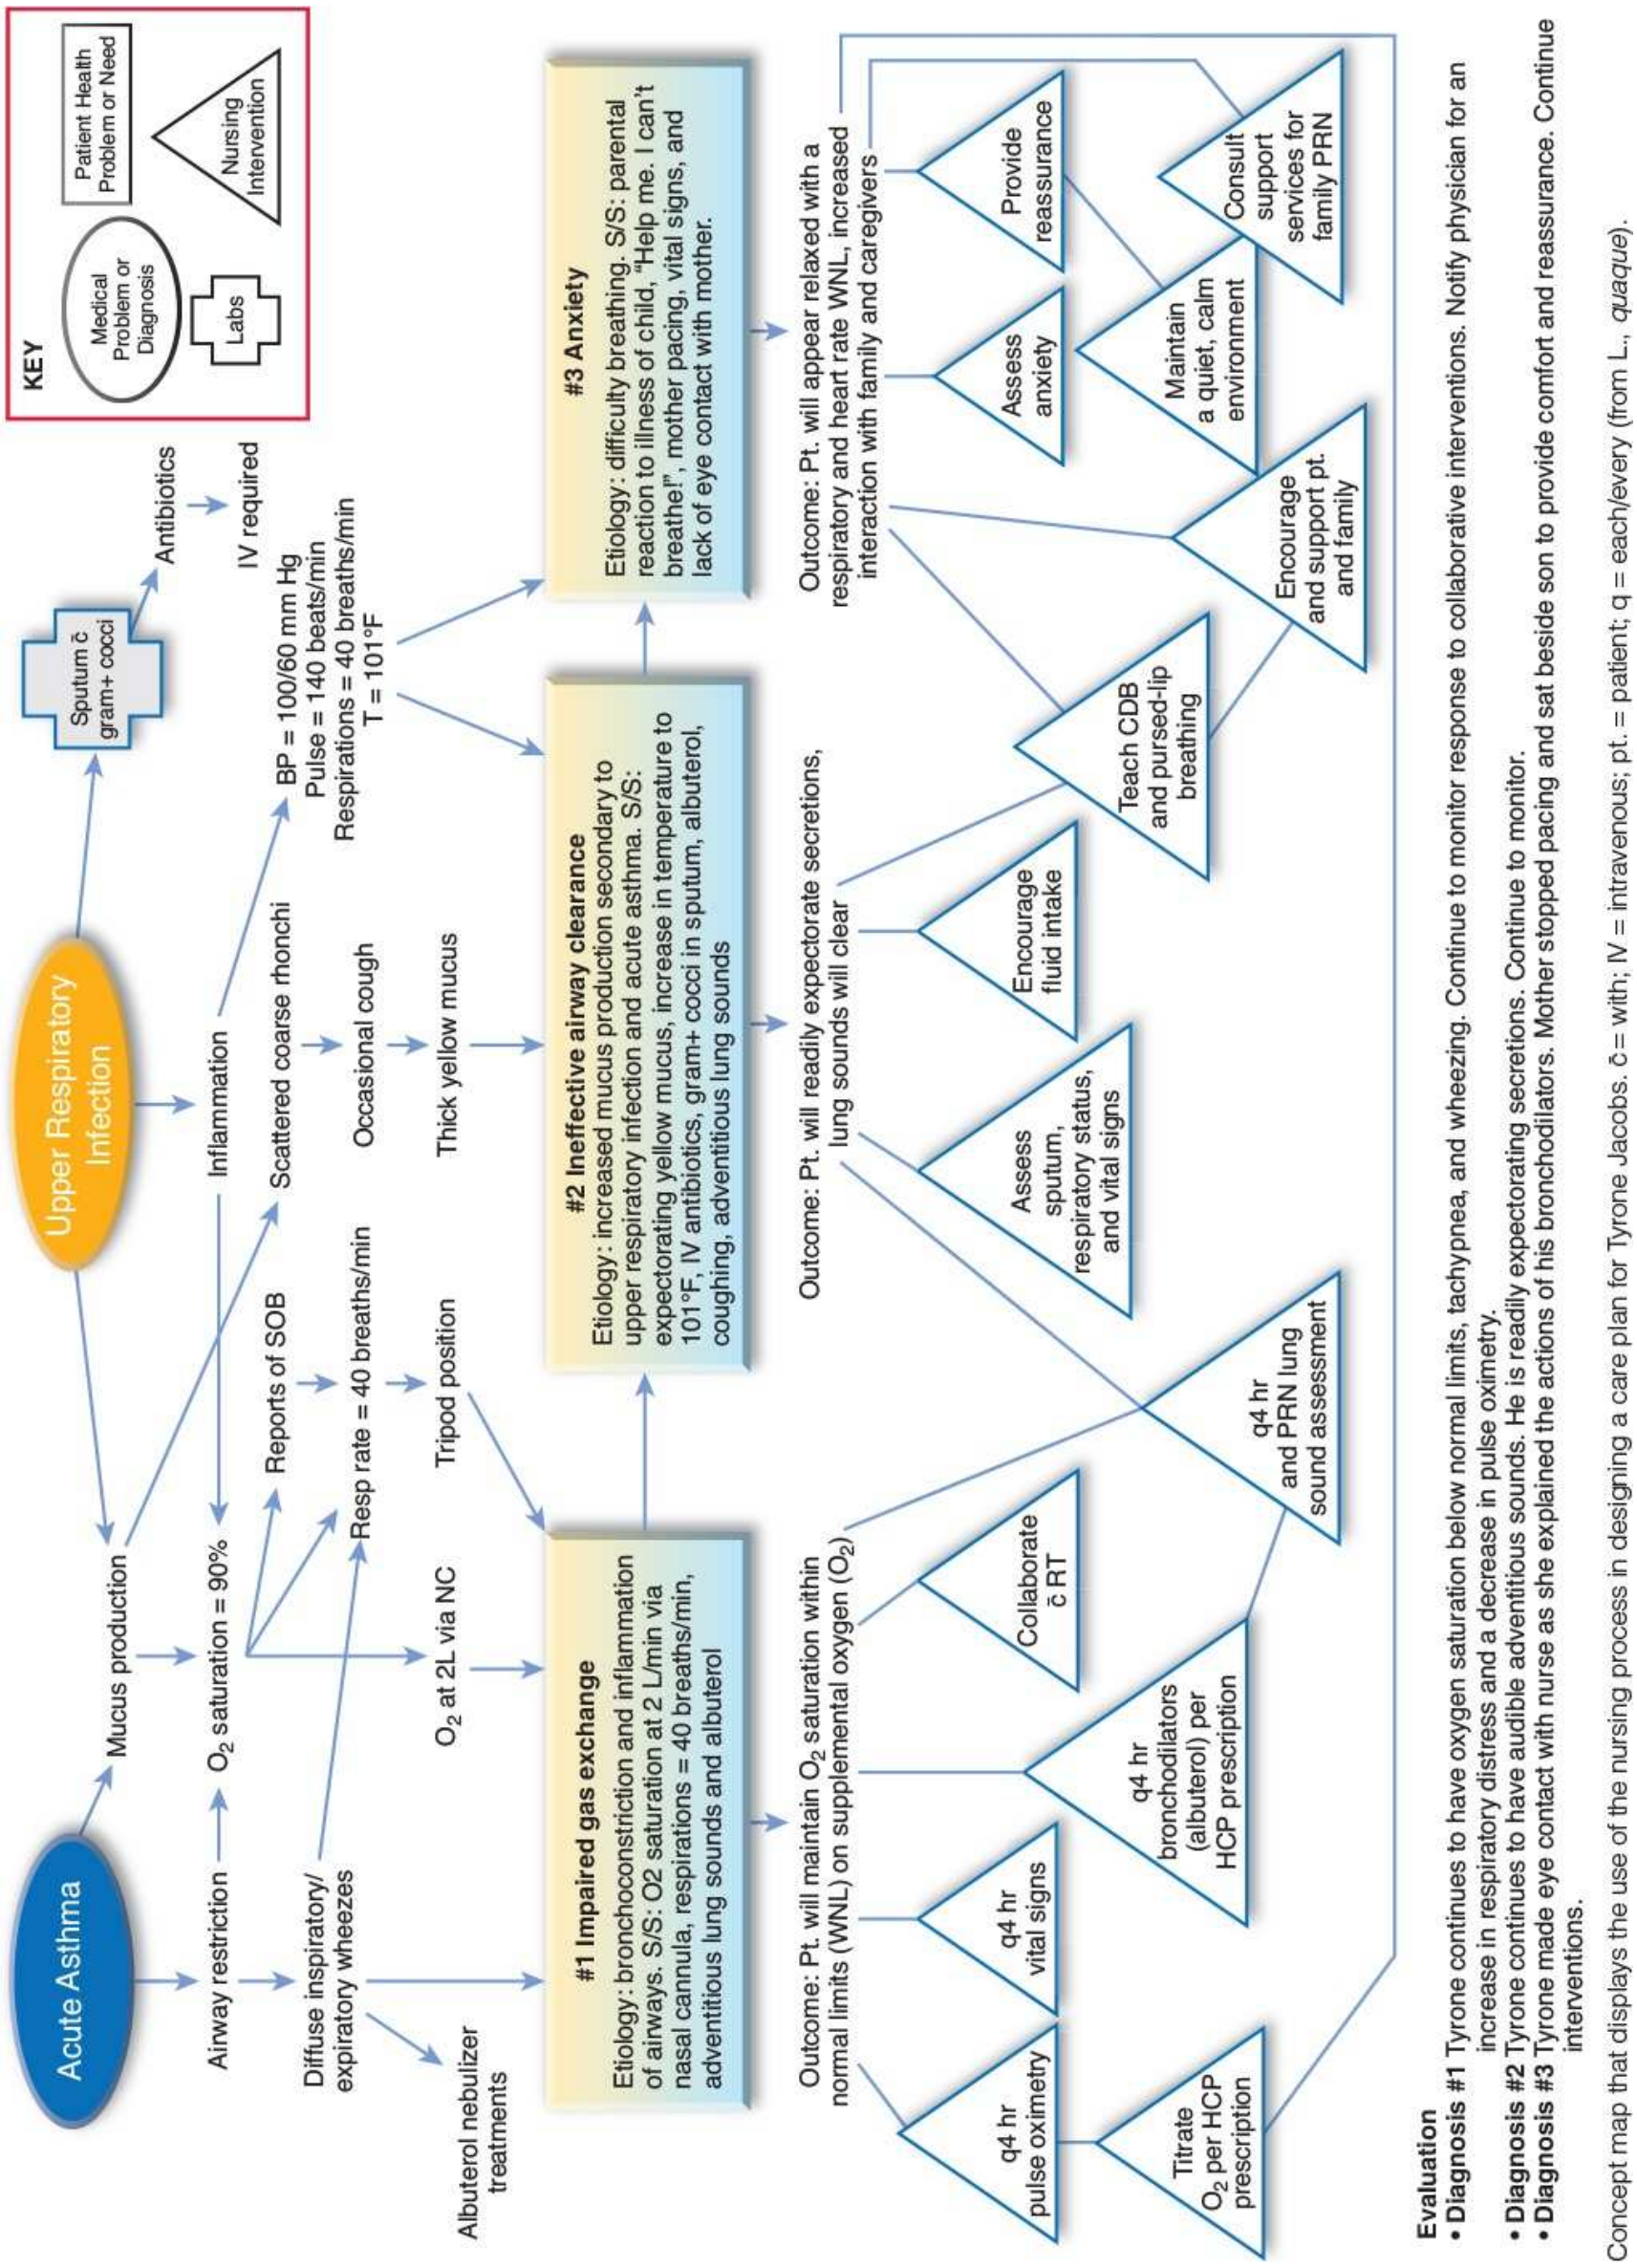
FIGURE 40-19. Pocket mask. (*Source:* Courtesy of Laerdal Medical.)

FIGURE 40-20. Automated external defibrillator (AED). **A.** AED device. **B.** Placement of the AED pad attached to the red cable connector to the left of the heart apex. To help remember where to place the pads, think "white right, red ribs." Placement of both electrode pads is the same as it is for manual defibrillation or cardioversion.

The automated external defibrillator (AED) has proved effective in reducing deaths attributed to cardiac arrest. This easy-to-use, computer-based device is designed to deliver a shock (defibrillation) to the heart muscle quickly to interrupt shockable rhythms that resets the heart's electrical system so a normal (organized) heart rhythm can return (AHA, 2020b). The AED has the ability to analyze the heart's rhythm, direct the operator to deliver a shock when appropriate or deliver one automatically, and then reanalyze the rhythm to determine whether it has returned to normal (Fig. 40-20). Using the AED is an integral part of resuscitation.

Health care providers must use clinical reasoning and judgment and maintain knowledge of current evidence for practice and the patient's health status and circumstances to adapt rescue interventions based on the health status of the patient to balance the immediate needs of the patient with the safety of rescuers. For example, in the setting of the

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com



coronavirus disease (COVID-19), the American Heart Association in collaboration with and the support of numerous professional organizations provided interim guidance for basic and advanced life support for patients with suspected or confirmed COVID-19 (Edelson et al., 2020). Another nonconventional CPR approach that has been suggested is the provision of CPR when the patient with an advanced airway is in the prone position if turning the patient supine would lead to delays or risk to providers or patients (Bhatnager et al., 2018). Compressions in the prone position are delivered on the thoracic spine (T7/10), 0 to 2 vertebral segments below the scapulae (reversed precordial compressions) (Bhatnager et al., 2018; Douma et al., 2020; Edelson et al., 2020). Collection of evidence on the provision of CPR in the prone position is ongoing, and further research is needed (Moscarelli et al., 2020).

Most professional organizations recommend and support widespread efforts to teach CPR to laypeople and all health professionals. The nurse is professionally responsible for maintaining proficiency in CPR skills and maintaining CPR certification. CPR must be administered quickly and accurately, without hesitation, when cardiac or pulmonary arrest occurs.

The AHA provides guidelines related to emergency interventions outside of health care facilities. Learning conventional CPR is still recommended, and trained lay rescuers should provide rescue breaths in addition to chest compressions (AHA, 2020b). However, the AHA guidelines recommend that when a teen or adult suddenly collapses, untrained lay bystanders should call 911 (activate the emergency response system) and push hard and fast in the center of the patient's chest (AHA, 2020b). These two steps, called "Hands-Only CPR," can be as effective as conventional CPR (AHA, 2021). Providing Hands-Only CPR to a teen or adult who has collapsed from a sudden cardiac arrest can more than double or triple that person's chance of survival (AHA, 2021).

Evaluating

Evaluation is an ongoing and deliberate part of the nursing process, comparing the patient's health status with previously defined expected outcomes and involves the nurse, patient, family/caregivers, and other health care team members. Refer to the accompanying concept map that illustrates the nursing process and plan of care for Tyrone Jacobs. Everyone involved in the evaluation process reflects on the effectiveness of the plan of care to promote oxygenation and perfusion by evaluating whether the patient has met the individualized patient goals. Adjustments in the plan of care are made accordingly.

Concept map that displays the use of the nursing process in designing a care plan for Tyrone Jacobs. c- = with; IV = intravenous; pt. = patient; q = each/every (from L., *quaque*).

REFLECTIVE PRACTICE LEADING TO PERSONAL LEARNING

Remember that the goal of reflective practice is to look at an experience, understand it, and learn from it. As you begin to develop expertise in implementing measures related to oxygenation and perfusion, reflect on your experiences—successes and failures—in order to improve your practice. How can you do it better next time? What did you learn today that can help you tomorrow? Begin your reflection by paying close attention to the following while performing

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

interventions related to oxygenation and perfusion and providing nursing care:

- Did your preparation and practice related to performing interventions related to oxygenation and perfusion result in your feeling confident in your ability to provide care? Did your competence and confidence inspire the patient's and family/caregiver's trust?
- Did your commitment to engage your patients and families and to collaborate with your fellow students, instructor, and other members of the health care team as you implemented the care plan result in successful partnerships?
- How did you prioritize the data you collected? What patterns in the data did you identify?
- What knowledge from your learning, personal experience and intuition did you use to make decisions and develop your plan of care?
- How confident are you that the data you communicated and recorded accurately communicates the health status, health problems, issues, risks, and strengths of the patient? How successfully have you communicated this information to other members of the health care team?
- Did you need to modify the care plan as a result of ongoing assessments? Did you think of better interventions to produce the expected outcomes?
- As you concluded your care, did the patient/family/caregivers know your name, and know what to expect of you and your nursing? Did the patient sense that you are respectful, caring, and competent to provide care?

Perhaps the most important questions to reflect on are: Are your patients and their families/caregivers better for having had *you* share in the critical responsibility of partnering with them to address their oxygenation and perfusion needs? Are your patients now receiving thoughtful, person-centered, prioritized, holistic, evidence-based treatment and care because of your efforts?

Skill 40-1 Using a Pulse Oximeter

DELEGATION CONSIDERATIONS

The measurement of oxygen saturation using a pulse oximeter may be delegated to assistive personnel (AP) as well as to licensed practical/vocational nurses (LPN/LVNs). The decision to delegate must be based on careful analysis of the patient's needs and circumstances as well as the qualifications of the person to whom the task is being delegated. Refer to the Delegation Guidelines in Appendix A.

EQUIPMENT

- Pulse oximeter with an appropriate sensor or probe
- Disposable cleansing cloth or skin cleanser and water
- Nail polish remover (if necessary)
- PPE, as indicated

IMPLEMENTATION

ACTION	RATIONALE
1. Review the patient's health record for any health problems that would affect the patient's oxygenation status. Gather equipment.	Identifying influencing factors aids in interpretation of results. Assembling equipment provides for an organized approach to the task.
 2. Perform hand hygiene and put on PPE, if indicated.	Hand hygiene and PPE prevent the spread of microorganisms. PPE is required based on transmission precautions.
 3. Identify the patient.	Identifying the patient ensures the right patient receives the intervention and helps prevent errors.
4. Assemble equipment on the bedside stand or overbed table or other surface within reach.	Bringing everything to the bedside conserves time and energy. Arranging items nearby is convenient, saves time, and avoids unnecessary stretching and twisting of muscles on the part of the nurse.
5. Close the curtains around the bed and close the door to the room, if possible. Explain to the patient what you are going to do and why.	This ensures the patient's privacy. Explanation relieves anxiety and facilitates engagement with care.
6. Select an appropriate site for application of the sensor.	Inadequate circulation can interfere with the oxygen saturation (SpO_2) reading.
a. Use the patient's index, middle, or ring finger (Figure 1).	Fingers are easily accessible.
b. Check the proximal pulse (Figure 2) and capillary refill (Figure 3) closest to the site.	Brisk capillary refill and a strong pulse indicate adequate circulation to the site.
c. If circulation to the site is inadequate, consider using the earlobe or forehead. Use the appropriate oximetry sensor for the chosen site.	These alternative sites are highly vascular. Correct use of appropriate equipment is vital for accurate results.
d. Use a toe only if lower extremity circulation is not compromised.	Peripheral vascular disease is common in lower extremities.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

FIGURE 1. Selecting an appropriate finger.

FIGURE 2. Assessing pulse.

FIGURE 3. Assessing capillary refill.

7. Select the proper equipment:	
a. If one finger is too large for the probe, use a smaller finger.	Inaccurate readings can result if the probe or sensor is not attached correctly.
b. Use probes appropriate for the patient's age and size. Use a pediatric probe for a small adult, if necessary.	Probes come in adult, pediatric, and infant sizes.
c. Check if the patient is allergic to the adhesive. A nonadhesive finger clip or reflectance sensor is available.	A reaction may occur if the patient is allergic to an adhesive substance.
8. Prepare the monitoring site. Cleanse the selected area with a disposable cleansing cloth, as necessary; alternatively, have the patient wash their hands. Allow the area to dry. If necessary, remove any nail polish and artificial nails after checking the pulse oximeter's manufacturer's instructions.	Skin oils, dirt, or grime on the site can interfere with the passage of light waves. Research is conflicting regarding the effect of dark color nail polish and artificial nails. However, it is prudent to remove the nail polish (American Thoracic Society, 2021; USFDA, 2021; World Health Organization [WHO], 2011; Yönt et al., 2014). Refer to facility policy and the pulse oximeter's manufacturer's instructions regarding nail polish and artificial nails for additional information.
9. Attach the probe securely to the skin (Figure 4). **Make sure that the light-emitting sensor and the light-receiving sensor are aligned opposite each other (not necessary to check if placed on the forehead).**	Secure attachment and proper alignment promote satisfactory operation of the equipment and an accurate recording of the SpO_2.
10. Connect the sensor probe to the pulse oximeter (Figure 5), turn the oximeter on, and check operation of the equipment (audible beep and fluctuation of the bar of light or waveform on the face of the oximeter).	An audible beep represents the arterial pulse, and a fluctuating waveform or light bar indicates the strength of the pulse. A weak signal will produce an inaccurate recording of the SpO_2. The tone of the beep reflects the SpO_2 reading. If SpO_2 drops, the tone becomes lower in pitch.

11. Set alarms on the pulse oximeter. Check the manufacturer's alarm limits for high and low pulse rate settings (Figure 6).

The alarm provides an additional safeguard and signals when high or low limits have been surpassed.

FIGURE 4. Attaching probe to patient's finger.

FIGURE 5. Connecting sensor probe to unit.

FIGURE 6. Checking alarms.

12. Check oxygen saturation at regular intervals, as prescribed, as per nursing assessment, and as signaled by alarms. Monitor the hemoglobin level.

Monitoring SpO_2 provides ongoing assessment of the patient's condition. A low hemoglobin level may be satisfactorily saturated yet inadequate to meet a patient's oxygen needs.

13. Remove the sensor on a regular basis and check for skin irritation or signs of pressure (every 2 hours for a spring-tension sensor and every 4 hours for an adhesive finger or toe sensor).

Prolonged pressure may lead to tissue necrosis. An adhesive sensor may cause skin irritation.

14. Clean nondisposable sensors according to the manufacturer's directions. Remove PPE, if used. Perform hand hygiene.

Cleaning equipment between each patient use reduces the spread of microorganisms. Proper removal of PPE reduces the risk for infection transmission and contamination of other items. Hand hygiene prevents the spread of microorganisms.

Documentation

Guidelines

Documentation should include the type of sensor and location used, assessment of the proximal pulse and capillary refill, the pulse oximeter reading, the amount of oxygen, and delivery method if the patient is receiving supplemental oxygen, respiratory status, and any other relevant interventions required as a result of the reading.

Sample Documentation

9/03/25 Pulse oximeter placed on patient's index finger on right hand. Radial pulse presents with brisk

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

capillary refill. Pulse oximeter reading 98% on oxygen at 2 L/min via nasal cannula. Heart rate measured by oximeter correlates with the radial pulse measurement.

—C. Bausler, RN

DEVELOPING CLINICAL REASONING AND CLINICAL JUDGMENT

UNEXPECTED SITUATIONS AND ASSOCIATED INTERVENTIONS

- *Absent or weak signal:* Check vital signs and patient condition. If satisfactory, check connections and circulation to site. Hypotension and other conditions that result in low blood flow make an accurate recording difficult (Hess et al., 2021). Equipment such as a restraint or blood pressure cuff may compromise circulation to the site and cause venous blood to pulsate, giving an inaccurate reading. If the extremity is cold, cover it with a warm blanket and/or use another site.
- *Potentially inaccurate reading:* Check prescribed medications and history of circulatory disorders. Try the device on another person to see if the problem is equipment related or patient related. Drugs that cause vasoconstriction interfere with accurate recording of the oxygen saturation.

SPECIAL CONSIDERATIONS

General Considerations

- Review facility procedures for obtaining pulse oximetry readings if the patient's fingers are not suitable. Correct use of appropriate equipment is vital for accurate results. The appropriate ear oximetry sensor should be used to obtain measurements from a patient's ear. A finger sensor should be limited to use on the finger. The oximetry measurement obtained during clinical assessment should include a record of the type of sensor used.
- Accuracy of readings can be influenced by conditions that decrease arterial blood flow, such as peripheral edema, hypotension, and peripheral vascular disease. Bradycardia and irregular cardiac rhythms may also cause inaccurate readings.
- Accuracy of readings may also be affected by skin pigmentation (deeply pigmented skin) (Hess et al., 2021; Sjoding et al., 2020; USFDA, 2021), nail polish, and intravascular dyes (methylene blue and indocyanine green) (Hess et al., 2021; USFDA, 2021).
- Pulse oximetry may be less reliable in patients with chronic bronchitis and emphysema (Amalakanti & Pentakota, 2016).
- Inexpensive, portable over-the-counter pulse oximeters may be less reliable and are not intended for medical purposes, do not undergo FDA review, and should not be used for medical purposes (USFDA, 2021).
- Correlate the pulse reading on the pulse oximeter with the patient's heart rate (American Thoracic Society, 2021). Variation between pulse and heart rate may indicate that not all pulsations are being detected, and another sensor site may be required.
- Excessive motion of the sensor probe site, such as with extremity tremors or shivering, can also interfere with obtaining an accurate reading.
- In patients with low cardiac output, the forehead or ear sensor may be better than the digit sensor for pulse oximetry.

INFANT AND CHILD CONSIDERATIONS

- For infants, the oximeter probe may be placed on the toe or foot (Figure 7).

FIGURE 7. Oximetry probe on infant's toe.

OLDER ADULT CONSIDERATIONS

- Careful attention to the patient's skin integrity and condition is necessary to prevent injury. Pressure or tension from the probe, as well as any adhesive used, can damage older, dry, thin skin.

Community-Based Care Considerations

- Portable prescription units are available for use in the home or in an outpatient setting (USFDA, 2021).

Skill 40-2 Suctioning the Oropharyngeal and Nasopharyngeal Airways

DELEGATION CONSIDERATIONS

Suctioning of the oropharyngeal airway may be delegated to assistive personnel (AP) who have received appropriate training. Depending on the state's nurse practice act and the organization's policies and procedures, the suctioning of the oropharyngeal and nasopharyngeal airways may be delegated to licensed practical/vocational nurses (LPN/LVNs). The decision to delegate must be based on careful analysis of the patient's needs and circumstances as well as the qualifications of the person to whom the task is being delegated. Refer to the Delegation Guidelines in Appendix A.

EQUIPMENT

- Portable or wall suction unit with tubing
- A commercially prepared suction kit with an appropriate-size catheter or
  - Sterile suction catheter with Y-port in the appropriate size (adult: 10 to 16 Fr)
  - Sterile disposable container
  - Sterile gloves
- Sterile water or saline
- Towel or waterproof pad
- Goggles and mask or face shield; N95 mask or equivalent, based on patient's health status
- Disposable, clean gloves
- Water-soluble lubricant (nasopharyngeal and nasotracheal suctioning)
- Additional PPE, as indicated

IMPLEMENTATION

ACTION	RATIONALE
1. Gather equipment.	Assembling equipment provides for an organized approach to the task.
 2. Perform hand hygiene and put on PPE, if indicated.	Hand hygiene and PPE prevent the spread of microorganisms. PPE is required based on transmission precautions.
 3. Identify the patient.	Identifying the patient ensures the right patient receives the intervention and helps prevent errors.
4. Assemble equipment on the overbed table or other surface within reach.	Bringing everything to the bedside conserves time and energy. Arranging items nearby is convenient, saves time, and avoids unnecessary stretching and twisting of muscles on the part of the nurse.
5. Close the curtains around the bed and close the door to the room, if possible.	This ensures the patient's privacy.
6. Perform assessments to determine the need for suctioning. Verify the prescribed suctioning intervention in the patient's health record, if	Suctioning should be performed only when clinically indicated based on assessment and not routinely (AARC, 2010; Burns & Delgado, 2019; Hess et al.,

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

necessary. Anticipate the administration of pharmacologic (analgesic medication) and use of nonpharmacologic interventions for the patient before suctioning. **Assess for pain or the potential to cause pain. Administer pain medication, as prescribed, before suctioning.**	2021; Morton & Fontaine, 2018). Some facilities require that naso- and oropharyngeal suctioning are a prescribed intervention. At a minimum, suctioning is an uncomfortable procedure, and it can be a very painful and/or distressing experience. Individualized pain management must be performed in response to the patient's needs (Arroyo-Novoa et al., 2008; Chaseling et al., 2014; Wrona et al., 2021; Düzkaya & Kuğuoğlu, 2015).
7. Explain to the patient what you are going to do and why, even if the patient does not appear to be alert. Reassure the patient that you will interrupt the procedure if they indicate respiratory difficulty.	Explanation alleviates fears. Even if the patient appears unconscious, explain what is happening. Any procedure that compromises respiration is frightening for the patient.
8. Adjust the bed to a comfortable working height (VHACEOSH, 2016). Lower the side rail closest to you. **If the patient is conscious, place them in a semi-Fowler position. If the patient is unconscious, place them in the lateral position, facing you.** Move the bedside table close to your work area and raise it to waist height.	Having the bed at the proper height prevents back and muscle strain. A sitting position helps the patient to cough and makes breathing easier. Gravity also facilitates catheter insertion. The lateral position prevents the airway from becoming obstructed and promotes drainage of secretions. The bedside table provides a work surface and helps maintain sterility of objects on the work surface.
9. Place a towel or waterproof pad across the patient's chest.	This protects bed linens.
10. **Adjust suction to the appropriate pressure** (Hess et al., 2021) (Figure 1): • No more than 150 mm Hg for adults and adolescents • No more than 125 mm Hg for children • No more than 100 mm Hg for infants **Put on a disposable, clean glove and occlude the end of the connecting tubing to check suction pressure.** Place the connecting tubing in a convenient location.	Higher pressures can cause excessive trauma, hypoxemia, and atelectasis.

FIGURE 1. Adjusting wall suction.

11. Open the sterile suction package using aseptic technique. The open wrapper or container becomes a sterile field to hold other supplies. Carefully remove the sterile container, touching only the outside surface. Set it up on the work surface and pour sterile saline into it.	Sterile normal saline or water is used to lubricate the outside of the catheter, minimizing irritation of the mucosa during introduction. It is also used to clear the catheter between suction attempts.
12. Place a small amount of water-soluble lubricant on the sterile field, taking care to avoid touching the sterile field with the lubricant package.	Lubricant facilitates passage of the catheter and reduces trauma to mucous membranes.
13. Increase the patient's supplemental oxygen level, or	Suctioning removes air from the patient's airway and

apply supplemental oxygen per facility policy or prescribed intervention.	can cause hypoxemia. Hyperoxygenation can help prevent suction-induced hypoxemia (Morton & Fontaine, 2018).
14. Put on a face shield or goggles and mask. Put on sterile gloves. Your dominant hand will manipulate the catheter and must remain sterile. The nondominant hand is considered clean rather than sterile and will control the suction valve (Y-port) on the catheter. In the home setting and other community-based settings, maintenance of sterility is not necessary.	Gloves and other PPE protect the nurse from microorganisms. Handling the sterile catheter using a sterile glove helps prevent introducing organisms into the respiratory tract. In the home setting and other community-based settings, clean (instead of sterile) technique is used because the patient is not exposed to disease-causing organisms that may be found in health care settings, such as hospitals.
15. With your dominant gloved hand, pick up the sterile catheter. Pick up the connecting tubing with the nondominant hand and connect the tubing and suction catheter (Figure 2).	Sterility of the suction catheter is maintained.
16. Moisten the catheter by dipping it into the container of sterile saline (Figure 3). Occlude the Y-tube to check suction.	Lubricating the inside of the catheter with saline helps move secretions in the catheter. Checking suction ensures equipment is working properly.

FIGURE 2. Connecting suction catheter to tubing.

FIGURE 3. Dipping catheter into sterile saline.

17. Encourage the patient to take several deep breaths.	Hyperventilation can help prevent suction-induced hypoxemia (Hess et al., 2021).
18. Apply lubricant to the first 2 to 3 inches of the catheter, using the lubricant that was placed on the sterile field.	Lubricant facilitates passage of the catheter and reduces trauma to mucous membranes.
19. Remove the oxygen delivery device, if appropriate. Do not apply suction as the catheter is inserted. Hold the catheter between your thumb and forefinger.	Suctioning removes air from the patient's airway and can cause hypoxemia. Using suction while inserting the catheter can cause trauma to the mucosa and remove excessive oxygen from the respiratory tract.
20. Insert the catheter: a. **For nasopharyngeal suctioning**, gently insert the catheter through the naris and along the floor of the nostril toward the trachea (Figure 4). Roll the catheter between your fingers to help advance it. Advance the catheter approximately 6 to 8 inches to reach the pharynx (Hinkle et al., 2022). b. **For oropharyngeal suctioning**, insert the catheter through the mouth, along the side of the mouth toward the trachea. Advance the catheter 3 to 4 inches to reach the pharynx.	The correct distance for insertion ensures proper placement of the catheter. The general guideline for determining insertion distance for nasopharyngeal suctioning for an individual patient is to estimate the distance from the patient's earlobe to the nose.
21. **Apply suction by intermittently occluding the Y-port on the catheter with the thumb of your nondominant hand and gently rotating the catheter as it is being withdrawn (Figure 5). Do not suction for more than 15 seconds at a time** (AARC, 2010; Hess et al., 2021).	Turning the catheter as it is withdrawn minimizes trauma to the mucosa. Suctioning for longer than 15 seconds robs the respiratory tract of oxygen, which may result in hypoxemia. Suctioning too quickly may be ineffective at clearing all secretions.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

22. Replace the oxygen delivery device using your nondominant hand, if appropriate, and have the patient take several deep breaths.

Suctioning removes air from the patient's airway and can cause hypoxemia. Hyperventilation can help prevent suction-induced hypoxemia.

23. Flush the catheter with saline (Figure 6). Assess the effectiveness of suctioning and repeat, as needed, and according to the patient's tolerance. Wrap the suction catheter around your dominant hand between attempts.

Flushing clears the catheter and lubricates it for next insertion. Reassessment determines the need for additional suctioning. Wrapping prevents inadvertent contamination of the catheter.

FIGURE 4. Inserting catheter into naris.

FIGURE 5. Rotating the catheter as it is withdrawn to suction the nasopharynx.

FIGURE 6. Rinsing catheter.

24. **Allow at least a 30-second interval if additional suctioning is needed. Alternate the naris, unless contraindicated, if repeated suctioning is required.** No more than three suction passes should be made per suctioning episode. Do not force the catheter through the naris. Encourage the patient to cough and deep breathe between suctioning. **Suction the oropharynx after suctioning the nasopharynx.**

The interval allows for reventilation and reoxygenation of airways. Excessive suction passes contribute to complications. Alternating the naris reduces trauma. Suctioning the oropharynx after the nasopharynx clears the mouth of secretions. More microorganisms are usually present in the mouth, so it is suctioned last to prevent transmission of contaminants.

25. When suctioning is complete, remove the glove from your dominant hand over the coiled catheter, pulling it off inside out. Remove the glove from your nondominant hand, and dispose of gloves, catheter, and the container with the solution in the appropriate receptacle. Perform hand hygiene.

This technique of glove removal and hand hygiene reduces transmission of microorganisms.

26. Assist the patient to a comfortable position. Raise the bed rail and place the bed in the lowest position.

Proper positioning with raised side rails and the proper bed height provides for patient comfort and safety.

	Proper removal of PPE and hand hygiene reduce the risk of transmission of microorganisms.
27. Turn off the suction. Remove the supplemental oxygen placed for suctioning, if appropriate. Remove the face shield or goggles and mask. Perform hand hygiene.	
28. Perform oral hygiene after suctioning. Oral hygiene measures are discussed in Chapter 32.	Respiratory secretions that are allowed to accumulate in the mouth are irritating to mucous membranes, pose a risk for aspiration, and are unpleasant for the patient. Diligent oral hygiene care can improve oral health and limit the growth of pathogens in the oropharyngeal secretions, decreasing the incidence of aspiration pneumonia, community-acquired pneumonia, nonventilator health care–associated pneumonia (NV-HAP), and ventilator-associated pneumonia (VAP) (AACN, 2017; Chick & Wynne, 2020; Jenson et al., 2018; Quinn et al., 2020).
29. Reassess the patient's respiratory status, including respiratory rate, effort, oxygen saturation, and lung sounds, and their response to suctioning.	This assesses effectiveness of suctioning and the presence of complications.
	Proper removal of PPE reduces the risk for infection transmission and contamination of other items. Hand hygiene prevents the spread of microorganisms.
30. Remove additional PPE, if used. Perform hand hygiene.	

DOCUMENTATION

Guidelines

Document the time of suctioning, assessments before and after the intervention, the reason for suctioning, route used, and the characteristics and amount of secretions.

Sample Documentation

9/17/25 1440 Patient with gurgling on inspiration and weak cough; unable to clear secretions. Lungs with rhonchi (sonorous wheezes) in upper airways. Nasopharyngeal suction completed with 12-Fr catheter. Large amount of thick, yellow secretions obtained. After suctioning, lung sounds clear in all lobes, respirations 18 breaths/min, no gurgling noted.

—C. Bausler, RN

Developing Clinical Reasoning and Clinical Judgment

UNEXPECTED SITUATIONS AND ASSOCIATED INTERVENTIONS

- *Patient vomits during suctioning:* If the patient gags or becomes nauseated, remove the catheter; it has probably entered the esophagus inadvertently. If the patient needs to be suctioned again, change the catheter, because it is probably contaminated. Turn the patient to the side and elevate the head of the bed to prevent aspiration.
- *Epistaxis (bleeding) is noted with continued suctioning:* Notify the health care team and anticipate the need for a nasal trumpet. The nasal trumpet will protect the nasal mucosa from further trauma related to suctioning (Morton & Fontaine, 2018).

SPECIAL CONSIDERATIONS

General Considerations

- The use of suction pressure higher than the pressure guidelines presented in the skill have been suggested by some researchers (Maras et al., 2020; Yazdannik et al., 2019).

Infant and Child Considerations

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

- For infants, use a 5- to 6-Fr catheter.
- For children, use a 6- to 10-Fr catheter.

Skill 40-3 Administering Oxygen by Nasal Cannula

DELEGATION CONSIDERATIONS

The administration of oxygen by nasal cannula is not delegated to assistive personnel (AP). Reapplication of the nasal cannula during nursing care activities, such as during bathing, may be performed by AP. Depending on the state's nurse practice act and the organization's policies and procedures, administration of oxygen by nasal cannula may be delegated to licensed practical/vocational nurses (LPN/LVNs). The decision to delegate must be based on careful analysis of the patient's needs and circumstances as well as the qualifications of the person to whom the task is being delegated. Refer to the Delegation Guidelines in Appendix A.

EQUIPMENT

- Flow meter connected to oxygen supply
- Humidifier with sterile, distilled water (based on circumstances, system, and facility policy)
- Nasal cannula and tubing
- Gauze to pad tubing over ears or commercial padding (optional)
- PPE, as indicated

IMPLEMENTATION

ACTION	RATIONALE
1. Review the prescribed intervention to verify the use of the nasal cannula, flow rate, and administration parameters. Gather equipment.	Verifying the prescribed intervention ensures the patient receives the prescribed amount of oxygen. Assembling equipment provides for an organized approach to the task.
 2. Perform hand hygiene and put on PPE, if indicated.	Hand hygiene and PPE prevent the spread of microorganisms. PPE is required based on transmission precautions.
 3. Identify the patient.	Identifying the patient ensures the right patient receives the intervention and helps prevent errors.
4. Assemble equipment on the overbed table or other surface within reach.	Bringing everything to the bedside conserves time and energy. Arranging items nearby is convenient, saves time, and avoids unnecessary stretching and twisting of muscles on the part of the nurse.
5. Close the curtains around the bed and close the door to the room, if possible.	This ensures the patient's privacy.
6. Explain to the patient what you are going to do and why. Review safety precautions necessary when oxygen is in use.	Explanation relieves anxiety and facilitates engagement with care. Oxygen supports combustion; a small spark could cause a fire.
7. Connect the nasal cannula to the oxygen source (Figure 1), with humidification, if appropriate. Adjust the flow rate as prescribed (Figure 2). Check that oxygen is flowing out of prongs.	Oxygen forced through a water reservoir is humidified before it is delivered to the patient, thus preventing dehydration of the mucous membranes. Low-flow oxygen does not require humidification.

FIGURE 1. Connecting cannula to oxygen source.

FIGURE 2. Adjusting flow rate.

8. Place the prongs in the patient's nostrils (Figure 3). Place the tubing over and behind each ear with the adjuster comfortably under the chin. Alternatively, the tubing may be placed around the patient's head, with the adjuster at the back or base of the head. Place the gauze (Figure 4) or commercially available pads at the ear beneath the tubing, as necessary.

Correct placement of the prongs and fastener facilitates oxygen administration and patient comfort. Pads reduce irritation and pressure and protect the skin. Pressure injuries may be related to a medical device or other object (EPUAP, NPIAP, & PPPIA, 2019, p. 16; Joint Commission, 2018). Any tube, electrode, sensor, or other rigid or stiff device element under pressure can create pressure damage (Baranoski & Ayello, 2020; EPUAP, NPIAP, & PPPIA, 2019).

FIGURE 3. Putting the prongs in the patient's nostrils.

FIGURE 4. Placing gauze pad at ears.

9. Adjust the fit of the cannula, as necessary (Figure 5). The tubing should be snug but not tight against the skin.

Proper adjustment maintains the prongs in the patient's nose. Excessive pressure from the tubing could cause irritation and pressure to the skin. Nasal cannulas may cause pressure injuries behind the ears, around the nostril, or in the nasal vestibule (Camacho-Del Rio, 2018).

10. Reassess the patient's respiratory status, including the respiratory rate, effort, and lung sounds. Note any signs of respiratory distress, such as tachypnea, nasal flaring, use of accessory muscles, or dyspnea.

This assesses the effectiveness of oxygen therapy.

11. Remove PPE, if used. Perform hand hygiene.

Proper removal of PPE reduces the risk for infection transmission and contamination of other items. Hand hygiene prevents the spread of microorganisms.

12. Put on clean gloves. Remove and clean the cannula and assess the nares at least every 8 hours, or according to facility recommendations (Figure 6). Assess the areas of skin contact with the cannula for alterations in skin integrity.

The continued presence of the cannula causes irritation and dryness of the mucous membranes. Nasal cannulas may cause pressure injuries behind the ears, around the nostril, or in the nasal vestibule (Camacho-Del Rio, 2018).

FIGURE 5. Adjusting the fit of the cannula.

FIGURE 6. Cleaning cannula, when indicated.

DOCUMENTATION

Guidelines

Document your assessment before and after intervention. Document the amount of oxygen applied; the delivery method; and the patient's respiratory rate, oxygen saturation, and lung sounds.

Sample Documentation

Practice documenting the administration of oxygen by nasal cannula in *Lippincott DocuCare*.

9/17/25 1300 Oxygen via nasal cannula applied at 2 L/min. Humidification in place. Pulse oximeter before placing oxygen 92%; after oxygen at 2 L/min 98%. Respirations even and unlabored. Chest rises symmetrically. No nasal flaring or retractions noted. Lung sounds clear and equal in all lobes.

—C. Bausler, RN

DEVELOPING CLINICAL REASONING AND CLINICAL JUDGMENT

UNEXPECTED SITUATIONS AND ASSOCIATED INTERVENTIONS

- *Patient was fine on oxygen delivered by nasal cannula but now states they are short of breath, and the pulse oximeter reading is less than 93%:* Check to see that the oxygen tubing is still connected to the flow meter and the flow meter is still on the previous setting. Someone may have stepped on the tubing, pulling it from the flow meter, or the oxygen may have accidentally been turned off. Assess the patient's respiratory status, including respiratory rate, rhythm, effort, and lung sounds. Note any additional signs of respiratory distress. Collaborate with the health care team regarding any changes and assessment findings.
- *Areas over ear or back of head are reddened:* Ensure that areas are adequately padded and that the tubing is not pulled too tight. Consider consultation with the skin care team or wound nurse specialist.

SPECIAL CONSIDERATIONS

General Considerations

- Soft nasal cannulas have been shown to decrease the incidence of pressure injuries (Camacho-Del Rio, 2018).
- When providing oxygen via high-flow nasal cannula, protect the back of the ears with a hydrocolloid or foam dressing (Camacho-Del Rio, 2018).
- There is no evidence that mouth breathing influences the efficiency of oxygen delivery; even when the patient inspires through the mouth, oxygen still flows through the nose into the pharynx (O'Driscoll et al., 2017; Hess et al., 2021).

Community-Based Care Considerations

- Oxygen administration may need to be continued in the home setting. Liquid oxygen in a tank and oxygen concentrators are used frequently in home situations, including portable versions of both sources. Instruct caregivers about safety precautions with oxygen use and make sure they understand the rationale for the specific liter flow of oxygen.
- Oxygen supports combustion. To prevent fires and injuries, patients and families/caregivers should take the following precautions:

- Do not smoke in a home where oxygen is in use. Place "No Smoking" signs in conspicuous places in the patient's home. Instruct the patient and family/caregivers about the hazard of smoking when oxygen is in use.
- Keep oils, grease, alcohol, and other liquids that can burn away from the oxygen.
- Keep the oxygen at least 6 ft away from any source of fire, such as a stove, fireplace, or candle (MedlinePlus, 2020).
- Keep the oxygen 6 ft away from toys with electric motors, electric baseboard or space heaters, hairdryers, electric razors, and electric toothbrushes (MedlinePlus, 2020).
- Do not use electrical equipment near oxygen administration set (e.g., electric blanket; see also above).
- Use caution with gas or electric appliances.
- Ground oxygen concentrators.
- Secure the oxygen tank in a holder and away from direct sunlight or heat.
- Allow adequate airflow around the oxygen concentrator (avoid placing it flush against the wall).
- Notify the local fire department of the use of oxygen in the home.
- Have working smoke detectors and a working fire extinguisher in the home (MedlinePlus, 2020).

Skill 40-4 Administering Oxygen by Mask

DELEGATION CONSIDERATIONS

The administration of oxygen by a mask is not delegated to assistive personnel (AP). Reapplication of the mask during nursing care activities, such as during bathing, may be performed by AP. Depending on the state's nurse practice act and the organization's policies and procedures, administration of oxygen by a mask may be delegated to licensed practical/vocational nurses (LPN/LVNs). The decision to delegate must be based on careful analysis of the patient's needs and circumstances as well as the qualifications of the person to whom the task is being delegated. Refer to the Delegation Guidelines in Appendix A.

EQUIPMENT

- Flow meter connected to oxygen supply
- Humidifier with sterile distilled water, if necessary, for the type of mask prescribed (based on circumstances, system, and facility policy)
- Face mask, as prescribed or indicated based on the patient's condition and circumstances
- Gauze to pad elastic band or commercial padding; silicone border or hydrocolloid dressing (optional)
- PPE, as indicated

Implementation

ACTION	RATIONALE
1. Review the prescribed intervention to verify the use of the particular mask, flow rate/concentration, and administration parameters. Gather equipment.	Verifying the prescribed intervention ensures the patient receives prescribed amount of oxygen. Assembling equipment provides for an organized approach to the task.
 2. Perform hand hygiene and put on PPE, if indicated.	Hand hygiene and PPE prevent the spread of microorganisms. PPE is required based on transmission precautions.
 3. Identify the patient.	Identifying the patient ensures the right patient receives the intervention and helps prevent errors.
4. Assemble equipment on the overbed table or other surface within reach.	Bringing everything to the bedside conserves time and energy. Arranging items nearby is convenient, saves time, and avoids unnecessary stretching and twisting of muscles on the part of the nurse.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

5. Close the curtains around the bed and close the door to the room, if possible.	This ensures the patient's privacy.
6. Explain to the patient what you are going to do and why. Review safety precautions necessary when oxygen is in use.	Explanation relieves anxiety and facilitates engagement with care. Oxygen supports combustion; a small spark could cause a fire.
7. Attach the face mask to the oxygen source (with humidification, if appropriate, for the specific mask) (Figure 1). Start the flow of oxygen at the specified rate. For a mask with a reservoir, be sure to allow oxygen to fill the bag (Figure 2) before proceeding to the next step.	Oxygen forced through a water reservoir is humidified before it is delivered to the patient, thus preventing dehydration of the mucous membranes. A reservoir bag must be inflated with oxygen because the bag is the oxygen supply source for the patient.

FIGURE 1. Connecting face mask to oxygen source.

FIGURE 2. Allowing oxygen to fill bag.

8. Position face mask over the patient's nose and mouth (Figure 3). **Adjust the elastic strap so that the mask fits snugly but comfortably on the face (Figure 4).** Adjust to the prescribed flow rate (Figure 5).	A loose or poorly fitting mask will result in oxygen loss and decreased therapeutic value. Masks may cause a feeling of suffocation, so the patient needs frequent attention and reassurance.

FIGURE 3. Applying face mask over nose and mouth.

FIGURE 4. Adjusting elastic straps.

FIGURE 5. Adjusting flow rate.

9. If the patient reports irritation or you note any alteration in skin integrity, use gauze pads under the elastic strap at pressure points to reduce irritation to the ears and scalp. Consider use of a silicone border or hydrocolloid dressings over bony prominences or other areas that come in contact with the device and between the device and the skin (Camacho-Del Rio, 2018).	Pressure injuries may be related to a medical device or other object (EPUAP, NPIAP, & PPPIA, 2019, p. 16; Joint Commission, 2018). Any tube, electrode, sensor, or other rigid or stiff device element under pressure can create pressure damage (Baranoski & Ayello, 2020; EPUAP, NPIAP, & PPPIA, 2019). Pads reduce irritation and pressure and protect the skin.
10. Reassess the patient's respiratory status, including respiratory rate, effort, and lung sounds, and their oxygen saturation. Note any signs of respiratory distress, such as tachypnea, nasal flaring, use of accessory muscles, or dyspnea.	This helps assess the effectiveness of oxygen therapy.
 11. Remove PPE, if used. Perform hand hygiene.	Proper removal of PPE reduces the risk for infection transmission and contamination of other items. Hand hygiene prevents the spread of microorganisms.
12. **Remove the mask and dry the skin under the mask every 2 to 3 hours if the oxygen is running continuously. Do not use powder around the mask.** Assess the areas of skin contact with the mask for alterations in skin integrity at least every 8 hours or according to facility recommendations.	The tight-fitting mask and moisture from condensation can irritate the skin on the face. There is a danger of inhaling powder if it is placed on the mask. Masks may cause pressure injuries behind the ears, and to the cheeks, chin, or bridge of the nose (Camacho-Del Rio, 2018).

DOCUMENTATION

Guidelines

Document the type of mask used, the amount of oxygen used, oxygen saturation level, lung sounds, and rate/pattern of respirations. Document your assessment before and after the intervention.

Sample Documentation

Practice documenting the administration of oxygen by mask in *Lippincott DocuCare*.

9/22/25 Patient reports feeling short of breath. Respirations 30 breaths/min and labored. Lung sounds decreased throughout. Oxygen saturation via pulse oximeter 88%. Findings reported to Dr. Lu. Oxygen via nonrebreather face mask applied at 12 L/min as prescribed. Oxygen saturation increased to 98%. Respirations even and unlabored. Chest rises symmetrically. Respiratory rate 18 breaths/min. Lungs remain with decreased breath sounds throughout. Patient denies dyspnea.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

—C. Bausler, RN

DEVELOPING CLINICAL REASONING AND CLINICAL JUDGMENT

UNEXPECTED SITUATIONS AND ASSOCIATED INTERVENTIONS

- *Patient was previously fine on oxygen delivered by mask but is now short of breath, and the pulse oximeter reading is less than 93%:* Check to see that the oxygen tubing for the mask is still connected to the flow meter and the flow meter is still on the previous setting. Someone may have stepped on the tubing, pulling it from the flow meter, or the oxygen may have accidentally been turned off. Assess the patient's respiratory status, including respiratory rate, rhythm, effort, and lung sounds. Note any additional signs of respiratory distress. Collaborate with the health care team regarding any changes and assessment findings.
- *Areas over ear, face, or back of head are reddened:* Ensure that areas are adequately padded and that the elastic band for the mask is not pulled too tight. Consider consultation with the skin care team or wound nurse specialist.

SPECIAL CONSIDERATIONS

General Considerations

- Different types of face masks are available for use.
- It is important to ensure the mask fits snugly around the patient's face. If it is loose, it will not effectively deliver the right amount of oxygen.
- The mask may be removed for the patient to eat, drink, and take medications. If appropriate, consult with the health care team regarding the use of oxygen via nasal cannula for use during mealtimes and limit the number of times the mask is removed to maintain adequate oxygenation.

Community-Based Care Considerations

- Oxygen administration may need to be continued in the home setting. Liquid oxygen in a tank and oxygen concentrators are used frequently in home situations, including portable versions of both sources. Instruct caregivers about safety precautions with oxygen use and make sure they understand the rationale for the specific liter flow of oxygen.
- Oxygen supports combustion. To prevent fires and injuries, patients and families/caregivers should take the following precautions:
  - Do not smoke in a home where oxygen is in use. Place "No Smoking" signs in conspicuous places in the patient's home. Instruct the patient and family/caregivers about the hazard of smoking when oxygen is in use.
  - Keep oils, grease, alcohol, and other liquids that can burn away from the oxygen.
  - Keep the oxygen at least 6 ft away from any source of fire, such as a stove, fireplace, or candle (MedlinePlus, 2020).
  - Keep the oxygen 6 ft away from toys with electric motors, electric baseboard or space heaters, hairdryers, electric razors, and electric toothbrushes (MedlinePlus, 2020).
  - Do not use electrical equipment near oxygen administration set (e.g., electric blanket; see also above).
  - Use caution with gas or electric appliances.
  - Ground oxygen concentrators.
  - Secure the oxygen tank in a holder and away from direct sunlight or heat.
  - Allow adequate airflow around the oxygen concentrator (avoid placing it flush against the wall).
  - Notify the local fire department of the use of oxygen in the home.
  - Have working smoke detectors and a working fire extinguisher in the home (MedlinePlus, 2020).

Skill 40-5 Providing Care of a Tracheostomy Tube and Site

DELEGATION CONSIDERATIONS

Care of a tracheostomy tube is not delegated to assistive personnel (AP). Depending on the state's nurse practice act and the organization's policies and procedures, care of a tracheostomy tube in a stable situation may be delegated to licensed practical/vocational nurses (LPN/LVNs). The decision to delegate must be based on careful analysis of the patient's needs and circumstances as well as the qualifications of the person to whom the task is being delegated. Refer to the Delegation Guidelines in Appendix A.

EQUIPMENT

- Disposable gloves
- Sterile gloves
- Goggles and mask or face shield; N95 mask or equivalent, based on patient's health status
- Additional PPE, as indicated
- Sterile normal saline
- Sterile cup or basin
- Sterile cotton-tipped applicators
- Sterile gauze sponges
- Disposable inner tracheostomy cannula, appropriate size for the patient
- Sterile suction catheter and glove set
- Commercially prepared tracheostomy or drain dressing
- Commercially prepared tracheostomy holder
- Plastic disposal bag
- Assistant (additional nurse or respiratory therapist)

IMPLEMENTATION

ACTION	RATIONALE
1. Gather equipment.	Assembling equipment provides for an organized approach to the task.
 2. Perform hand hygiene and put on PPE, if indicated.	Hand hygiene and PPE prevent the spread of microorganisms. PPE is required based on transmission precautions.
 3. Identify the patient.	Identifying the patient ensures the right patient receives the intervention and helps prevent errors.
4. Assemble equipment on the overbed table or other surface within reach.	Arranging items nearby is convenient, saves time, and avoids unnecessary stretching and twisting of muscles on the part of the nurse.
5. Close the curtains around the bed and close the door to the room, if possible.	This ensures the patient's privacy.
6. Determine the need for tracheostomy care. **Assess the patient's pain and administer pain medication, if indicated.**	If the tracheostomy is new or changes in integrity of the site are present, pain medication may be needed before performing tracheostomy care.
7. Explain to the patient what you are going to do and why, even if the patient does not appear to be alert. Reassure the patient that you will interrupt the procedure if they indicate respiratory difficulty.	Explanation alleviates fears. Even if the patient appears unconscious, the nurse should explain what is happening. Any procedure that compromises respiration is frightening for the patient.
8. Adjust the bed to a comfortable working position (VHACEOSH, 2016). Lower the side rail closest to you. **If the patient is conscious, place them in a semi-Fowler position. Assist the patient to slightly extend their neck, if not contraindicated. If the patient is unconscious, place them in an appropriate position based on assessment of individual circumstances.** Move the overbed table close to your work area and raise it to waist height. Place a trash receptacle within easy reach of the work area.	Having the bed at the proper height prevents back and muscle strain. A sitting position helps the patient to cough and makes breathing easier. Gravity also facilitates catheter insertion if suctioning is indicated. Having the neck slightly extended can facilitate easier removal of the inner cannula (Patton, 2019). Positioning of the unconscious patient is based on the circumstances of the individual patient, health status, health problems, presence of drains and/or monitoring devices, etc. The overbed table provides a work surface and maintains sterility of the objects on the work surface. A trash receptacle within reach prevents reaching over the sterile field or turning your back to the field to dispose of trash.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

9. Put on a face shield or goggles and a mask. Suction the tracheostomy, if necessary. Refer to Skill 40-6. If the tracheostomy has just been suctioned, remove the soiled site dressing and discard it before removal of the gloves used to perform suctioning.	PPE prevents contact with contaminants. Suctioning removes secretions to prevent occluding the outer cannula while the inner cannula is removed.

Cleaning the Tracheostomy: Disposable Inner Cannula

10. Carefully open the package with the new disposable inner cannula, taking care not to contaminate the cannula or the inside of the package (Figure 1). Carefully open the package with the sterile cotton-tipped applicators, taking care not to contaminate them. Open the sterile cup or basin and fill 0.5 inch deep with saline. Open the plastic disposable bag and place it within reach on the work surface.	The inner cannula must remain sterile. Saline and applicators will be used to clean the tracheostomy site. The plastic disposable bag will be used to discard removed inner cannula.
11. Put on disposable gloves.	Gloves protect against exposure to blood and body fluids.

FIGURE 1. Carefully opening package with new disposable inner cannula. (*Source:* Used with permission from Shutterstock. *Photo by B. Proud.*)

12. Remove the oxygen source if one is present. Stabilize the outer cannula and faceplate of the tracheostomy with your nondominant hand. Grasp the locking mechanism of the inner cannula with your dominant hand. Press the tabs and release the lock (Figure 2). Gently remove the inner cannula and place it in the disposal bag. If not already removed, remove the site dressing and dispose of it in the trash.	Stabilizing the faceplate prevents trauma to, and pain from, the stoma. Releasing the lock permits removal of the inner cannula.
13. Working quickly, discard your current gloves and put on sterile gloves. Pick up the new inner cannula with your dominant hand; stabilize the faceplate with your nondominant hand and gently insert the new inner cannula into the outer cannula. Press the tabs to allow the lock to grab the outer cannula (Figure 3). Reapply the oxygen source, if one is in use.	Sterile gloves are necessary to prevent contamination of the new inner cannula. Locking to the outer cannula secures the inner cannula in place. Reapplying the oxygen source maintains an oxygen supply to the patient.

FIGURE 2. Releasing lock on inner cannula.

FIGURE 3. Locking new inner cannula in place.

Applying Clean Dressing and Holder

14. Remove the oxygen source, if necessary. Dip the cotton-tipped applicator or gauze sponge in the cup or basin with sterile saline and clean the stoma under the faceplate. Use each applicator or sponge only once, moving from the stoma site outward (Figure 4).

    Saline is nonirritating to tissue. Cleansing from the stoma outward and using each applicator only once promotes aseptic technique.

FIGURE 4. Cleaning from stoma site, outward.

15. Pat the skin gently with a dry 4 × 4 gauze sponge.

    Gauze removes excess moisture.

16. Slide the commercially prepared tracheostomy dressing or prefolded non–cotton-filled 4 × 4-inch dressing under the faceplate.

    Lint or fiber from a cut cotton-filled gauze pad can be aspirated into the trachea, causing respiratory distress, or can embed in the stoma and cause irritation or infection.

17. Alternatively, implement use of a hydrocolloid or polyurethane foam dressing at the tracheostomy site (Dixon et al., 2018; O'Toole et al., 2017). If this type of dressing is already in use, frequency of change is based on the type of dressing in use, assessment of dressing, and facility policy.

    Use of a hydrocolloid dressing under the tracheostomy flange during the postoperative period and/or placing a polyurethane foam dressing at the tracheostomy site after suture removal reduces the risk for medical device–related alterations in skin integrity. (Dixon et al., 2018; O'Toole et al., 2017). These types of dressings may remain in place for longer periods of time.

18. Change the tracheostomy tube holder:

    a. **Obtain the assistance of a second person to hold the tracheostomy tube in place while the old collar is removed and the new collar is placed.**

       Holding the tracheostomy tube in place ensures that the tracheostomy will not inadvertently be expelled if the patient coughs or moves. Doing so provides attachment for one side of the faceplate.

    b. Open the package for the new tracheostomy collar.

       This allows access to the new collar.

    c. Both nurses should put on clean gloves.

       Gloves prevent contact with blood, body fluids, and contaminants.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

d. One nurse holds the faceplate while the other pulls up the Velcro tabs. Gently remove the collar.	Holding the tracheostomy tube in place ensures that the tracheostomy will not inadvertently be expelled if the patient coughs or moves. Pulling up the Velcro tabs loosens the collar.
e. The first nurse continues to hold the tracheostomy faceplate.	This prevents accidental extubation.
f. The other nurse places the collar around the patient's neck and inserts first one tab, then the other, into the openings on the faceplate and secures the Velcro tabs on the tracheostomy holder (Figure 5).	Securing the Velcro tabs holds the tracheostomy in place and prevents accidental expulsion of the tracheostomy tube.
g. Check the fit of the tracheostomy collar. You should be able to fit no more than two fingers between the neck and the collar (Cleveland Clinic, 2021; Morton & Fontaine, 2018). Check to make sure that the patient can flex the neck comfortably. Reapply the oxygen source, if necessary (Figure 6).	Allowing one to two fingerbreadths under the collar permits neck flexion that is comfortable and ensures that the collar will not compromise circulation to the area but is sufficiently secure to prevent excessive movement of the tracheostomy tube in the stoma and decannulation. Maintains oxygen supply to the patient.

FIGURE 5. Securing tabs on tracheostomy holder.

FIGURE 6. Reapplying oxygen source.

19. Remove gloves. Perform hand hygiene. **If the tracheostomy tube is cuffed, check the pressure of the balloon by attaching a handheld pressure gauge to the pilot balloon of the endotracheal tube.**	Removal of gloves and hand hygiene reduce the risk for pathogen transmission and contamination of other items. Careful monitoring of cuff pressure is necessary to decrease the risk for tracheal necrosis, tracheal rupture, laryngeal nerve palsy, tracheal stenosis, microaspiration, and inadequate ventilation (Turner, Feeney, et al., 2020). The smallest amount of air that results in an airtight seal between the trachea and the tube is desirable and less likely to result in complications; maintain pressure between 20 and 30 cm H_2O (AACN, 2018; Hess et al., 2021; Hinkle et al., 2022; Patton, 2019).
20. Remove the face shield or goggles and mask. Perform hand hygiene. Assist the patient to a comfortable position. Raise the bed rail and place the bed in the lowest position.	Proper removal of PPE reduces the risk for infection transmission and contamination of other items. Hand hygiene prevents the spread of microorganisms. Proper positioning with raised side rails and the proper bed height provides for patient comfort and safety.
21. Reassess the patient's respiratory status, including respiratory rate, effort, oxygen saturation, and lung sounds.	Assessments determine the effectiveness of interventions and the presence of complications.
22. Remove additional PPE, if used. Perform hand hygiene.	Proper removal of PPE reduces the risk for infection transmission and contamination of other items. Hand hygiene prevents the spread of microorganisms.

DOCUMENTATION

Guidelines

Document your assessments before and after interventions, including site assessment, skin assessment, the presence of pain, lung sounds, and oxygen saturation levels. Document the procedure, including site care, changing of dressing, and tube securement. Document the presence of any alterations in skin integrity and associated interventions. Document cuff pressure.

Sample Documentation

9/26/25 1300 Tracheostomy care completed; lung sounds clear in all lobes; respirations even/unlabored; site without erythema or edema; small amount of thick, yellow secretions noted at site, oxygen saturation 95% on O_2 35% via trach collar, cuff pressure 25 cm H_2O. Site dressing and trach securement collar changed.

—C. Bausler, RN

DEVELOPING CLINICAL REASONING AND CLINICAL JUDGMENT

UNEXPECTED SITUATIONS AND ASSOCIATED INTERVENTIONS

- *Patient coughs hard enough to dislodge tracheostomy:* Keep a spare tracheostomy and obturator at the bedside. Insert the obturator into the new tracheostomy and insert the tracheostomy into the stoma. Remove the obturator. Secure the ties and auscultate lung sounds. Palpate for any subcutaneous emphysema.
- *Tracheostomy becomes dislodged and is not easily replaced:* Notify the health care team immediately. This is an emergency situation. Cover the tracheostomy stoma. Assess the patient's respiratory status. Anticipate the possible need for maintaining ventilation using a manual resuscitation device and mask and for possible oro- or nasotracheal intubation.
- *On palpating around the insertion site, you note a moderate amount of subcutaneous emphysema in tissue:* Assess for dislodgment of the tracheostomy tube. If the tube has become displaced, a buildup of air in the subcutaneous portion of the skin is likely. Notify the health care team if the subcutaneous emphysema is a change in the patient's status.

SPECIAL CONSIDERATIONS

General Considerations

- One nurse working alone should always place new tracheostomy ties before removing old ties to prevent accidental extubation of the tracheostomy. If it is necessary to remove the old ties first, obtain the assistance of a second person to hold the tracheostomy tube in place while the old tie is removed and the new tie is replaced.
- Keep emergency equipment easily accessible at the bedside. Keep a bag-valve mask, oxygen, the obturator from the current tracheostomy, a spare tracheostomy of the same size, a spare tracheostomy one size smaller, and suction equipment at the bedside of a patient with a tracheostomy tube at all times (Dawson, 2014; Patton, 2019).
- If the patient is currently using a tracheostomy without a cuff, keep a spare tracheostomy of the same size with a cuff at the bedside for emergency use.
- Monitoring of the cuff pressure using a handheld cuff pressure manometer should take place at the beginning of each shift or following any procedure during which movement of the tube may have taken place (e.g., dressing/tape/collar change, patient repositioning) (Patton, 2019).
- *Pilot balloon is accidentally cut while caring for a tracheostomy tube with a cuff:* Notify the health care team. Obtain a 22-gauge IV catheter and thread it into the pilot balloon tubing, being careful not to puncture the tubing with the needle, below the cut. Remove the needle from the catheter and apply a stopcock or needleless Luer-Lok to the catheter. Alternatively, a blunt needle can be passed into the pilot balloon tubing and a stopcock or Luer-Lok attached to the needle hub (Hess et al., 2021). If air is needed to reinflate the balloon, a syringe can be attached to the stopcock or Luer-Lok so that air may be added. Anticipate the need for a tracheostomy tube change.
- Consider implementation of medical device–related pressure injury prevention strategies to reduce the risk for alterations in skin integrity, including use of a hydrocolloid dressing under the tracheostomy flange during the postoperative period or a polyurethane foam dressing at the tracheostomy site after suture removal instead of a gauze dressing (Dixon et al., 2018; O'Toole et al., 2017).

Community-Based Care Considerations

- Instruct the patient and home caregiver on how to perform tracheostomy care. Observe a return demonstration and provide feedback.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

- Clean, rather than sterile, technique can be used in the home setting.
- Sterile saline can be made by mixing 1 teaspoon of table salt in 1 quart of water and boiling for 15 minutes. The solution is cooled and stored in a clean, dry container. Discard the saline at the end of each day to prevent growth of bacteria. In the home, tap water may also be used, but distilled water or homemade saline should be used if the patient has well water (Cleveland Clinic, 2021).
- Instruct the patient who is performing self-care to use a mirror to view the steps in the procedure.

Skill 40-6 Suctioning a Tracheostomy: Open System

DELEGATION CONSIDERATIONS

Suctioning a tracheostomy is not delegated to assistive personnel (AP). Depending on the state's nurse practice act and the organization's policies and procedures, suctioning of a tracheostomy in a stable situation, such as long-term care and other community-based care settings, may be delegated to licensed practical/vocational nurses (LPN/LVNs). The decision to delegate must be based on careful analysis of the patient's needs and circumstances as well as the qualifications of the person to whom the task is being delegated. Refer to the Delegation Guidelines in Appendix A.

EQUIPMENT

- Portable or wall suction unit with tubing
- A commercially prepared suction kit with an appropriate-size catheter (see General Considerations) or
  - Sterile suction catheter with Y-port in the appropriate size
  - Sterile, disposable container
  - Sterile gloves
- Towel or waterproof pad
- Goggles and mask or face shield; N95 mask or equivalent, based on patient's health status
- Additional PPE, as indicated
- Disposable, clean gloves
- Resuscitation bag connected to 100% oxygen

Implementation

ACTION	RATIONALE
1. Gather equipment.	Assembling equipment provides for an organized approach to the task.
 2. Perform hand hygiene and put on PPE, if indicated.	Hand hygiene and PPE prevent the spread of microorganisms. PPE is required based on transmission precautions.
 3. Identify the patient.	Identifying the patient ensures the right patient receives the intervention and helps prevent errors.
4. Assemble equipment on the overbed table or other surface within reach.	Arranging items nearby is convenient, saves time, and avoids unnecessary stretching and twisting of muscles on the part of the nurse.
5. Close the curtains around the bed and close the door to the room, if possible.	This ensures the patient's privacy.
6. Determine the need for suctioning. Verify the prescribed suctioning intervention in the patient's health record, if necessary. Anticipate the administration of pharmacologic (analgesic medication) and use of nonpharmacologic interventions for the patient before suctioning.	Suctioning should be performed only when clinically indicated based on assessment and not routinely (AARC, 2010; Burns & Delgado, 2019; Hess et al., 2021; Morton & Fontaine, 2018). At a minimum, suctioning is an uncomfortable procedure, and it can be a very painful and/or distressing experience.

Assess for pain or the potential to cause pain. Administer pain medication, as prescribed, before suctioning.	Individualized pain management must be performed in response to the patient's needs (Arroyo-Novoa et al., 2008; Chaseling et al., 2014; Düzkaya & Kuğuoğlu, 2015; Wrona et al., 2021).
7. Explain to the patient what you are going to do and why, even if the patient does not appear to be alert. Reassure the patient that you will interrupt the procedure if they indicate respiratory difficulty.	Explanation alleviates fears. Even if the patient appears unconscious, the nurse should explain what is happening. Any procedure that compromises respiration is frightening for the patient.
8. Adjust the bed to a comfortable working position (VHACEOSH, 2016). Lower the side rail closest to you. **If the patient is conscious, place them in a semi-Fowler position (Figure 1). If the patient is unconscious, place them in an appropriate position based on assessment of individual circumstances.** Move the overbed table close to your work area and raise it to waist height.	Having the bed at the proper height prevents back and muscle strain. A sitting position helps the patient to cough and makes breathing easier. Gravity also facilitates catheter insertion. Positioning of the unconscious patient is based on the circumstances of the individual patient; health status, health problems, presence of drains and/or monitoring devices, etc. The overbed table provides a work surface and maintains the sterility of the objects on the work surface.

FIGURE 1. Patient in semi-Fowler position.

9. Place a towel or waterproof pad across the patient's chest.	This protects bed linens and the patient.
10. **Adjust suction to the appropriate pressure** (Hess et al., 2021) (Figure 2): • No more than 150 mm Hg for adults and adolescents • No more than 125 mm Hg for children • No more than 100 mm Hg for infants	Higher pressures can cause excessive trauma, hypoxemia, and atelectasis.

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

FIGURE 2. Turning suction unit to appropriate pressure.

11. Put on a disposable, clean glove and occlude the end of the connecting tubing to check suction pressure. Place the connecting tubing in a convenient location. If using a resuscitation bag, place it connected to oxygen within convenient reach.

The glove prevents contact with blood and body fluids. Checking pressure ensures that equipment is working properly. Preparation allows for an organized approach to the procedure.

12. Open the sterile suction package using aseptic technique. The open wrapper or container becomes a sterile field to hold other supplies. Carefully remove the sterile container, touching only the outside surface. Set it up on the work surface and pour sterile saline into it.

Sterile normal saline or water is used to lubricate the outside of the catheter, minimizing irritation of the mucosa during introduction. It is also used to clear the catheter between suction attempts.

13. Put on a face shield or goggles and a mask (Figure 3). Put on sterile gloves. Your dominant hand will manipulate the catheter and must remain sterile. The nondominant hand is considered clean rather than sterile and will control the suction valve (Y-port) on the catheter.

Handling the sterile catheter using a sterile glove helps prevent introducing organisms into the respiratory tract; the clean glove protects the nurse from microorganisms.

FIGURE 3. Putting on goggles and mask.

14. With your dominant gloved hand, pick up the sterile catheter. Pick up the connecting tubing with your nondominant hand and connect the tubing and suction catheter (Figure 4).

This maintains sterility of the suction catheter.

FIGURE 4. Connecting suction catheter to suction tubing.

15. Moisten the catheter by dipping it into the container of sterile saline, unless it is a silicone catheter (Figure 5). Occlude the Y-tube to check suction (Figure 6).

    Lubricating the inside of the catheter with saline helps move secretions in the catheter. Silicone catheters do not require lubrication. Checking ensures that equipment is working properly.

FIGURE 5. Moistening catheter in saline solution.

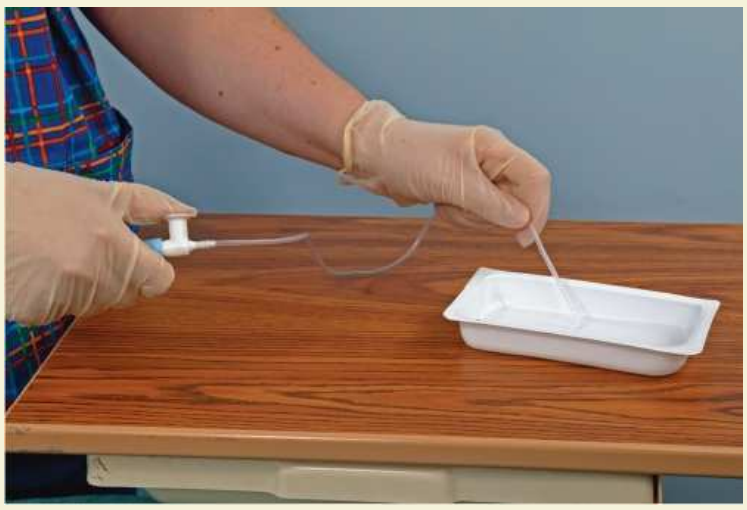

FIGURE 6. Occluding Y-port to check for proper suction.

16. Using your nondominant hand, remove the ventilator tubing or oxygen source (if in use) from the tracheostomy tube and attach the manual resuscitation bag. Hyperoxygenate the patient using your nondominant hand and the manual resuscitation bag for a minimum of 30 seconds (Burns & Delgado, 2019). Alternatively, use the sigh mechanism on a mechanical ventilator.

    Hyperoxygenation aids in preventing hypoxemia during suctioning.

17. Using your nondominant hand, remove the manual resuscitation bag from the tracheostomy tube. Alternatively, open the adapter on the mechanical ventilator tubing.

    This exposes the tracheostomy tube without contaminating your sterile gloved hand.

18. Using your dominant hand, gently and quickly insert the catheter into the tracheostomy tube. **Advance the catheter to the predetermined length. Do not occlude the Y-port when inserting the catheter.**

    Catheter contact and suction cause tracheal mucosal damage, loss of cilia, edema, and fibrosis and increase the risk of infection and bleeding. Insertion of the suction catheter to a predetermined distance, no more than the tip of the artificial airway to no more than 1 cm past the length of the endotracheal tube (adults) and 0.5 cm (pediatric patients) (Boroughs & Dougherty, 2015; Hess et al., 2021; Kendrick, 2020) avoids contact with the trachea and carina, reducing the effects of tracheal mucosal damage (Boroughs & Dougherty, 2015; Hahn, 2010; Ireton, 2007; Pasrija & Hall, 2020; Pate & Zapata, 2002). If resistance is met, the carina or tracheal mucosa has been hit. Withdraw the catheter at least

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

	0.5 inch before applying suction. Occluding the Y-port (i.e., suctioning) when inserting the catheter increases the risk for trauma to the airway mucosa and increases the risk of hypoxemia.
19. Apply suction by intermittently occluding the Y-port on the catheter with the thumb of your nondominant hand, and gently rotate the catheter as it is being withdrawn (Figure 7). **Do not suction for more than 10 to 15 seconds at a time** (AARC, 2010; Burns & Delgado, 2019; Hess et al., 2021; Pasrija & Hall, 2020).	Turning the catheter as it is withdrawn minimizes trauma to the mucosa. Suctioning for longer than 15 seconds robs the respiratory tract of oxygen, which may result in hypoxemia (AARC, 2010; Pasrija & Hall, 2020). Suctioning too quickly may be ineffective at clearing all secretions.

FIGURE 7. Intermittently occluding the Y-port on the catheter to apply suction while withdrawing catheter.

20. Hyperoxygenate the patient using your nondominant hand and a manual resuscitation bag for a minimum of 30 seconds (Burns & Delgado, 2019). Replace the oxygen delivery device, if applicable, using your nondominant hand, and have the patient take several deep breaths. If the patient is mechanically ventilated, close the adapter on the mechanical ventilator tubing and use the sigh mechanism on a mechanical ventilator.	Suctioning removes air from the patient's airway and can cause hypoxemia. Hyperoxygenation can help prevent suction-induced hypoxemia.
21. Flush the catheter with saline. Assess the effectiveness of suctioning and repeat, as needed, according to the patient's tolerance. Wrap the suction catheter around your dominant hand between attempts.	Flushing clears the catheter and lubricates it for the next insertion. Reassessment determines the need for additional suctioning. Wrapping the catheter around your hand prevents inadvertent contamination of the catheter.
22. **Allow at least a 30-second interval if additional suctioning is needed** (Burns & Delgado, 2019). Do not make more than three suction passes per suctioning episode. If the patient is spontaneously breathing, **encourage them to cough and deep breathe between suctioning attempts.** Suction the oropharynx after suctioning the trachea. Do not reinsert the tracheostomy tube after suctioning the mouth.	The interval allows for reventilation and reoxygenation of airways. Excessive suction passes contribute to complications. Suctioning the oropharynx clears the mouth of secretions. Routine oral suctioning to aspirate secretions that accumulate above the cuff of the tube is also necessary to reduce the risk of pneumonia and provide patient comfort (AACN, 2018; Hess et al., 2021; Morton & Fontaine, 2018). More microorganisms are usually present in the mouth, so it is suctioned last to prevent transmission of contaminants.
23. Perform oral hygiene after tracheal suctioning.	Respiratory secretions that are allowed to accumulate in the mouth are irritating to mucous membranes, pose a risk for aspiration, are unpleasant for the patient, and contribute to the colonization of the

oropharyngeal secretions by respiratory pathogens. Diligent oral hygiene care can improve oral health and limit the growth of pathogens in the oropharyngeal secretions, decreasing the incidence of aspiration pneumonia, community-acquired pneumonia, nonventilator health care–associated pneumonia (NV-HAP), and ventilator-associated pneumonia (VAP) (AACN, 2017; Chick & Wynne, 2020; Jenson et al., 2018; Quinn et al., 2020).

FIGURE 8. Removing gloves while keeping catheter inside.

24. When suctioning is completed, coil the catheter in one hand. Remove the glove from the hand over the coiled catheter (the catheter remains inside the glove), pulling the glove off inside out (Figure 8). Remove the glove from the other hand, pulling inside out, and dispose of gloves, catheter, and container with solution in the appropriate receptacle. Perform hand hygiene. Assist the patient to a comfortable position. Raise the bed rail and place the bed in the lowest position.	This technique of glove removal, disposal of equipment, and hand hygiene reduces transmission of microorganisms. Proper positioning with raised side rails and the proper bed height provides for patient comfort and safety.
25. Turn off the suction. Remove the supplemental oxygen placed for suctioning, if appropriate. Remove the face shield or goggles and mask. Perform hand hygiene.	Proper removal of PPE reduces the risk for infection transmission and contamination of other items. Hand hygiene prevents transmission of microorganisms.
26. Reassess the patient's respiratory status, including respiratory rate, effort, oxygen saturation, lung sounds, tracheal sounds, and presence/absence of secretions in artificial airway, and the patient's response to the intervention.	This assesses the effectiveness of suctioning and the presence of complications.
27. Remove additional PPE, if used. Perform hand hygiene.	Proper removal of PPE reduces the risk for infection transmission and contamination of other items. Hand hygiene prevents the spread of microorganisms.

DOCUMENTATION

Guidelines

Document the time of suctioning, assessments before and after interventions, the reason for suctioning, oxygen saturation levels, and the characteristics and amount of secretions.

Sample Documentation

9/1/25 1515 Yellow secretions noted in opening of tracheostomy tube; coarse crackles noted to auscultation over trachea. Lungs auscultated for wheezes in upper and lower lobes bilaterally. Respirations at 24 breaths/min. Weak, ineffective cough noted. Tracheal suction completed with 12-Fr catheter. Large amount of thick, yellow secretions obtained. Specimen for culture collected and sent. After suctioning, no secretions noted in tracheostomy tube, auscultation over trachea clear, faint wheezing persists, oxygen saturation at 97%, respirations 18 breaths/min.

—C. Bausler, RN

DEVELOPING CLINICAL REASONING AND CLINICAL JUDGMENT

UNEXPECTED SITUATIONS AND ASSOCIATED INTERVENTIONS

- *Patient coughs hard enough to dislodge tracheostomy:* Keep a spare tracheostomy and obturator at the bedside. Insert the obturator into the tracheostomy tube and reinsert the tracheostomy into the stoma. Remove the obturator. Secure the ties and auscultate lung sounds. Palpate the tracheostomy site for any **subcutaneous emphysema**, a result of air or gas collecting under the skin (crepitus).
- *Tracheostomy becomes dislodged and is not easily replaced:* Notify the health care team immediately. This is an emergency situation. Cover the tracheostomy stoma. Assess the patient's respiratory status. Anticipate the possible need for maintaining ventilation using a manual resuscitation device and mask and for possible oro- or nasotracheal intubation.
- *Lung sounds do not improve greatly, and oxygen saturation remains low after three suctioning attempts:* Allow the patient time to recover from previous suctionings. If needed, hyperoxygenate again. Suction the patient again and assess whether the oxygen saturation increases, lung sounds improve, and secretion amount decreases.
- *Patient develops signs of intolerance to suctioning; oxygen saturation level decreases and remains low after hyperoxygenation; patient becomes cyanotic; or patient becomes bradycardic:* Stop suctioning. Auscultate lung sounds. Consider hyperventilating the patient with a manual resuscitation device. Remain with the patient. Alert staff to notify the health care team of the change in the patient's status.

SPECIAL CONSIDERATIONS

General Considerations

- Determine the size of the catheter to use by the size of the tracheostomy tube. The suction catheter should be small enough not to occlude the airway being suctioned but large enough to remove secretions; use a suction catheter that occludes less than 50% of the lumen of the endotracheal tube (AARC, 2010; Pasrija & Hall, 2020). Larger catheters can contribute to trauma and hypoxemia.
- If the patient eats by mouth, it is recommended that the tracheostomy tube be suctioned prior to eating to prevent the need for suctioning during or after meals, which may stimulate excessive coughing and could result in vomiting (Hess et al., 2021, p. 429).
- The practice of instillation of saline solution directly into the airway during tracheal suctioning is not supported by evidence and is not recommended for inclusion as part of evidence-based practice and suctioning (AARC, 2010; Boroughs & Dougherty, 2015; Burns & Delgado, 2019; Leddy & Wilkinson, 2015; Owen et al., 2016; Wang et al., 2017).
- Keep emergency equipment easily accessible at the bedside. Keep a bag-valve mask, oxygen, the obturator from the current tracheostomy, a spare tracheostomy of the same size, a spare tracheostomy one size smaller, and suction equipment at the bedside of a patient with a tracheostomy tube at all times (Dawson, 2014; Patton, 2019). If the patient is currently using a tracheostomy without a cuff, keep a spare tracheostomy of the same size with a cuff at the bedside for emergency use.

INFANT AND CHILD CONSIDERATIONS

- Insertion of the suction catheter to a predetermined distance, no more than the tip of the artificial airway to no more than 0.5 cm past the length of the endotracheal tube avoids contact with the trachea and carina, reducing the effects of

tracheal mucosal damage (Boroughs & Dougherty, 2015; Kendrick, 2020).

- The maximal time for application of negative pressure (suction) for neonates, children, and adolescents should be less than 5 to 10 seconds (Boroughs & Dougherty, 2015; Dawson et al., 2012, as cited in Edwards, 2018, p. 51; Hockenberry et al., 2019).

EVOLVING CASE STUDY 40-1

Scenario: Joan McIntyre, age 72, has been admitted to the medical unit with an acute exacerbation of chronic obstructive pulmonary disease (COPD). This is the fifth time she has been in the hospital this year. She is receiving supplemental oxygen and multiple medications to support her breathing. Her activity level is decreased, and she is reporting fatigue.

QUESTION r/t CUES: Which assessment should the nurse prioritize in caring for this patient?

A. Auscultation of lung/breath sounds and oxygen saturation via pulse oximetry
B. Vital signs: temperature, pulse, respiration, blood pressure
C. General history: subjective and objective
D. Cardiac assessment: heart sounds, peripheral pulses

Scenario: The nurse completes the assessment and notes that the blood pressure, pulse, and respirations are slightly elevated, and the oxygen saturation via pulse oximetry is 86%. Upon auscultation the nurse notes the patient has this loud high-pitched sound that is obvious on expiration, especially end-expiration.

QUESTION r/t ANALYZING CUES: The nurse is completing documentation in the electronic health record (EHR) on this client. How should the nurse document these findings?

A. Expiratory wheezes
B. Coarse rhonchi/coarse crackles
C. Baseline lung/breath sounds
D. Diffuse rales/fine crackles

Scenario: The nurse completes the documentation and asks the patient to describe her breathing. The patient states, "I get like this sometimes, but it's not as bad as it was yesterday…<cough>"

QUESTION r/t PRIORITIZING HYPOTHESIS: Based on the objective and subjective assessment of this patient, which priority problem should the nurse identify to guide the plan of care?

A. Impaired gas exchange
B. Activity intolerance
C. Sensory impairment
D. Ineffective health management

Scenario: The nurse opts to provide teaching on key methods to enhance breathing for this patient.

QUESTION r/t GENERATING SOLUTIONS: Which nonpharmacologic teaching interventions will be most effective for promoting self-care in a patient with COPD?

A. Return demonstration of tripod positioning and use of pursed-lip breathing
B. Review caloric intake and encourage the patient to eat one larger meal per day
C. Encourage the use of home oxygen only when sleeping or resting
D. Teach the patient the signs and symptoms of COPD, with an emphasis on pathophysiology

Scenario: The patient is beginning to have increasing difficulty breathing, and her oxygen saturation via pulse oximetry drops briefly to 84%.

QUESTION r/t TAKING ACTION: The nurse notes the patient is audibly wheezing, has increased use of accessory muscles, and has increasing anxiety. What is the priority nursing intervention?

A. Sit the patient up and increase the oxygen flow rate
B. Call the provider
C. Provide therapeutic touch and soft speech to calm the patient
D. Explain to the patient what is happening in clear terms

Scenario: The patient has returned to baseline respiratory function and has received the annual influenza vaccine (flu shot).

QUESTION r/t EVALUATING OUTCOMES: Which of the following parameters must be in place before discharging a patient with COPD home? Select all that apply.

A. Correct return demonstration of all inhaled and oral medications
B. Ability to complete activities of daily living with frequent rest periods

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

C. Effective expectoration of secretions using breathing and coughing techniques
D. Articulation of when to call the provider for follow-up and/or intervention
E. Oxygen saturation via pulse oximetry >98% on room air

DEVELOPING CLINICAL REASONING AND CLINICAL JUDGMENT

. Work through the Evolving Case Study 40-1 Joan McIntyre to help develop your clinical reasoning and clinical judgment skills.

. Using the Focused Assessment Guide in this chapter, work with a partner to assess the respiratory functioning of the following patients. Discuss ways in which you would modify your assessment to meet the specific needs of individual patients:

- A 6-year-old who presents in the pediatrician's office with asthma and is experiencing difficulty breathing
- A 12-year-old who is brought to the emergency department after illicit use of inhalants ("huffing")
- An adult dying of cancer receiving hospice care at home who is receiving increasing doses of narcotics, which depress respiratory functioning
- A hospitalized young adult with a 24-pack/year history of smoking who is noted to have a persistent, hacking cough

. A postoperative patient who is at high risk for pulmonary complications because of a long history of smoking refuses to use the incentive spirometer or to cooperate with instructions to breathe deeply. How would you respond to this patient? Discuss with other students what nursing response is most likely to secure his engagement in necessary self-care measures.

PRACTICING FOR NCLEX

. A nurse is assessing a patient with COPD who is experiencing dyspnea. What action will the nurse take first?

a. Place the patient in Fowler position.
b. Encourage diaphragmatic breathing.
c. Ask the patient to cough.
d. Initiate oral suctioning of secretions.

. A nurse is maintaining airway patency in an unconscious patient by providing frequent nasopharyngeal suction. When would the nurse anticipate inserting a nasopharyngeal airway (nasal trumpet)?

a. Vomiting during suctioning occurs.
b. Secretions appear to contain stomach contents.
c. The suction catheter touches an unsterile surface.
d. Epistaxis is noted with continued suctioning.

. A nurse in the PACU is performing oral suctioning for a patient with an oropharyngeal airway, when the patient begins to vomit. What is the nurse's priority nursing action at this time?

a. Removing the suction catheter and elevating the head of the bed
b. Notifying the primary health care provider
c. Confirming the size of the oral airway is correct
d. Placing the patient in the supine position

. A nurse plans to suction a patient's endotracheal tube using the open suction technique. Which intervention is appropriate for this technique?

a. Using a suction catheter that is the diameter of the endotracheal tube
b. Maintaining the patient in the supine position
c. Administering oxygen prior to suctioning
d. Changing the inline suction device every 24 hours

. A nurse is caring for a patient admitted for an acute asthma exacerbation. The patient reports extreme dyspnea, stating, "Turn up the oxygen, I'm not getting enough air." Which actions would the nurse take first?

a. Suction the airway.
b. Assess the pulse oximetry reading.
c. Obtain a peak flow meter reading.
d. Assess for cyanosis of the lips.

. A patient with COPD is unable to perform personal hygiene without becoming exhausted. What nursing intervention would be appropriate for this patient?

a. Assisting with all bathing and hygiene

b. Telling the patient to avoid speaking during hygiene
c. Teaching the patient to take short shallow breaths during activity
d. Taking rest periods between activities

. A nurse working in the pulmonary clinic is providing teaching to patients with altered oxygenation due to conditions such as asthma and COPD. Which measures would the nurse recommend? Select all that apply.

a. Avoid exercise.
b. Take steps to manage or reduce anxiety.
c. Eat meals 1 to 2 hours prior to breathing treatments.
d. Eat a high-protein/high-calorie diet.
e. Maintain a high-Fowler position when possible.
f. Drink 2 to 3 pints of clear fluids daily.

. A student with a history of asthma visits the school nurse reporting difficulty breathing and wheezing. Which tool would the nurse use to assess the severity of airway resistance?

a. Peak flow meter
b. End-tidal CO_2 monitor
c. Chest tube
d. Arterial blood gas

. A nurse is teaching a patient how to use a metered-dose inhaler for asthma. Which comments from the patient assure the nurse that the teaching has been effective? Select all that apply.

a. "I'll be careful not to shake the canister before using it."
b. "It's important to hold the canister upside down when using it."
c. "I have to remember to inhale the medication through my nose."
d. "I will continue to inhale when the cold propellant is in my throat."
e. "I won't inhale more than one spray with one breath."
f. "I will activate the device while continuing to inhale."

. A nurse is caring for a patient with chronic lung disease who is receiving oxygen through a nasal cannula. What nursing action is performed correctly? Select all that apply.

a. Making sure the oxygen is flowing into the prongs
b. Maintaining oxygen saturation between 94% and 98%
c. Encouraging the patient to breathe through their nose with their mouth closed
d. Initiating the oxygen flow rate at 6 L/min or more
e. Protecting the patient's skin from irritation by the oxygen tubing

. A nurse is securing a patient's endotracheal tube with tape and observes that the tube depth changed during the retaping. Which action would be appropriate related to this incident?

a. Instructing the assistant to notify the health care team
b. Assessing the patient's vital signs
c. Removing the tape, adjusting the depth to the ordered depth, and retaping securely
d. Taking no action, as the depth will adjust automatically

. A nurse is providing teaching for a patient who will undergo cardiac surgery and return to the intensive care unit with an endotracheal tube. What education is most important for the nurse to provide?

a. "The endotracheal tube will drain out excess secretions from the surgical site."
b. "This tube is used to facilitate breathing; you will not be able to speak while it is in place."
c. "This is a surgically placed tube in your neck; we will suction it frequently to remove mucus."
d. "Your oxygenation will be monitored frequently using pulse oximetry."

. A nurse is caring for a patient who has a pleural chest tube attached to a disposable chest drainage system. Which nursing actions are indicated for this patient? Select all that apply.

a. Avoiding turning the patient to prevent disconnections in the tubing
b. Maintaining an occlusive dressing on the site
c. Assessing the patient for signs of respiratory distress
d. Keeping the chest drainage device at the level of the patient's thorax
e. Ensuring there are no dependent loops or kinks in the tubing
f. Observing for bubbles indicating air leak in the water seal chamber

. A nurse in the emergency department is caring for a patient who was brought in by fire rescue due to a heroin

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

overdose. The nurse notes the patient is not breathing. What action will the nurse take immediately? Select all that apply.

a. Tilt the patient's head forward.
b. Begin ventilation using a manual resuscitation bag (Ambu bag).
c. Place the mask tightly over the patient's nose and mouth.
d. Pull the patient's jaw backward.
e. Compress the bag twice the normal respiratory rate for the patient.
f. Recommend that a sputum culture for cytology is obtained.

. Which assessments and interventions should the nurse consider when performing tracheal suctioning? Select all that apply.

a. Closely assessing the patient before, during, and after the procedure
b. Hyperoxygenating the patient before and after suctioning
c. Limiting the application of suction to 20 to 30 seconds
d. Monitoring the pulse to detect effects of hypoxia and stimulation of the vagus nerve
e. Using an appropriate suction pressure (80 to 150 mm Hg)
f. Inserting the suction catheter no further than 1 cm past the length of the tracheal or endotracheal tube

. A nurse is monitoring a patient with a pleural effusion after a thoracentesis removing 1,400 mL of dark yellow liquid. What is the expected outcome of this procedure?

a. Tachycardia
b. Hypotension
c. Reduced dyspnea
d. Pulse oximetry of 88%

. A nursing student attending clinical on a medical-surgical unit receives report from the off-going nurse stating the patient has adventitious breath sounds that clear after expectorating sputum. Which adventitious breath sound will the student expect to auscultate?

a. Bronchial
b. Bronchovesicular
c. Vesicular
d. Wheezing

. A nurse in the emergency department is caring for a patient who had eaten shellfish and is now wheezing. The nurse explains to the patient that the health care provider has prescribed a bronchodilator, which will have what action?

a. Helping the patient cough up thick mucus
b. Opening narrowed airways and relieving wheezing
c. Acting as a cough suppressant
d. Blocking the effects of histamine

. A nurse is planning to suction a patient's tracheostomy tube the day after its placement. Which action by the nurse is absolutely essential?

a. Assessing the need to premedicate with an analgesic
b. Placing the patient in low Fowler position
c. Inserting the obturator into the outer cannula
d. Maintaining aseptic technique

ANSWERS WITH RATIONALES

. **a.** Patients with COPD experience dyspnea related to problems with ventilation and/or hypoxemia. One of the most common symptoms of hypoxia is dyspnea (difficulty breathing). Elevating the head of the bed will improve respiratory expansion and oxygenation. Coughing to facilitate secretion removal, pursed-lip breathing, and/or diaphragmatic breathing may be indicated, after sitting the patient up. Suction is indicated for patients demonstrating the presence of secretions, such as adventitious breath sounds or moist cough with phlegm; there is no indication this patient requires suctioning at this time.

. **d.** Repeated suctioning may injure or traumatize the nares, resulting in nosebleed (epistaxis). The nurse would recommend insertion of a nasal trumpet, which will facilitate suction while protecting the nasal mucosa from further trauma.

. **a.** The nurse discontinues suctioning, elevates the head of the bed, and turns the patients to the side to prevent aspiration. Airway protection takes priority; after positioning the patient, the nurse continues to suction the airway and oropharynx. Once airway patency has been established, the nurse will notify the provider of vomiting. There is no

indication the oral airway is too large. Placing the patient supine while vomiting is inappropriate, as that could promote aspiration.

- **c.** To prevent hypoxemia, prior to endotracheal suctioning, the nurse provides 100% oxygen for a minimum of 30 seconds. This is referred to as hyperoxygenation. The nurse limits the application of suction to no more than 10 to 15 seconds (AARC, 2010; Burns & Delgado, 2019; Hess et al., 2021; Pasrija & Hall, 2020). The external diameter of the suction catheter should not exceed half of the internal diameter of the endotracheal tube. An inline suction device is considered a closed, self-contained system used for a "closed technique" for suction; these are changed every 24 hours.
- **b.** Using the nursing process, the nurse first assesses the oxygen saturation via pulse oximetry before changing the oxygen flow rate. Suctioning is provided to remove respiratory secretions; the nurse would note adventitious breath sounds or phlegm with cough indicating a need for suction. A peak flow meter is used to assess the point of highest flow during forced expiration. It is routinely used for patients with moderate or severe asthma to measure the severity of the disease and degree of disease management. While cyanosis of the lips is a late sign of hypoxemia, the nurse can quickly begin to alleviate or lessen dyspnea by simply repositioning the patient.
- **d.** To prevent fatigue during activities including hygiene, the nurse should group (personal care) activities into smaller steps and encourage rest periods between activities. The nurse promotes and maintains dignity, independence, and strength by assisting with activities when the patient has difficulty. The nurse should encourage the patient to voice feelings and concerns about self-care deficits and teach the patient to coordinate pursed-lip or diaphragmatic breathing with the activity.
- **b, d, e.** When caring for patients with COPD, it is important to help create an environment that is likely to reduce anxiety, which increases oxygen demand. A high-protein/high-calorie diet is recommended to meet increased energy needs due to the work of breathing. People with dyspnea and orthopnea are most comfortable in a high-Fowler (upright) position because accessory muscles can easily be used to facilitate respiration and lung expansion. Meals should be eaten 1 to 2 hours after breathing treatments; exercises and drinking 2 to 3 quarts (1.9 to 2.9 L) of clear fluids daily is recommended, rather than 2 to 3 pints.
- **a.** A peak flow meter is used to assess the point of highest flow during forced expiration. It is routinely used by and for patients with moderate or severe asthma to measure the severity of the disease and degree of disease management. Capnography or end-tidal CO_2 monitoring is used for assessing and monitoring ventilation and placement of artificial airways, predicting patients who are at risk for respiratory compromise, are experiencing partial or complete airway obstruction, or are experiencing hypoventilation (Burns & Delgado, 2019; Seckel, 2018). A chest tube is used to remove air or fluid from the pleural space. The arterial blood gas (ABG) is used to assess oxygenation, ventilation, and acid–base status; it is invasive and not performed in the school setting.
- **d, e, f.** Common mistakes that patients make when using MDIs include failing to shake the canister, holding the inhaler upside down, inhaling through the nose rather than the mouth, inhaling too rapidly, stopping the inhalation when the cold propellant is felt in the throat, failing to hold their breath after inhalation, inhaling two sprays with one breath, and not activating the device while inhaling.
- **a, c, e.** The nurse should assure that the oxygen is flowing out of the prongs prior to inserting them into the patient's nostrils. The nurse should encourage the patient to breathe through their nose with the mouth closed. The nurse should adjust the flow rate and maintain the patient's oxygen saturation as prescribed. The nurse should implement pressure injury prevention strategies; pressure from the tubing could result in medical device–related alterations in skin integrity.
- **11. c.** The tube depth should be maintained at the same level unless otherwise prescribed. If the depth changes, the nurse should remove the tape or securement device, adjust the tube to the ordered depth, and reapply the tape or securement device.
- **b.** Patients with an endotracheal tube are unable to speak. Explaining this to the patient preoperatively, along with information that they will be closely monitored, can help decrease anxiety. The endotracheal tube is used during anesthesia or for mechanical ventilation; it is not a surgical drain. A tracheostomy, located in the neck area, is a surgically placed artificial airway. While pulse oximetry will be used to monitor oxygenation, to prevent undue anxiety, it is most important that the patient understands speech will not be possible.
- **b, c, e, f.** The chest drainage collection device must be positioned below the tube's insertion site. Maintaining an occlusive dressing helps prevent air leak; assess for crepitus around the chest tube site indicating air leak. Avoid dependent loops or kinks in the tubing, which could impede drainage. Assess for bubbling in the water seal, maintaining the water level at the 2-cm mark. When a chest tube becomes separated from the drainage device, the nurse should submerge the tube's end in water, creating a temporary water seal and allowing air to escape until a new drainage unit can be attached.
- **b, c.** The priority is to establish ventilation using the manual resuscitation bag to provide emergency or rescue breathing. The nurse tilts the head back, pulls the jaw forward, and positions the mask tightly over the patient's nose and mouth. The bag is compressed at a rate that approximates normal respiratory rate (e.g., 12 to 20 breaths/min in adults). Sputum for cytology is done primarily to detect cells that may be malignant, determine organisms causing

for more ebook/ testbank/ solution manuals requests: email 960126734@qq.com

infection, and identify blood or pus in the sputum. Note that the bag, with the mask removed, also fits easily over tracheostomy and endotracheal tubes.

. **a, b, d, e, f.** Close assessment of the patient before, during, and after the procedure is necessary to identify complications such as hypoxia, infection, tracheal tissue damage, dysrhythmias, and atelectasis. The nurse should hyperoxygenate the patient before and after suctioning and limit the application of suction to 10 to 20 seconds. In addition, monitor the patient's pulse frequently to detect potential effects of hypoxia and stimulation of the vagus nerve. Using an appropriate suction pressure (80 to 150 mm Hg) will help prevent atelectasis caused by excessive negative pressure. Research suggests that insertion of the suction catheter should be limited to a predetermined length (no further than 1 cm past the length of the tracheal or endotracheal tube) to avoid tracheal mucosal damage.

. **c.** Thoracentesis involves inserting a needle into the pleural space to aspirate pleural fluid, air, or both (Morton & Fontaine, 2018). A thoracentesis may be performed to obtain a specimen for diagnostic purposes, to remove fluid or air that has accumulated in the pleural cavity and is causing respiratory difficulty and discomfort, or to instill medications (Hinkle et al., 2022).

. **d.** Wheezing and crackles represent adventitious or abnormal breath sounds. Bronchial, bronchovesicular, and vesicular breath sounds are normal.

. **b.** A bronchodilator opens narrowed airways which result in wheezing. An expectorant encourage cough to clear secretions. A cough suppressant reduces, treats, or stops a cough. Medications that block histamine (antihistamine) are often used for allergy but are not specific bronchodilators.

. **d.** Sterile technique is used for tracheal suctioning, to reduce the risk of introduction of disease-causing organisms. Aseptic technique is imperative to avoid introducing organisms into the lower airway. An obturator, which guides the direction of the outer cannula, is inserted into the tube during placement and removed once the outer cannula of the tube is in place. In the home setting, clean technique is used.

Fluid, Electrolyte, and Acid–Base Balance

Grace Gilligan

Grace, a 28-year-old female, arrives at the emergency department reporting severe episodes of nausea and vomiting over the last 48 hours. She has a medical history of Crohn's disease, a gastrointestinal (GI) problem for which she underwent bowel resection surgery 1 month ago. "I thought the surgery would help my problems," she says. Intravenous (IV) therapy was prescribed to restore her fluid balance.

Jeremiah Stein

Jeremiah, a 22-year-old student, comes to the campus health center because he has been having two or three loose, watery bowel movements a day for the past week. "I kept thinking I would get better. I didn't have time to come to the clinic because of exams and I have been so busy, but now I don't feel good and I'm weak." Fluid volume deficit and electrolyte imbalances are a concern.

Jack Soo Park

Jack, a 78-year-old male receiving IV therapy with antibiotics, states, "I'm having trouble breathing. It just started a little while ago." Physical examination reveals a bounding pulse, distended neck veins, and

crackles and wheezes in the lungs. Excess fluid volume is suspected. Further checking reveals an IV fluid-administration error that has resulted in overhydration.

Learning Outcomes

After completing the chapter, you will be able to accomplish the following:

. Describe the location and functions of body fluids, including the factors that affect variations in fluid compartments.
. Describe the functions, regulation, sources, and losses of the main electrolytes of the body.
. Explain the principles of osmosis, diffusion, active transport, and filtration.
. Describe how thirst and the organs of homeostasis (kidneys, heart and blood vessels, lungs, adrenal glands, pituitary gland, parathyroid glands) function to maintain fluid homeostasis.
. Describe the role of buffer systems and respiratory and renal mechanisms in achieving and maintaining acid–base balance.
. Identify the etiologies and defining characteristics for common fluid, electrolyte, and acid–base imbalances.
. Perform assessments related to fluid, electrolyte, and acid–base balance.
. Describe the role of dietary modification, modification of fluid intake, medication administration, IV therapy, blood replacement, and parenteral nutrition (PN) as part of care to address fluid, electrolyte, and acid–base imbalances.
. Plan, implement, and evaluate nursing care related to selected actual and potential health problems and needs associated with alterations in fluid, electrolyte, and acid–base balance.

Nursing Concepts

Acid–Base Balance
Assessment
Cellular Regulation
Clinical Decision Making/Clinical Judgment
Fluids and Electrolytes
Safety

Key Terms

acid
acidosis
active transport
alkalosis
anions
antibody
antigen
autologous transfusion
base
blood typing
buffer
capillary filtration
cations
colloid osmotic pressure
cross-matching
dehydration
diffusion
edema
electrolytes
extracellular fluid (ECF)
homeostasis

hydrostatic pressure
hypercalcemia
hyperchloremia
hyperkalemia
hypermagnesemia
hypernatremia
hyperphosphatemia
hypertonic solution
hypervolemia
hypocalcemia
hypochloremia
hypokalemia
hypomagnesemia
hyponatremia
hypophosphatemia
hypotonic solution
hypovolemia
intracellular fluid (ICF)
ion
isotonic
osmolality
osmosis
pH
